Acerca de este libro

Esta es una copia digital de un libro que, durante generaciones, se ha conservado en las estanterías de una biblioteca, hasta que Google ha decidido escanearlo como parte de un proyecto que pretende que sea posible descubrir en línea libros de todo el mundo.

Ha sobrevivido tantos años como para que los derechos de autor hayan expirado y el libro pase a ser de dominio público. El que un libro sea de dominio público significa que nunca ha estado protegido por derechos de autor, o bien que el período legal de estos derechos ya ha expirado. Es posible que una misma obra sea de dominio público en unos países y, sin embargo, no lo sea en otros. Los libros de dominio público son nuestras puertas hacia el pasado, suponen un patrimonio histórico, cultural y de conocimientos que, a menudo, resulta difícil de descubrir.

Todas las anotaciones, marcas y otras señales en los márgenes que estén presentes en el volumen original aparecerán también en este archivo como testimonio del largo viaje que el libro ha recorrido desde el editor hasta la biblioteca y, finalmente, hasta usted.

Normas de uso

Google se enorgullece de poder colaborar con distintas bibliotecas para digitalizar los materiales de dominio público a fin de hacerlos accesibles a todo el mundo. Los libros de dominio público son patrimonio de todos, nosotros somos sus humildes guardianes. No obstante, se trata de un trabajo caro. Por este motivo, y para poder ofrecer este recurso, hemos tomado medidas para evitar que se produzca un abuso por parte de terceros con fines comerciales, y hemos incluido restricciones técnicas sobre las solicitudes automatizadas.

Asimismo, le pedimos que:

+ *Haga un uso exclusivamente no comercial de estos archivos* Hemos diseñado la Búsqueda de libros de Google para el uso de particulares; como tal, le pedimos que utilice estos archivos con fines personales, y no comerciales.

+ *No envíe solicitudes automatizadas* Por favor, no envíe solicitudes automatizadas de ningún tipo al sistema de Google. Si está llevando a cabo una investigación sobre traducción automática, reconocimiento óptico de caracteres u otros campos para los que resulte útil disfrutar de acceso a una gran cantidad de texto, por favor, envíenos un mensaje. Fomentamos el uso de materiales de dominio público con estos propósitos y seguro que podremos ayudarle.

+ *Conserve la atribución* La filigrana de Google que verá en todos los archivos es fundamental para informar a los usuarios sobre este proyecto y ayudarles a encontrar materiales adicionales en la Búsqueda de libros de Google. Por favor, no la elimine.

+ *Manténgase siempre dentro de la legalidad* Sea cual sea el uso que haga de estos materiales, recuerde que es responsable de asegurarse de que todo lo que hace es legal. No dé por sentado que, por el hecho de que una obra se considere de dominio público para los usuarios de los Estados Unidos, lo será también para los usuarios de otros países. La legislación sobre derechos de autor varía de un país a otro, y no podemos facilitar información sobre si está permitido un uso específico de algún libro. Por favor, no suponga que la aparición de un libro en nuestro programa significa que se puede utilizar de igual manera en todo el mundo. La responsabilidad ante la infracción de los derechos de autor puede ser muy grave.

Acerca de la Búsqueda de libros de Google

El objetivo de Google consiste en organizar información procedente de todo el mundo y hacerla accesible y útil de forma universal. El programa de Búsqueda de libros de Google ayuda a los lectores a descubrir los libros de todo el mundo a la vez que ayuda a autores y editores a llegar a nuevas audiencias. Podrá realizar búsquedas en el texto completo de este libro en la web, en la página `http://books.google.com`

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

+ *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.

+ *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.

+ *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.

+ *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at `http://books.google.com/`

AMERICAN ELECTRICIAN

A Journal of Practical Electrical and Steam Engineering

VOLUME XIII

JANUARY—DECEMBER, 1901.

American Electrician Company
Beard Building
New York

GENERAL INDEX

:eferences to Notes in "Abstracts from Foreign Contemporaries" are distinguished by an asterisk preceding the page number.
escriptions of central stations and telephone exchanges are indexed only under the respective heads, "Central" and "Telephone."

A

Accident, An odd, By O. C. Thompson.. 598
——, An unaccountable, By Wm. D. Treloar 409
Accumulator. See Storage Battery.
Alkali chlorides, Electrolysis of fused....*536
——process, Outhenin-Chalandre electrolytic *289
Allis steam engines for the Glasgow Tramways 390
Alternating-current ammeter, arc lamp, central station, diagrams, etc See Ammeter, Arc lamp, Central station, Diagrams, etc.
Alternating-current duplicate feeder system *577
—— —— terminology (Edit.).......... 584
Alternations and cycles. (Edit.).......... 180
Alternators, Parallel operation of.......... 583
—— —— ——, By A. S. McAllister..... 435
——Engine-driven, By Ralph J. Patterson 239
American Institute of Electrical Engineers, Library of the, 353; (Edit.).... 355
—— —— —— —— Annual Convention 445
American Street Railway Association Convention 531
Ammeter and socket plug, Grabosch combined, (patent) 222
——and voltmeter, Alternating-current.. *74
——, Construction of an.......... 500
——shunts and transformers for switchboard service; Machado & Roller.... 244
Arc-lamp carbon, Hachmann, (patent).. 78
—— ——carbon-holder contact, Stevens, (patent) 27
—— —— circuits, Baker regulating device for series alternating-current, (patent) 579
—— —— ——, Regulating devices for series alternating-current, By J. Henry Hallberg, 529; (Edit.).......... 540
—— ——for series circuits, Alternating-current *219
—— ——, Hackl *220
—— ——, Nernst effect.......... *24
—— ——, Rice polyphase, (patent)...... 396
—— ——trouble, High-voltage..........*174
—— ——using highly refractory electrodes *175
Arc lamps for street illumination, Relative merits of open and enclosed, By W. D'A. Ryan, 522; (Edit.).......... 541
—— ——, Photometric values of, By C. P. Matthews, 324; (Edit.).......... 354
—— ——, System of regulation for series alternating-current; Western Elec. Co.......... 94
—— ——, Warner gas check for enclosed, (patent).......... 444
Arc-light carbons, Automatic plating machine for; U. S. Carbon Co.......... 51
—— ——dynamo, Unusual action of an By E. C. Sutton.......... 46
—— —— —— troubles and their remedies, Some Brush, By F. B. O'Hanlon 596
—— ——dynamos, Rebuilding old........ 497
Arc lighting at the beginning of the Twentieth Century, By H. W. Hillman, 326; (Edit.).......... 354
—— ——practice, Modern.......... 324
—— ——problem. See Problem.
Armature torque, Formula for direct-current, (Q. & A.).......... 510
Armatures, A comparison of dynamos with surface-wound and slot-wound, By P. M. Heldt.......... 106
——, Stripped railway motor, By Frank Berry, Jr.......... 454
——, Weak fields and grounded, By Frank Berry, Jr.......... 189
Aron meter for four-wire three-phase systems *288
Australasia, Electrical progress in, By Lawrence Birks.......... 267
Automobile battery. See Storage battery.

B

Battery. See Cell and Storage battery.
——solution, Electropoion, (Q. & A.).... 510
Beissel feed-water softener.......... 576
Bell system, Return call, with one battery (Q. & A.).......... 601
Bell-wiring problem. See Problem.
Bells, Electric, on 110-volt circuits, By Ed. S. Morgan, 89; A. R. Van Volkenburgh 46
Berliner patent, The, (Edit.).......... 120
Bernard Company at the Pan-American Exposition, The..........Adv. 35, Sept.
Blow-out for railway controllers, Magnetic *114
Boats, Submarine 293
Boiler construction, Radical departure in.*534
——economy, A practical demonstration in, By C. Watson.......... 505
——feeding and feed-water heating, By L. B. Mather.......... 67
——furnace performance, (Edit.).......... 498
——, Modern horizontal tubular.......... 102
——room, Central station, By William D. Ennis 327
—— ——efficiencies, By W. D. Ennis... 388
—— ——practice (Edit.).......... 226
——scale. See Scale.
——troubles, A few common, By R. A. Douglass 265
Boilers and engines for superheated steam*395
——, Effect of scale in.......... 495
——, Makins' attachment for improving circulation in..........*534
——, Relation of the rate of evaporation to the fuel economy of, By William D. Ennis 521
——, The use of zinc in, By R. A. Douglass 572

BOOKS, NEW:
A B C of the Telephone. James E. Homans 447
American Street Railway Investments. Street Railway Publishing Company.. 292
Annual Report of the Board of Regents of the Smithsonian Institution. Government Printing Office.......... 496
Central Station Experiences. Power Publishing Company 398
Copper Handbook, The. Horace J. Stevens 178
Design and Construction of Oil Engines. A. H. Goldingham.......... 118
Electric Gas Lighting. H. S. Norrie,
Electric Lighting. Francis B. Crocker.. 223
Electrical Designs. American Electrician Company 561
Electrical Engineers' Pocket-Book. Horatio A. Foster..........Adv. 35, Dec.
Electrical Units for Boys. Arthur A. Kent 28
Electricity Made Simple, Clark Caryl Haskins 561
Electrochemistry, Outlines of. Prof. H. C. Jones ....Adv. 35, Dec.
Electromagnets; Their Design and Construction. A. N. Mansfield.......... 561
Elements of Electrical Engineering. Charles Proteus Steinmetz.......... 398
Engine Tests. Geo. W. Barrus, S. B.. 28
"Engineering" and Electric Traction Pocket Book, The. Philip Dawson.... 496
Handbook on Engineering. Henry C. Tulley 223
High Speed Steam Engines. Wm. Norris and Ben. H. Morgan.......... 28
Induction Coils. H. S. Norrie.......... 292
Induction Motor, The. B. A. Behrend.. 398
International Association of Municipal Electricians, Report of the Fifth Annual Convention of the.......... 118
Inventor's Manual. Norman W. Henley & Co. 223
Machinists' and Draftsmen's Handbook. P. Lobben 118
Mechanical Drawing and Elementary Machine Design. John S. and David Reid 78
National Electric Light Association, Twenty-Third Convention of the....... 118
Progress of Invention in the Nineteenth Century, The. Edward W. Byrn...... 178
Saw Filing. Robert Grimshaw.......... 352
School Chemistry, A. John Waddell, B. A. 447
Telephone Lines and Their Properties. William J. Hopkins.......... 292
Telephones Furnished by the United States Signal Corps, Instructions for using. Capt. Samuel Reber.......... 352
Universal Electrical Directory, The. J. A. Berly's; H. Alabaster, Gatehouse & Co. 223
Booster, An Improvised, By Ed. S. Morgan, 47; C. C. Webster, 186; H. P. Wood, 186; E. W. Lothrop.......... 239
Boosters, Improvised, By Walter M. Hollis 524
——and storage batteries, (Diagrams).. 196
——, Storage batteries controlled by reversible *442
Brake dynamometer. See Prony Brake.
——electromagnets, Direct-current *288
——, Lindstrom electric elevator, (patent) 444
Bronze varnish, A recipe for.......... 224
Brush arc-light dynamo troubles and their remedies, Some, By F. B. O'Hanlon 596
——motor, An old-time, By A. B. Weeks 573
Brushes, Increasing the life of copper... 497
——, Rohrer connection for carbon, (patent) 77
Brush-holder, Kragh, (patent).......... 117
——, Pomeroy, (patent).......... 221
Bryan-Marsh comparimeter.......... 50
Bucking of railway generators, By Eugene C. Parham, 86, 408; Geo. W. Malcolm, 135; Ed. S. Morgan.......... 240
Buffalo terminal transformer station of the Cataract Power and Conduit Company, By Fred P. Woodbury.... 385
Bulkhead doors, Electrically controlled, By George E. Walsh.......... 218

C

Cable carriers, Telephone, By W. S. Henry 408
——for three-phase currents, Esson, (patent) 538
Caldwell electrolytic interrupter..........*288
Calibrating a voltmeter, A simple method of, By J. Rowland Brown.......... 573
Calorimeter, Barrel, By Chas. L. Hubbard 503
——, New form of Goodman steam.......*78
——Separator, By Chas. L. Hubbard.... 591
C & C series-parallel system of control for printing-press motors.......... 50
Candle-power of incandescent lamps. Standard. By Joel Gomborow, 403; G. E. Rosenfield, 455 (Edit.).......... 294
Carbon, Arc-lamp (patent).......... 78
——brushes. See Brushes.
Carbons, Automatic plating machine for arc-light; United States Carbon Co. 51
Cataract Power and Conduit Company, The new Buffalo terminal transformer station of the, By Fred. P. Woodbury 385
Catechism, Electrical..........
48, 90, 137, 194, 241, 311, 364, 410, 457, 509, 551, 600
Cell, Commelin-Viau gas..........*349
——, Electrolytic alkali..........*220
——, German Imperial electrical standard *395
——, Haas & Oettel hypochlorite........*395
——, Hussey bisulphate of mercury...... 366
——, New carbon-zinc *577
Cells and batteries in the Royal Navy, Testing *175
Central station, Boston Edison. By Alton D. Adams, 268; (Edit.).......... 295
—— ——, Brooklyn Edison, 1; New Westinghouse engines for 108
—— ——, Consolidated Electric Light & Power Co., By J. R. Williams...... 421
—— ——, Georgia Electric Light Company, 465; (Edit.).......... 496
—— ——, Glasgow 13
—— ——, Gloucester 12
—— ——, Hoboken, 278; (Edit.).......... 295
—— ——, Santa Monica, Cal., By J. R. Cravath, 251; (Edit.) 294
—— ——, Urbana, Ill., By W. H. Zimmerman 482
—— ——, Wallsend-on-Tyne, 377; (Edit.) 400
—— ——, Wappinger's Falls, N. Y., By C. W. Obert, 565; (Edit.).......... 584
—— ——, West Ham.......... 9
Central station boiler room, By William D. Ennis. 327
—— ——, Hints on laying out a........ 495
—— ——methods, By S. T. Webber.... 550
—— ——working, A point in.......... 29
——stations, American and English, (Edit.) 80
—— ——, Charging in, By Ralph J. Patterson 185
—— ——, Coal handling machinery, for, By F. L. Hutchinson.......... 496

—— ——, Electrical service in........... *26
—— ——, German, ... 581
—— ——, Small, (Edit.) 584
Chicago Electrical Association; Election of officers 79
Chimneys for power stations, Brick, By W. D. Ennis................................ 570
Chlorides, Electrolysis of fused alkali..*536
Chlorine, Electrolytic production of soda and, By Ernest Franke............... 104
Circuit breaker, Scott motor starter and, (patent) 28
Circuits, Resistance of simple and complex, (Lessons) 507
Circulation in boilers, Makins' method of improving *534
Clarke Automatic coal-weighing scales... 511
Clarke Automatic Telephone Company's system 141
Clearance and compression in steam engines *219
Clutches, Group-driven lathes with electromagnetic *76
Coal burning internal-combustion engine..*491
——handling machinery for central stations, By F. L. Hutchinson........... 486
Commelin-Viau gas battery cell............ *349
Commutator clamps, Geisenhöner, (patent) 495
—— connections for reducing voltage one-half (Q. & A.).............................. 411
——, Priest and Schermerhorn, (patent). 118
——, Repairing and connecting up a, By A. B. Weeks.................................... 187
——, Thomson anti-sparking, (patent).... 222
Comparimeter, Bryan-Marsh 50
Condensation, Water of, By C. W. Obert 187, 235
Condensing, Exhaust steam heating vs., By A. M. Earl.................................. 89
Conductors, A simple method of locating a short circuit between electrical, By Arthur R. Roe........................... 208
Conduit, Bathurst interior, (patent)...... 493
——, New railway.................................*175
——wiring, Alternating-current, By C. R. James 599
Connections, Problem in, See Problem
Connectors and fuses, Cable...............*493
Control. See also Regulation.
——, Electric railway car, (Edit.)........ 31
——for printing-press motors, C & C series-parallel system of.............. 50
——of lights from more than one point, By Francis M. Appleton.............. 47
——, Parham method of railway motor, (patent) 351
Controller at the Pan-American Exposition, Cutler-Hammer solenoidal electrical elevator 459
——, Stull, (patent).............................. 177
——, Wiring diagram for K2.............. 92
Controllers, Garrett contact finger for motor, (patent) 222
——, The care of street railway, By Frank Berry, Jr.............................. 596
Converters, Berg distribution system for (patent) 27
——, Lamme safety system for, (patent) 351
——, Rotary, By A. S. McAllister......... 568
——, Starting, By Arthur B. Weeks...... 358
——, Three-wire distribution from, By Chas. N. Black.............................. 550
Cooling towers, Commercial forms of, By C. W. Obert.................................. 475
—— ——, Stocker fanless,................ 412
—— ——, The use of, By B. Franklin Hart 474
Corliss valve gear and valve setting, By C. C. Major.................................. 230
Coulomb, Charles Augustin de........... 353
Coupling. See Clutch.
Current, A mysterious, 119; F. O. Broili, 308; H. Stanley Carr, 193; George T. Hanchett 192
Curve forms on measuring instruments, The influence of.............................*221
Curves for showing the charge remaining in a storage battery........................ 436
——of direct-current dynamos to parallel operation, Relation of characteristic, By Alton D. Adams............ 68
Cutler-Hammer solenoidal electric elevator controller at the Pan-American Exposition 459
Cycles, Alternations and, (Edit.).......... 180
Cylinder cutting, Engine, By A. M. Earl.. 408
——proportions, Steam engine............*491

D

De Laval steam turbine........................ 553
Deri alternating-current motor.............*493
DESIGNS FOR APPARATUS:
  Dynamo, Electroplating, 400-ampere, By Cecil P. Poole................................ 356
  ——, Incandescent, By Cecil P. Poole; 35-light, 450; 75-light.......................... 32
  ——, Sparking, for gas-engine service... 32
  Electrodynamometer, By S. M. Kintner 228
  Fan motor, Direct-current................... 182
  Gas engine, 1-h.p., By J. C. Brocksmith 586
  Indicator, Current and potential......... 500
  Intercommunicating telephone set........ 122
  Motor, 3-h.p. launch, By Cecil P. Poole. 542
  Photometer, A simple........................ 296
  Time signal apparatus, Simple, By S. M. Kintner 402
Desrumaux feed-water softener............ 576
Diagrams, Alternating-current, (Lessons) 87
——of electrical connections: Boosters and storage batteries, 195; K2 Controller 92
——of telephone systems, By H. S. Webb 409
Diesel oil engine.................................*221
Dimmer for incandescent lamps............*442
Direct-current vs. polyphase currents...... *26
Distribution from Sterling incandescent lamps 513
——, Berg system of, for rotary converters (patent) 27
——, Hewlett alternating-current system of, (patent).............................. 27
——, Kent system of electrical, (patent). 177
Dixon Crucible Company, Power plant of the Joseph 517
Dowsing luminous electric radiators...... *24
Draw-bar pull, Formula for, (Q & A.).... 196
Duty of a pumping engine (Q & A)........ 242
Dynamo, Arc-light, Unusual action of an, By E. C. Sutton........................... 46
——, Brush arc-light, troubles and their remedies, Some, By F. B. O'Hanlon 596
——, Design for a 400-ampere electroplating, By Cecil P. Poole................... 356
——, Design for a 35-light incandescent, By Cecil P. Poole, 450; 75-light design, 32
——, Direct-current, of the Elec. Const. Co., Wolverhampton...................*492
——, Effect of reversing a field coil on a multipolar, By B. Graham........... 90
——field magnet structure, Lamme revolving, (patent) 176
——for gas-engine service, A sparking... 82
——, Midget; Elbridge Electrical Mfg. Co. 197
——, Paralleling of a direct-connected and a belted, By John M. Schmidt.. 192
Dynamos and motors, The rating and speed of, (Edit.).......................... 227
——, Bucking of railway, By E. C. Parham, 86 and 408; Geo. W. Malcolm, 135; Ed. S. Morgan....................... 240
——, Heath three-wire system of, (patent) 494
——, Induction motors as.................. *26
——operated in parallel, Compound, By Geo. W. Malcolm.......................... 135
—— —— ——, Direct-current, By Alton D. Adams.................................... 237
—— —— ——, Starting and stopping direct-current, By Alton D. Adams. 37
——, Rebuilding old arc.................... 497
——with surface-wound and slot-wound armatures, A comparison of, By P. M. Heldt 106

E

Econometer, The, By A. Bement........... 484
Economy, A practical demonstration in boiler, By C. Watson...................... 505
——, Efficiency and, (Edit.)................. 449
——in steam production, By C. W. Obert 217
Effect of scale in boilers..................... 495
Efficiencies, Boiler room, by W. D. Ennis 388
Efficiency. See also Gas and Steam engine efficiency.
——and economy (Edit.)...................... 449
—— —— operation of water wheels (Edit) 585
——of telephone generators, By W. S. Henry 453
Electrical progress in Australasia, By Lawrence Birks 267
Electricity in coal mining in the Pittsburg District, By Wm. G. Irwin......... 255
——in the nineteenth and twentieth centuries, By A. E. Kennelly............ 14
Electrocution (Edit.) 400
Electrode, New form of platinum........*537
Electrodes and terminals, Polarity of (Edit.) 499
Electrodynamometer, Adjusting an, By P. M. Gallo................................... 240
——, Construction of an, By S. M. Kintner 228
——, Note on the use of the, By Fred P. Woodbury 107
Electrolysis of fused alkali chlorides......*536
Electrolyte for bichromate of potash battery (Q. & A.)............................ 510
Electrolytic alkali cell........................*220
——alkali process, Outhenin-Chalandre..*289
——production of soda and chlorine, By Ernest Franke 104
Electromagnetic couplings, Group-driven lathes with *76
Electromagnetism (Lessons) 548
Electromagnets and solenoids, 155; Windings for 209
——, Lifting, By E. B. Clark.............. 64
Electroplating dynamo, Design for a 400-ampere, By Cecil P. Poole............. 356
Electropoion battery solution (Q. & A.).. 510
Elevator controller at the Exposition, Cutler-Hammer solenoidal electric... 459
—— ——, Lindstrom electric, (patent).. 444
Emerson fan motors, Efficiency of........ 367
Engine. See also Gas and Steam engine.
Engine Builders' Association............... 23
——, Coal burning internal-combustion..*491
——, Duty of a pumping, (Q. & A.)..... 242
Engines for superheated steam, Boilers and *395
Engineer, The new chief, By E. D. Williams 478
Engineers, A hint for practical, By William D. Ennis................................. 264
——, A short talk to, (Edit.)............... 296
English central stations, Recent types of. 9
Eureka telephone switchboard............. 140
Evaporation, Relation of the rate of, to the fuel economy of boilers, By William D. Ennis.................................. 521
Exposition. See Pan-American and South Carolina.

F

Factory power plant of the Dixon Co.. 617
—— —— ——, of the Wetmore Tobacco Co. By F. E. Bausch................ 61
Fan motor, Design for a direct-current.. 182
——motors, Comparative testing of, By S. D. Gilbert, 307; By A. R. Everest. 366
—— ——, Efficiency of Emerson......... 367
—— —— for 1901 158
Feeder system, Duplicate *577
Feed-water heater *174
——heating, Boiler feeding and, By L. B. Mather, 67; (Edit.)................. 81
—— softeners, Two English boiler...... 576
Ferranti central station at West Ham.... 9
Field coil on a multipolar dynamo, Effect of reversing a, By B. Graham....... 90
——magnet structure, Lamme revolving, (patent) 176
Fields and grounded armatures in railway motors, Weak, By Frank Berry, Jr. 189
Five-wire distribution system..............*174
Flue cleaners, Steam, By James F. Hobart 86
Fly-wheel accidents, By C. W. Obert..... 181
Formulas (Q. & A.) Direct-current armature torque 510
  Draw-bar pull 196
  Horse-power of a three-phase motor 552
  Inductance of a coil 365
  Photometer scale 138
  Size of iron resistance 552
  Storage battery pasted plate 365
Fort Wayne shell-type transformer....... 142
French Corliss-type steam engine, A...... 214
Frequency, Alternating-current, (Edit.).. 499
——changer; Stanley Electric Mfg. Co.. 243
——indicator, Alternating-current........*175
——meter, A *174
Fuel economy of boilers, Relation of the rate of evaporation to the, By William D. Ennis.................................. 521
——, Loss in economy by the incomplete combustion of, By A. Bement, 484; (Edit.) 498
——, Pulverized, By R. A. Douglass, 434; (Edit.) 449
Furnace, New electric.........................*493
——performance, Boiler, (Edit.).......... 498
Fuse box, Lyons reserve, (patent).......... 177
——, Feuerlein enclosed, (patent)......... 117
——holder, Linton combined switch and, (patent) 444
Fuses, Cable connectors and................*493

G

Galvanometer shunts *536
Ganz three-phase motors for the London Metropolitan Underground Railway.*173
Gas analyzing apparatus, By A. Bement, 484; (Edit.) 498
Gas engine efficiency tests................... 329
—— ——, Design for a 1-h.p., By J. C. Brocksmith 586

A REPRESENTATIVE AMERICAN CENTRAL STATION.

THE PLANT OF THE EDISON ELECTRIC ILLUMINATING COMPANY OF BROOKLYN.

For several years past the system of the Brooklyn Edison Electric Illuminating Company has been in slow but sure process of transformation from an aggregation of more or less old-fashioned plants representing various epochs of central station practice into a concrete system embodying the latest types of apparatus and most modern methods of operation. The evolution has been slow because of the stupendous difficulties attending the remodeling of a system saddled with a rapidly increasing 24-hour load; it has been sure because of the unusual foresight and indomitable energy of the company's general manager, Mr. W. S. Barstow, under whose direction all of the work of weeding out obsolete machinery and modernizing the whole system has proceeded. The rehabilitation of the system has now reached a point where it is chiefly a question of getting the remainder of the machinery and apparatus which were ordered months ago, and installing them in the few stations that are yet incomplete.

The system comprises two main generating stations at which three-phase alternating currents are generated at 6600 volts e.m.f., and 25 cycles, and eleven substations to which this current is supplied and which change it into the proper class and voltage for the various classes of distribution. The distributive service consists of two-phase alternating current at 2400 volts and 62 cycles, which is transformed in the usual manner for supplying arc and incandescent lamps and motors in the outskirts of the city; constant direct current, for certain street lighting circuits on which it is deemed advisable to retain this class of service; and constant-potential direct current which supplies an Edison three-wire network in the congested part of the city.

One of the main generating stations is located on the river edge at the foot of Gold street and the other, known as the Union Station, is also on the water-side, but over in the southern part of the city at Bay Ridge. The Gold street station is equipped with six Stirling water-tube boilers of 500-h.p. capacity each. These are provided with under-feed stokers, built by the American Stoker Company, of New York; these machines consist broadly of a feeding retort in which a screw or worm is rotated, feeding the coal into the furnace as it is required. The view of the boiler room, which appears on another page, shows the arrangement for delivering coal to the mechanical stokers. A V-shaped coal bin extends lengthwise over the center of the boiler room and the coal feeds by gravity into the weighing hopper, shown at the top of each boiler front. This hopper contains a scale pan which is connected by a lever to a Fairbanks beam scale, and each hopper of coal is thus weighed before it can reach the chutes leading down to the stokers. Coal is delivered to the station in barges, from which it is carried up to a coal tower at

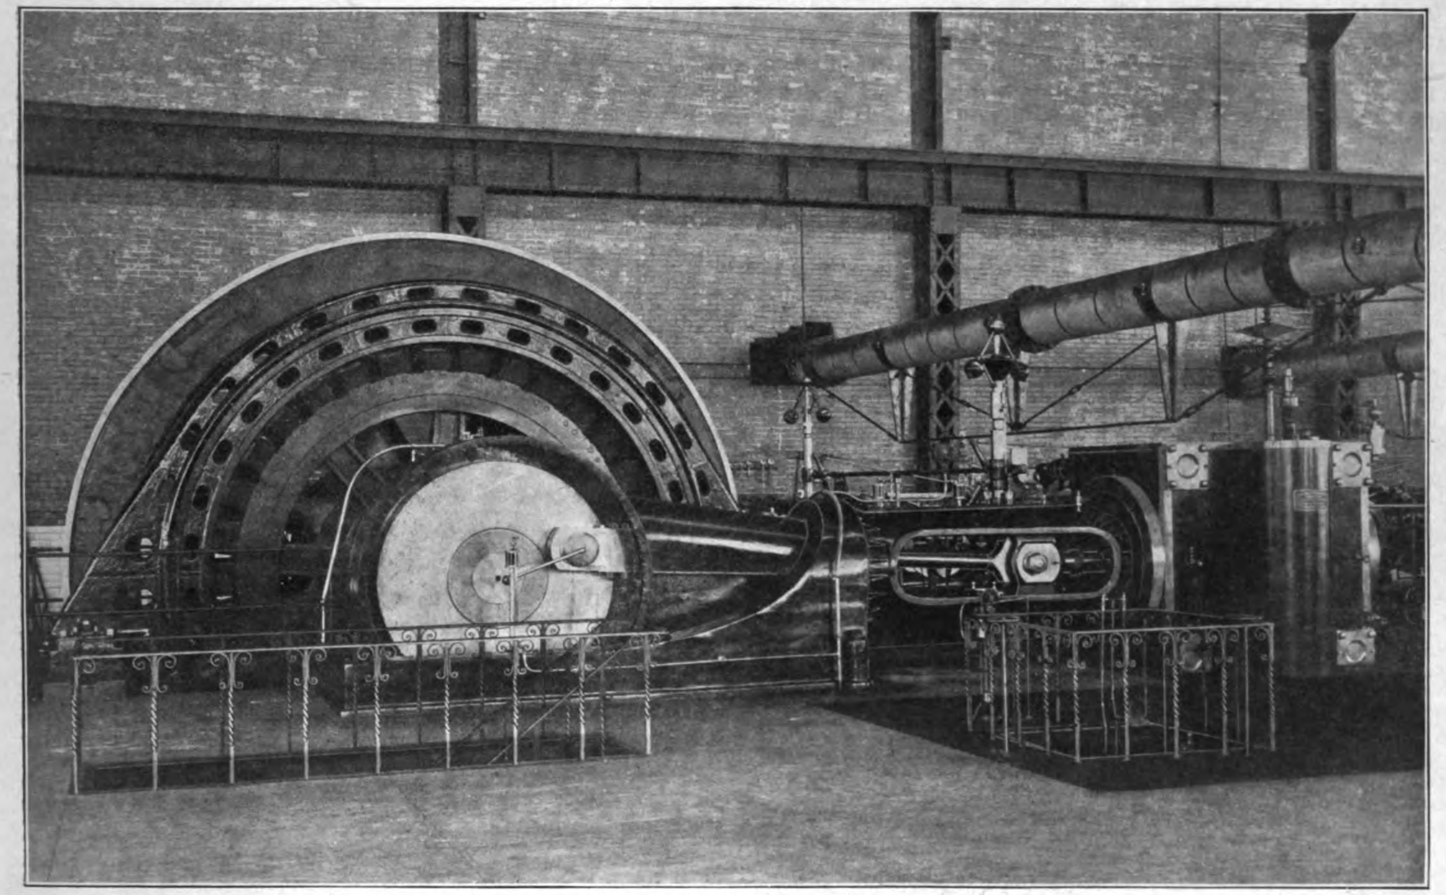

FIG. 1.—ONE OF THE 1000-HORSE-POWER GENERATING UNITS OF THE GOLD STREET STATION.

one end of the coal bin; from the tower a semi-automatic industrial railway car takes coal into the bin, distributing it according to the adjustment of the "trips." The coal-handling apparatus was installed by the C. W. Hunt Company, of New York.

The piping between the boilers and engines is in duplicate throughout. There are two headers in the boiler room and each boiler is connected to these by means of duplicate delivery pipes. From each header an omnibus or trunk supply pipe extends into the engine room, as shown in the general view of that room, Fig. 1. These pipes turn down and terminate in separators beneath the engine-room floor, and the separators deliver in turn to two steam headers from which duplicate individual supply pipes lead to the engines. The feed-water is heated entirely by the exhaust steam from the blower engines and various pumps, no heater being inserted in the exhaust piping of the main and exciter engines. Jet condensers built by the E. P. Allis Company, Milwaukee, are used in connection with all of the engines that drive generators.

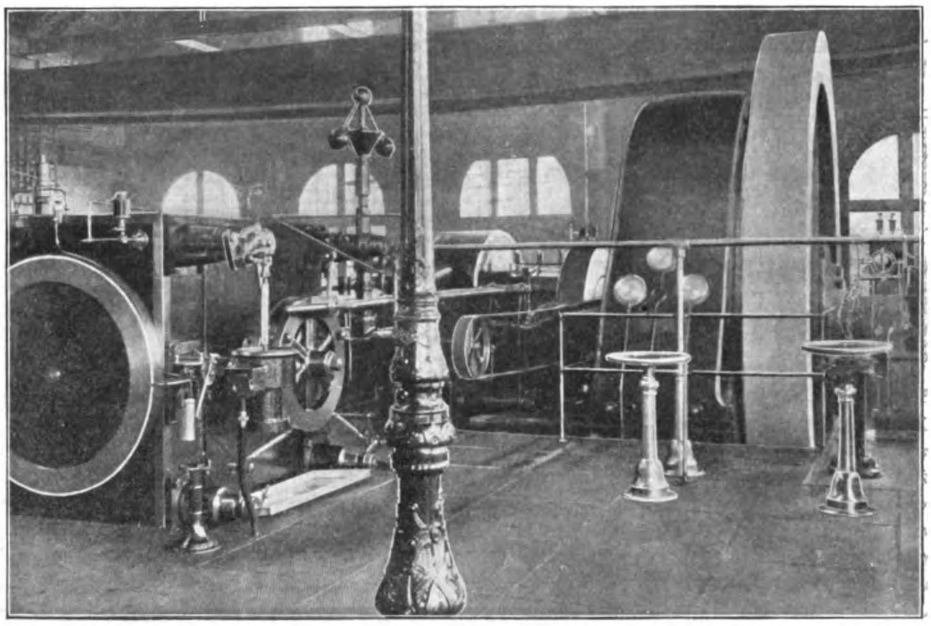

FIG. 3.—A PARTIAL VIEW OF THE VALVE-GEAR.

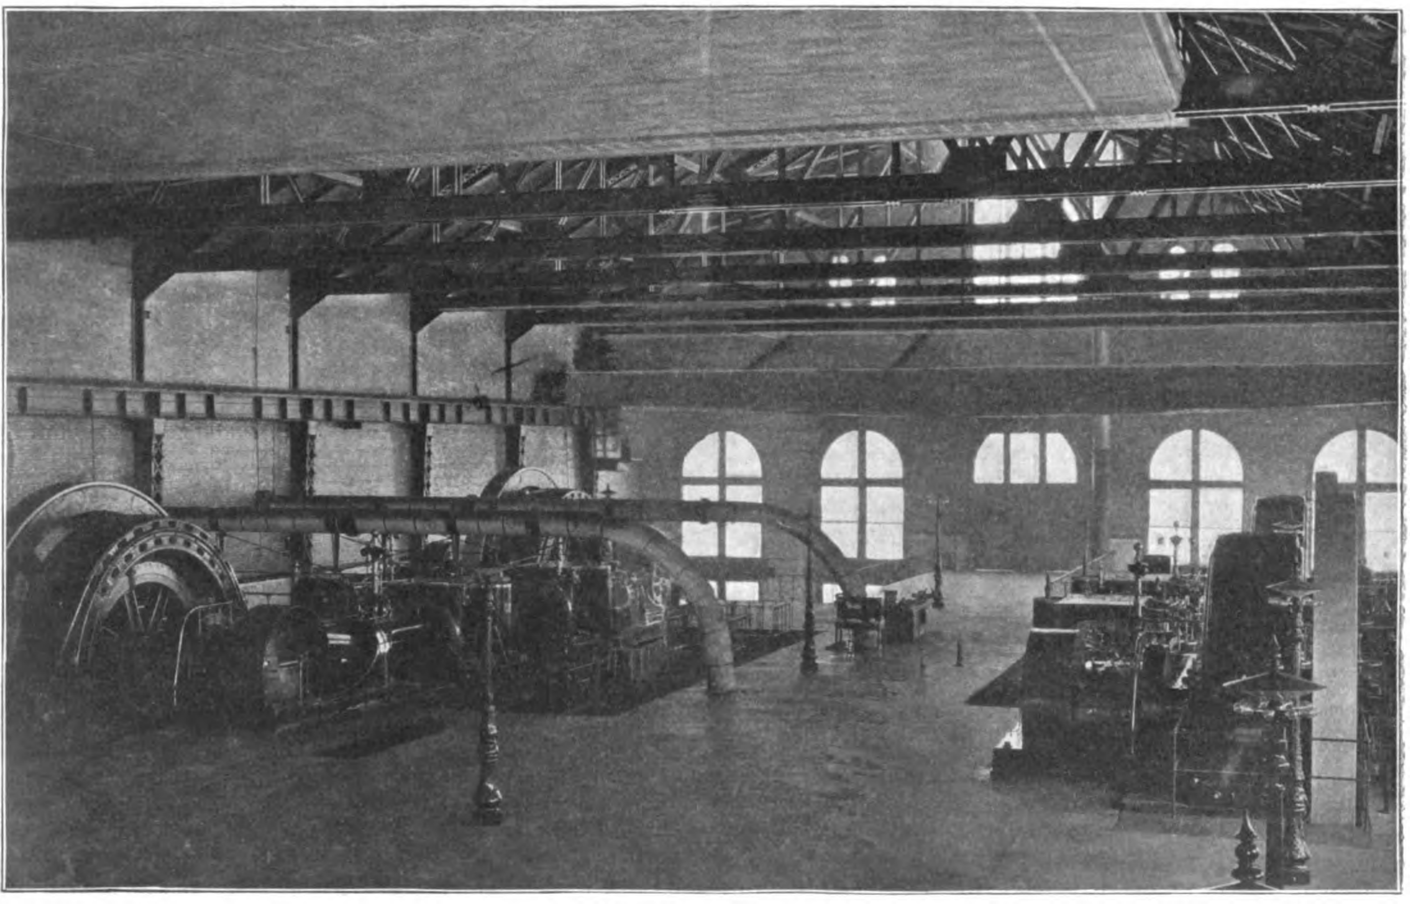

FIG. 2.—VIEW OF THE GOLD STREET ENGINE ROOM.

The main engines are cross-compound Reynolds-Corliss (E. P. Allis Company) machines, of 1000-h.p. capacity each; there are four of these, each driving direct a 750-kw. Westinghouse three-phase alterator at 94 r.p.m. Fig. 1 illustrates one of the engine-generating units. Fig. 3 gives a partial view of the valve-gear, which is of the familiar Reynolds type. The space which is nearly enclosed by the four cylinders of each pair of engines forms a sort of operating platform, containing a steam-chest, receiver and vacuum gauges for each engine, mounted on the generator frame, as shown in Fig. 3, and all of the manipulating valve-wheels; the latter are on floor-stands, as in marine practice. Each engine is equipped with a Monarch safety stop made by the Monarch Manufacturing Company, Waterbury, Conn., and an electro-mechanical synchronizing device. The safety stop consists simply of a fly-ball governor which closes a circuit through a magnet coil when the speed becomes excessive; a magnet armature which trips a latch and allows a heavy weight to close a stop-valve in the engine supply pipe, and an electric bell which is put in circuit by the same mechanism that closes the stop-valve. The synchronizing arrangement includes a Lundell motor mounted on the governor rod which connects the cut-off mechanism of the high and low pressure sides; this motor is controlled from the switchboard and is adapted to rotate the governor rod independently of the governor so as to vary the cut-off, and consequently the speed, of the engine.

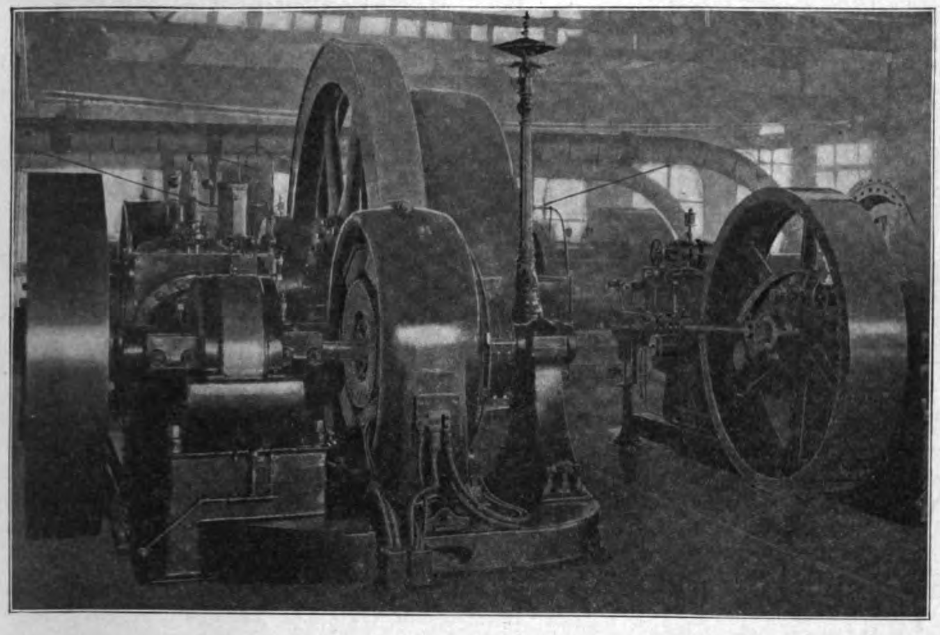

FIG. 4.—THE EXCITER SETS.

The four 750-kw. alternators are of the revolving-field type, with the rotating member built up on the engine shaft between the high-pressure and low-pressure cranks. They deliver three-phase currents directly to the line at 6600 volts and 25 cycles per second. The fields are excited by 125-volt Westinghouse dynamos each of 250 kw. capacity. These machines are standard lighting dynamos, with multipolar compound-wound fields and direct-driven by 400 h.p. Ball & Wood tandem-compound engines. The engines are equipped with the latest type of valve-gear. The exhaust valves are operated by an individual eccentric and wrist-plate motion, only the steam valves being affected by the action of the governor. The valves are of the rocking type and the gear gives them a peculiar quick-opening movement due to the change of angle between the rocker-arms on the valve-stems and the links which connect them with the wrist-plate. There are two of these exciter sets, each capable of supplying the fields of all four alternators. There is in process of installation an auxiliary storage battery of 8000 ampere-hours capacity, the function of which will be to prevent "loss of field" by the alternators in the event of having to shut down the active exciting set before its mate can be started up, when only one set is running. A motor-dynamo set has already been installed for use in connection with the storage battery. It comprises a Lundell dynamo of 50 volts and 100 amperes capacity and a Lundell motor of corresponding capacity; this set appears in the view of the switchboard, Fig. 5.

The switchboard is divided into ten panels, eight of which are in place; the other two will be installed immediately. There are four generator panels, one station panel, one exciter panel and two feeder panels now up; the two to be installed will be feeder panels. Three sets of 6600-volt bus-bars extend across the board, this number being provided for convenience in "changing over" generator sets. The station panel equipment consists of three General Electric Type F oil-break switches for tying the bus-bars together; synchronizing apparatus for synchronizing between bus-bars prior to "tying in"; a bus-bar voltmeter calibrated to indicate the line potential, and two static ground detectors. The generator panels contain each three Type F oil-break switches, one for each set of bus-bars; two G. E. induction indicating watt-

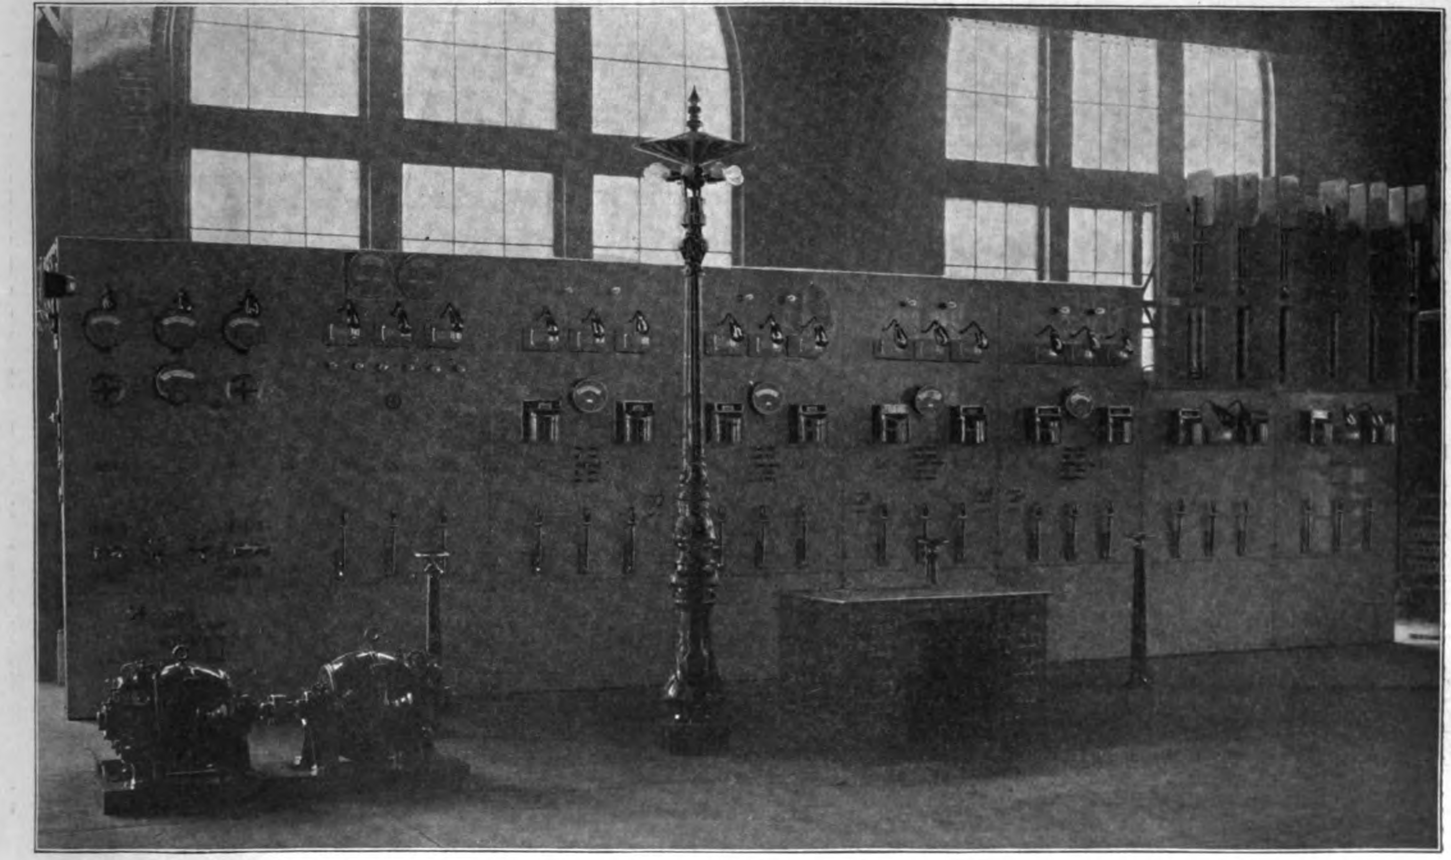

FIG. 5.—THE SWITCHBOARD OF THE GOLD STREET STATION.

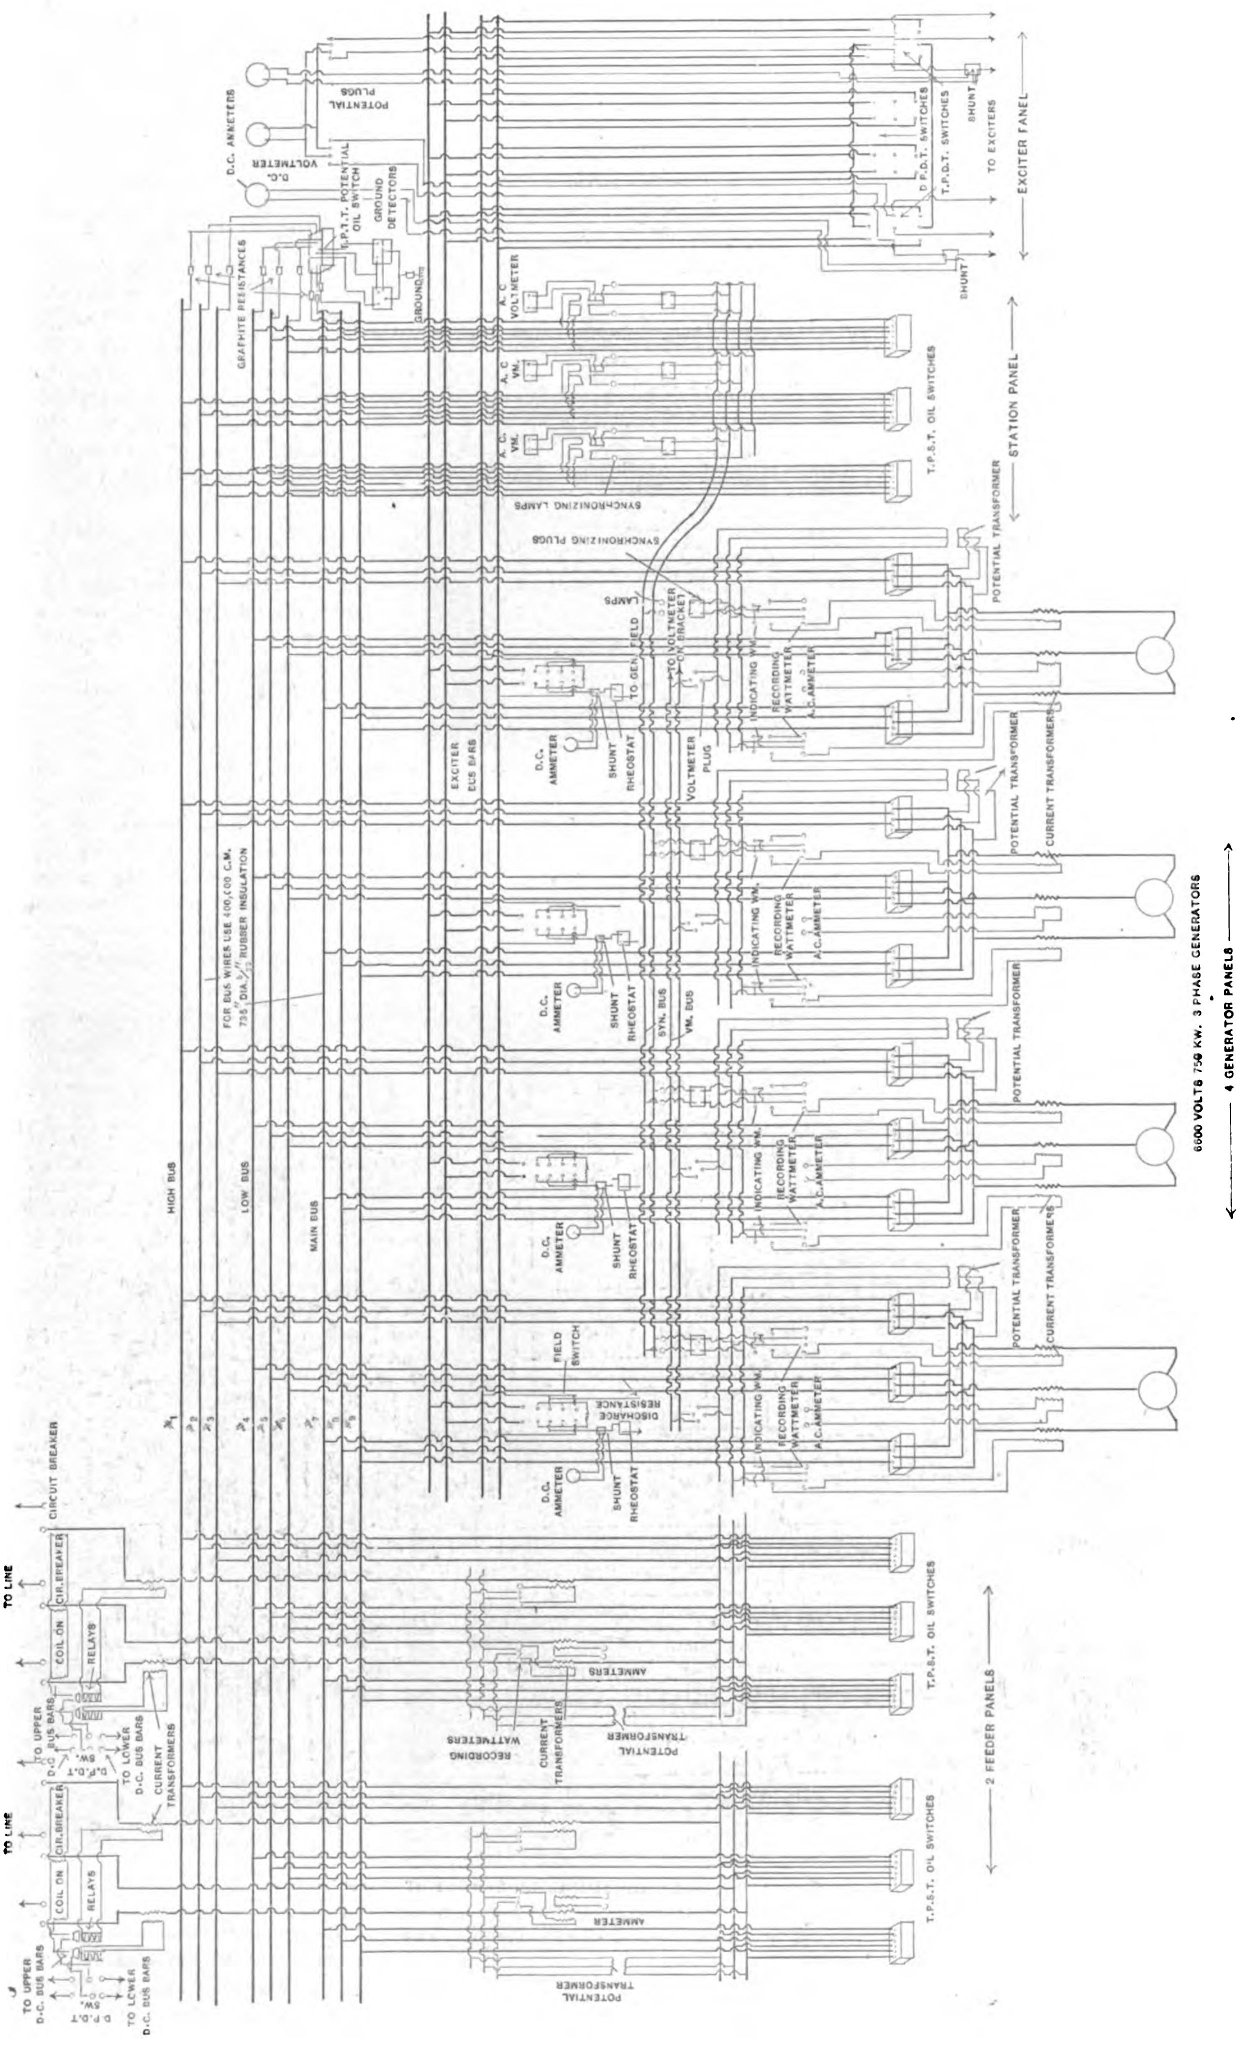

FIG. 6.—WIRING DIAGRAM OF THE GOLD STREET STATION SWITCHBOARD; FROM THE BACK OF THE BOARD.

meters; two Thomson recording watt-hour meters; a main ammeter; potential plugs and synchronizing apparatus; a field circuit switch and a Weston ammeter in the field circuit. The exciter panel carries the usual equipment of direct-current instruments and switches. The switching arrangement is such that any alternator field may be put on either of the exciters, and the latter may be operated in parallel or independently. Each feeder panel carries three Type F oil-break switches, one for each set of bus-bars; three circuit-breakers and two Thomson recording watt-hour meters. All of the switchboard equipment was manufactured by the General Electric Company excepting the direct-current voltmeters and ammeters, which were furnished by the Weston Instrument Company, Newark, N. J. The circuit-breakers are in compartments at the top of the panels, as shown in Fig. 5. The switches are all located beneath the engine-room floor and connected to the switch handles by means of long wooden rods, so that the attendants do not need to handle any apparatus that is metallically connected with the high-tension circuits. Before resetting a circuit-breaker the feeder is cut off by its oil-break switch.

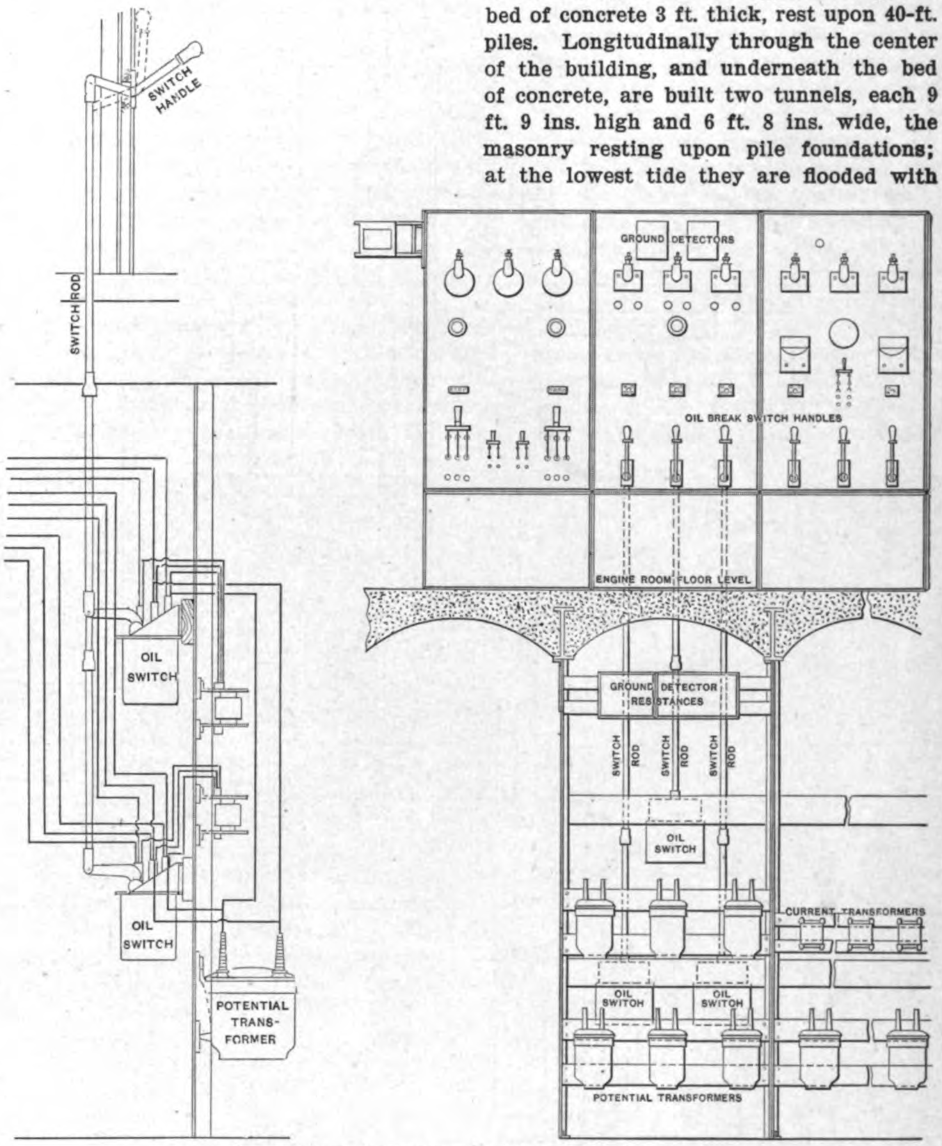

FIG. 7.—DETAILS OF HIGH-TENSION SWITCH MECHANISM.

The Bay Ridge station, or Union Station, is not yet complete. It contains at present twelve 500-h.p. water-tube boilers of the B. & W. type, built by the Aultman & Taylor Machinery Company, of Mansfield, Ohio; one McIntosh & Seymour twin tandem-compound engine of 2500-h.p. capacity; one Hamilton-Corliss cross-compound engine of 1200 horse-power, and two General Electric three-phase alternators, one of 1500 kw. and the other of 750-kw. output, with the necessary auxiliary machinery and apparatus. The station building is 206 ft. long and 120 ft. wide, of composite brick and iron construction. The foundations of the building, consisting of a bed of concrete 3 ft. thick, rest upon 40-ft. piles. Longitudinally through the center of the building, and underneath the bed of concrete, are built two tunnels, each 9 ft. 9 ins. high and 6 ft. 8 ins. wide, the masonry resting upon pile foundations; at the lowest tide they are flooded with 6 ft. of water. The tunnels extend out into New York Bay a distance of 50 ft. from the building, and at this point they are protected by heavy copper-wire screens. The purpose of these tunnels is to have water directly under each engine without requiring suction, the condenser pump of the engine taking the water from one tunnel, through the surface condenser, and discharging it into the other. This arrangement reduces the energy required for the circulation of the condensing water to that required to overcome the friction of the piping, the column of water that is discharged balancing the one that is lifted.

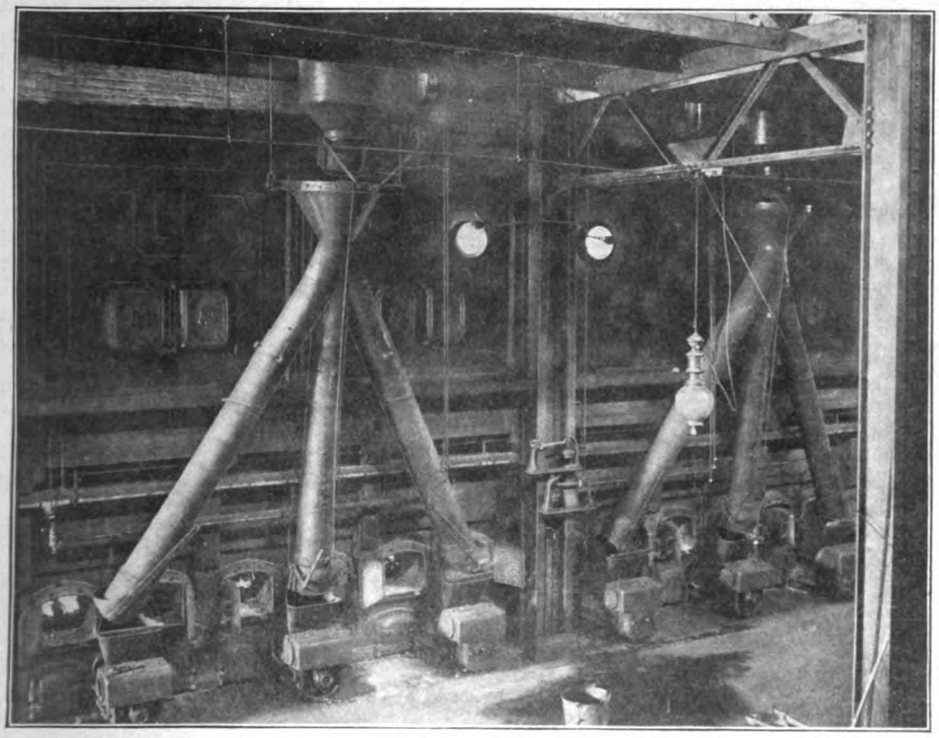

FIG. 8.—A PARTIAL VIEW OF THE BOILERS.

Extending out from the southern part of the water-front of the company is the coal pier, built to accommodate vessels of any length and draught. On this pier travels an unloading tower, which is operated entirely electrically by one man. The electric hoist, operated on the Leonard system, removes the coal from the boat on either side of the pier with a one-ton shovel and deposits it in a hopper in the center of the tower. The coal then falls by gravity onto the crushing rolls, which are driven continuously from a motor dynamo which supplies the hoist

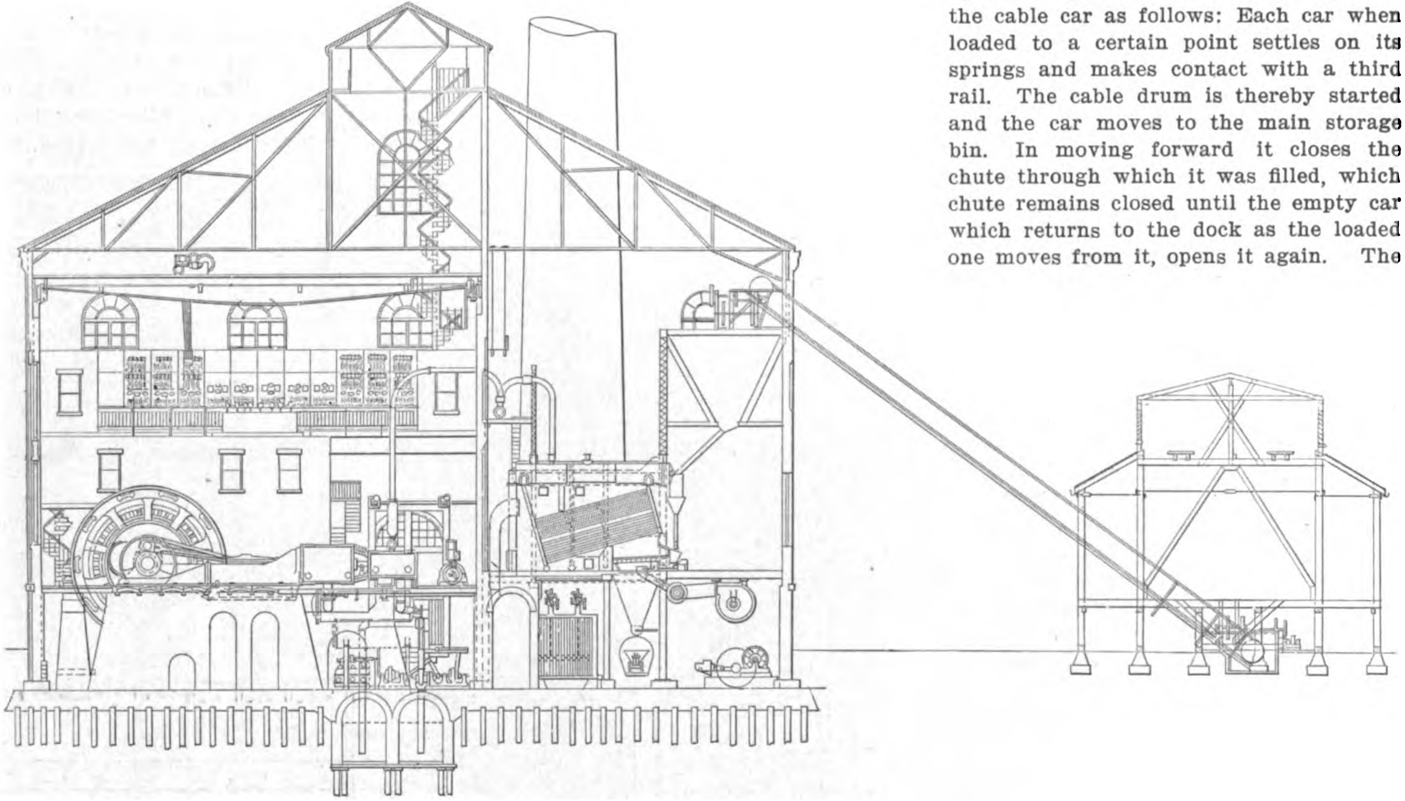

FIG. 9.—CROSS-SECTIONAL ELEVATION OF THE UNION STATION.

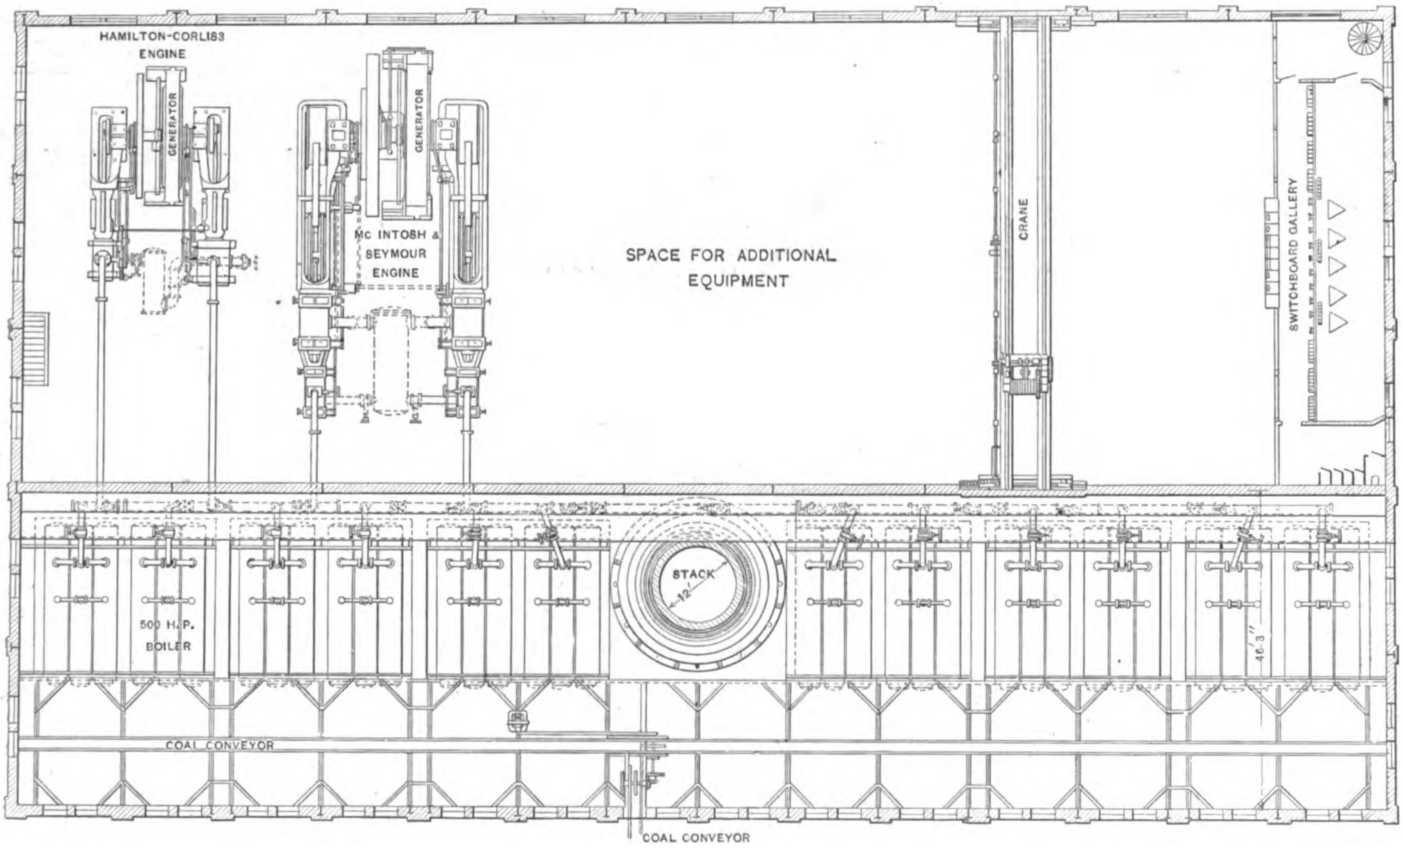

FIG. 10.—PLAN OF BOILER ROOM AND ENGINE ROOM AT UNION STATION.

above. From the crushers the coal passes to a Clarke self-weighing and self-feeding scale, which automatically records the weight of the coal on a dial. From the scale the coal descends into a cable car located beneath the tower and running on tracks laid on the pier.

The tower is capable of moving lengthwise to the pier, so as to render it possible to unload the coal at any point on either side of it. From the tower the coal is conveyed by means of a shuttle cable road up an incline to a 2000-ton coal storage bin, located about 300 ft. back of the tower and 60 ft. south of the main building. The motor operating this shuttle road is automatically stopped and started by the weight of the coal that drops into the cable car as follows: Each car when loaded to a certain point settles on its springs and makes contact with a third rail. The cable drum is thereby started and the car moves to the main storage bin. In moving forward it closes the chute through which it was filled, which chute remains closed until the empty car which returns to the dock as the loaded one moves from it, opens it again. The loaded car empties itself at any point desired; the car thus emptied is raised in its springs, breaks the circuit and is stopped.

The coal storage is a wooden structure 100 x 40 ft., and 30 ft. high, proportioned and built for the storing of 2000 tons of soft coal. Under the pocket, and for its entire length, runs a link-belt conveyor.

This conveyor takes the coal from the various chutes and deposits it into another conveyor, which, carrying it up an incline of 30°, transfers it to a third conveyor, which deposits it into hoppers over the boilers, which have a capacity for two days' supply. This arrangement is shown in the sectional view, Fig. 9. From these hoppers the coal passes down a chute and through a self-weighing scale (one for each battery of boilers) into a small distributing screw conveyor, which feeds it to the stokers. Thus the entire operation from the unloading of the coal on the tower to the burning of the coal in the furnace is performed automatically. The coal-unloading machinery was installed by John A. Mead & Co.

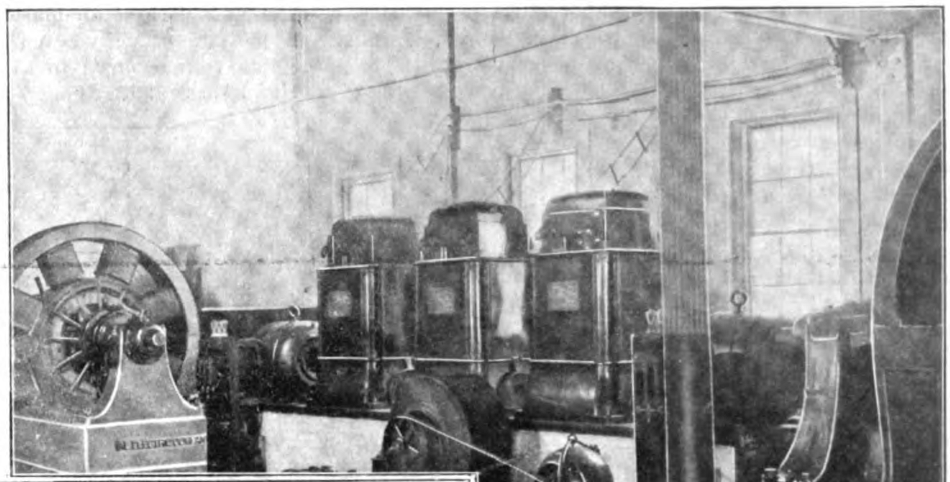

FIG. 12.—TRANSFORMERS AND ROTARIES.

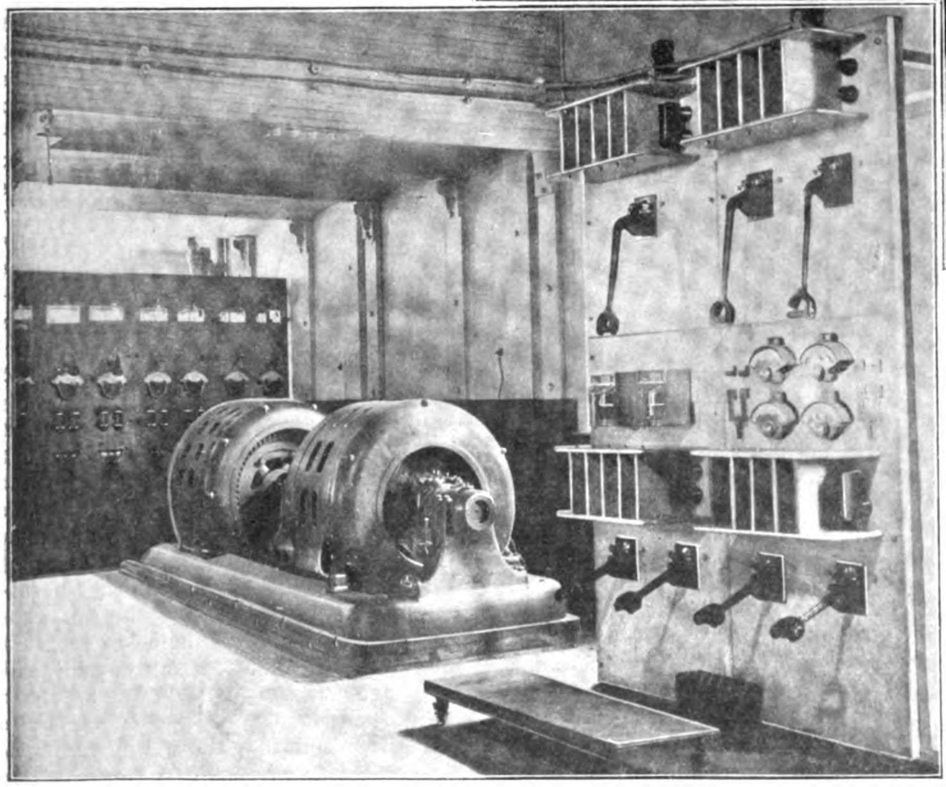

FIG. 11.—VIEW IN SECOND DISTRICT STATION.

Beneath the boiler room floor, and under the rear of the boilers, next to the firebrick flue, are located the Green economizers, so arranged as to provide for positive or natural circulation, as may be desired. The front of each economizer is fitted with a sectional sheet-iron filled cover so that any portion of the cover may be taken off and examination made of the sections of the economizer, and any section taken out without disturbing any other part of the economizer or disturbing the brickwork. These economizers were furnished by the Fuel Economizer Company, of Matteawan, N. Y.

In front of the economizers, and under the furnaces of the stokers, are placed the ash-receiving hoppers, beneath which runs an ash car the entire length of the boiler room, and through a bin in the west end of the building, to a point between two bulkheads, where the ashes are used for filling-in purposes.

Beneath the boiler room floor, directly under the passage of the front of the boilers, are placed the boiler-feed auxiliaries, blowers for the automatic stokers, and also the deep wells, used for the supplying of boiler feed water. In this station electric auxiliaries are used throughout. The circulating pumps are of the Knowles centrifugal type, direct-connected to a G. E. multipolar motor by insulated couplings, and run at a speed of 600 r.p.m. The air pumps are of the Worthington steeple three-plunger type, driven by means of single-reduction multipolar slow-speed G. E. motor, running at about 300 r.p.m Each group comprises a circulating and air pump, connected by short piping with a Worthington surface condenser, which is located immediately beneath the low-pressure cylinder, allowing, however, for suitable by-passes to free exhaust, and also for the introduction of a 2000-h.p. vertical Goubert heater, which is placed on either side of the engine in the basement The speed of these air and circulating pumps is controlled from the engine-room floor by means of field rheostats.

The total circulating water piping for each unit of 1500 horse-power does not exceed 12 ft. in length, there being but five joints. The total connection of the air-pump piping is about 14 ft. long. The total length of the piping between the low-pressure engine cylinder and the condensers, including the piping to the heaters for each unit, does not exceed 20 ft. in length, there being not more than seven joints. As will be seen from the above, special attention was paid to short connections.

The boiler feed pumps are of the Worthington horizontal three-plunger type, single-geared to a G. E. multipolar motor, running at 250 r.p.m. The speed of each unit is controlled from the boiler-room floor by means of a rheostat in the field circuit. Each boiler feed pump is directly connected to the feed system, which passes through Goubert heaters and auxiliaries into the main line, from which are taken the feeds to each boiler. Suitable by-passes are arranged for each piece of apparatus, so that any system of feed is provided for. The suctions of the feed pumps are connected to a main supplied from a number of driven wells, which are the chief source of water supply. The pumps draw from two large water tanks, where all particles of sand or suspended matter can settle. These tanks are supplied from the wells by an electrically-driven Deane duplex pump. Into the tanks are also connected all the leaders of the building, so that rain water can be used as boiler feed when desirable. Sturtevant blowers, which supply air to the stokers, are secured to the ceiling of the basement, or the underneath side of the boiler-room floor, and are directly connected by belts with slow-speed multipolar motors.

The plant, when completed, will contain

two 5000-h.p. Westinghouse-Allis engines, each driving a revolving-field Westinghouse three-phase alternator of 3000-kw. capacity; four Westinghouse synchronous 6600-volt motors of 225 horse-power each; two Westinghouse direct-current 125-volt excited dynamos of 150-kw. capacity each, direct-driven by two of the synchronous motors; two Westinghouse 250-volt direct-current dynamos of 150 kilowatts each, direct-driven by the other two synchronous motors and used to supply current to the motors which drive the pumps; and a switchboard embodying the latest practice of the General Electric Company.

As stated above, the three-phase 25-cycle currents are not used on any of the distribution mains, but are fed directly to the various sub-stations, of which there are eleven. The principal sub-station is what was formerly the central station of the old Citizens' Electric Illuminating Company. Here are located eight Brush arc dynamos direct-driven by four synchronous motors; a 400-kw. General Electric rotary converter, which supplies the outer wires of the three-wire incandescent system; a storage battery plant of 14,000 ampere-hours capacity which "floats" on the bus-bars of this system, and a 125-h.p. booster set for use in conjunction with the battery. The arc-lighting apparatus was described in the American Electrician for June, 1898, so that a detailed description here is not at all necessary. This sub-station serves also as a meeting-point for the main feeders from the Gold street and the Union stations; from its switchboard radiate feeders to other sub-stations, which feeders are thrown on either of the main generating stations according to controlling conditions.

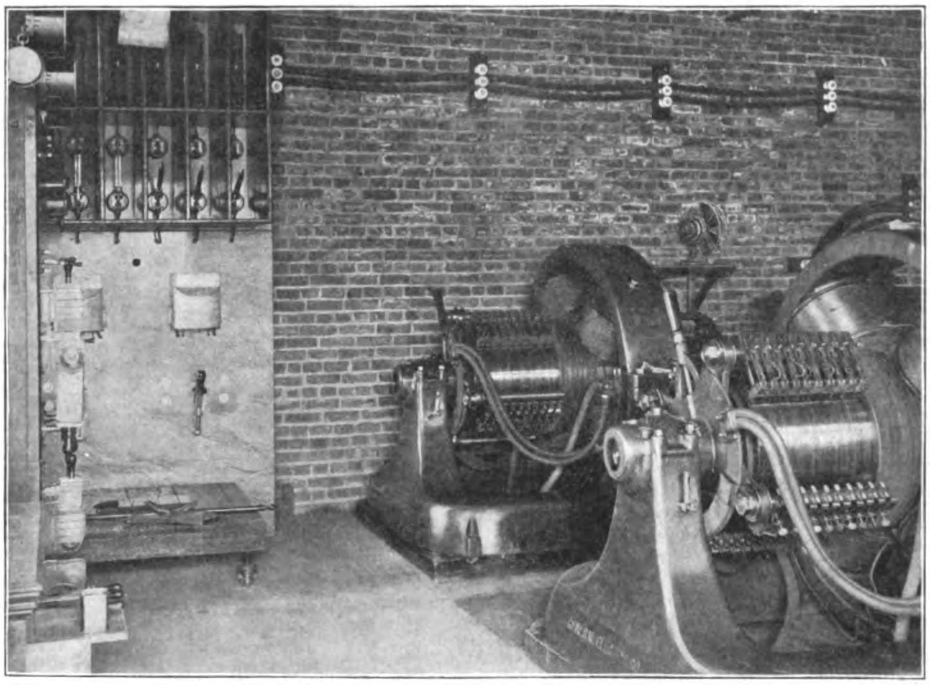

FIG. 13.—A COMPACT SUB-STATION.

There are three sub-stations from which two-phase primary circuits are supplied at 2400 volts and 62 cycles. These are the Second District, Coney Island and Forty-second Street stations. In all three, therefore, frequency changers are operated which change the generated currents not only from 25 to 62 cycles, but from 6600 to 2400 volts, and from three to two phases. Fig. 11 is a view in one corner of the Second District sub-station, in which the frequency changer appears. The machine consists of a synchronous 6000-volt motor of 100-kw. capacity direct-coupled to a machine which might be described as an induction motor with a 6000-volt three-phase stator and a two-phase 2400-volt rotor, the latter being provided with collector rings through which the two-phase primary circuits are supplied from the rotor winding. The synchronous motor drives the rotor in the opposite direction to that which it would take if allowed to run as a motor and the relation between the stator and rotor windings, of course, is such as to produce the change in frequency, phases and voltages. The capacity of the set is 200 kilowatts.

The switchboard which appears in the background of Fig. 11 is the 2400-volt board from which the two-phase primary distributing circuits are supplied.

To the right of the illustration is the 6000-volt switchboard, which is provided with the usual oil-break switches and instruments. From this board are supplied the frequency changer and three air-blast transformers of 150-kw. capacity each. These bring the line voltage down to 85 volts for use by two General Electric 25-cycle rotary converters, of 200-kw. output each. The transformers are supplied with air from a Buffalo blower-fan driven by a small General Electric direct-current motor. Between the rotary converters and the transformers are inserted induction regulators. Fig. 12 shows the transformers and converters. The direct-current brushes of the rotary converters feed into the three-wire incandescent mains at 125 volts, one converter supplying each side of the system.

Two of the sub-stations are of a somewhat novel character in that their sole purpose is the supply of current to private industrial establishment. One is located at the Worthington Pump Works and the other at Milliken Brothers' Structural Iron Works. Fig. 13 is a view in the Milliken station, which contains in the small space of 500 sq. ft. a complete 300-kw. power plant. The plant comprises two General Electric rotary converters and a Churchward converter of 100-kw. capacity each; three General Electric transformers of 30 kw. and three Wagner transformers of 75-kw. capacity each; and all the accessory apparatus. General Electric induction regulators are interposed between the transformers and the collector ring of the rotary converters, and there are the usual high-tension altenating-current and low-tension direct-current switchboards. The high-tension board faces the doorway and may be seen in the engraving; the edge of the direct-current board is toward the observer, so that it does not show plainly. The General Electric rotaries are four-pole machines and the Churchward converter has six poles; the frequency being 25 cycles, the speeds are 750 and 500 r.p.m., respectively. The direct-current e.m.f. is 250 volts, and the current is used to drive motors throughout the works. Among these are the motors on two huge cranes spanning the stock yards and railroad tracks, and the changes in load are consequently as erratic as in a small railway power house.

The feeders which connect the various sub-stations with the two generating stations are all underground, excepting those running down to the Coney Island Station. The feeders between the Union Station and Coney Island, and those from the Union Station to the Citizens' Station are quadruple; all of the others are in duplicate. The underground cables consist of three conductors each insulated with paper covering 3/16 in. thick and twisted together, the whole being again covered with paper to a depth of 3/16 in. and armored with lead ⅛ in. thick. The lead armoring is grounded permanently and the cables are run in vitrified conduits, each cable in an individual duct.

All three-phase energy entering a sub-station is measured by a recording wattmeter before it is distributed to the various transformer devices; all energy leaving a sub-station in any form whatever is also measured by wattmeter, as is also all energy used in a sub-station for lighting, heating, etc.; all energy generated and used at as well as that leaving the generating stations is metered, so that a complete record of the entire system is obtained.

It was not thought that the extra expense was justified to separately meter the energy entering the various transforming devices, as tests at frequent intervals will satisfactorily determine, mechanically and electrically, the efficiency. All business done by the company is on the meter basis.

RECENT TYPES OF BRITISH CENTRAL STATIONS.

THE CENTRAL STATION AT WEST HAM, LONDON.

English central stations are in many respects different from those in the United States, and one of the prominent points of variance is the heterogeneous nature of the plant. In most cases there are to be found generators by two or more makers, and other electrical apparatus gathered indiscriminately from many manufacturers, possibly with the intention of testing the merits of all in order to arrive at definite conclusions for future orders. It therefore results that British central stations have not that uniformity that characterizes our own, where more fortunate conditions of local government, as well as more definite demands for power, have enabled the installation to be proceeded with in a more complete manner from the start.

Foremost among the engineers associated with electric central station work in England is Sebastian Z. de Ferranti, who has been prominently connected with the development of electric light machinery and systems of distribution during the past decade. Although still a young man —he was born in 1864—Mr. Ferranti has had a life ripe in experience which has been turned to good account. In 1882 he was appointed engineer to a company formed to manufacture his dynamo with the wave-form coreless armature, which constituted an important step in the evolution of the practical machine of to-day, as these dynamos proved efficient and reliable, and capable of sustained service without fear of breakdown. In 1886 there were practically no large dynamos anywhere, certainly nothing of any importance; but Ferranti at one step went straight away to a 700-h.-p. high-tension generator, and followed this two years later by generators of 1600 horse-power capacity.

Many improvements in design were introduced in those early days, which have since proved their value by universal adoption; as, for instance, the use of copper strip wound on edge for the field coils. Later, this method of winding coils was applied to meters, and in 1893 to high-tension alternator fields. About this time Mr. Ferranti sent sample coils to Messrs. Brown, Boveri & Co., who adopted the idea, and strips wound on edge are now universally employed in the United States and all over Europe.

The first central station work with which Ferranti was connected was the first station of importance in operation in England—that built in the sub-basement of the Grosvenor Gallery in London, and equipped with three Siemens alternators of the wood-core bobbin type. The distribution was by means of Gaulard and Gibbs series transformers. The many difficulties incidental to the operation of a high-tension central station called for an experienced engineer to direct the work, and Mr. Ferranti undertook the responsible task of bringing the system to a commercial and practical basis.

Much trouble was experienced with the alternators, as they were of rather primitive design, and eventually the three were replaced by one Ferranti alternator of 700 horse-power, the armature being carried on the countershaft and the magnet frame placed on a baseplate sunk in the floor, with extension plates to allow of the frame, which was in halves, being slid away from the armature for purposes of inspection. This construction is now employed in nearly all large machines of the present day. The station was later supplied with a self-contained unit of 700 horse-power, with grooved pulley for rope driving, and an outboard bearing. Still later, it was decided to start the supply of current on a larger scale, and Mr. Ferranti determined on a radical departure from existing procedure by drawing up

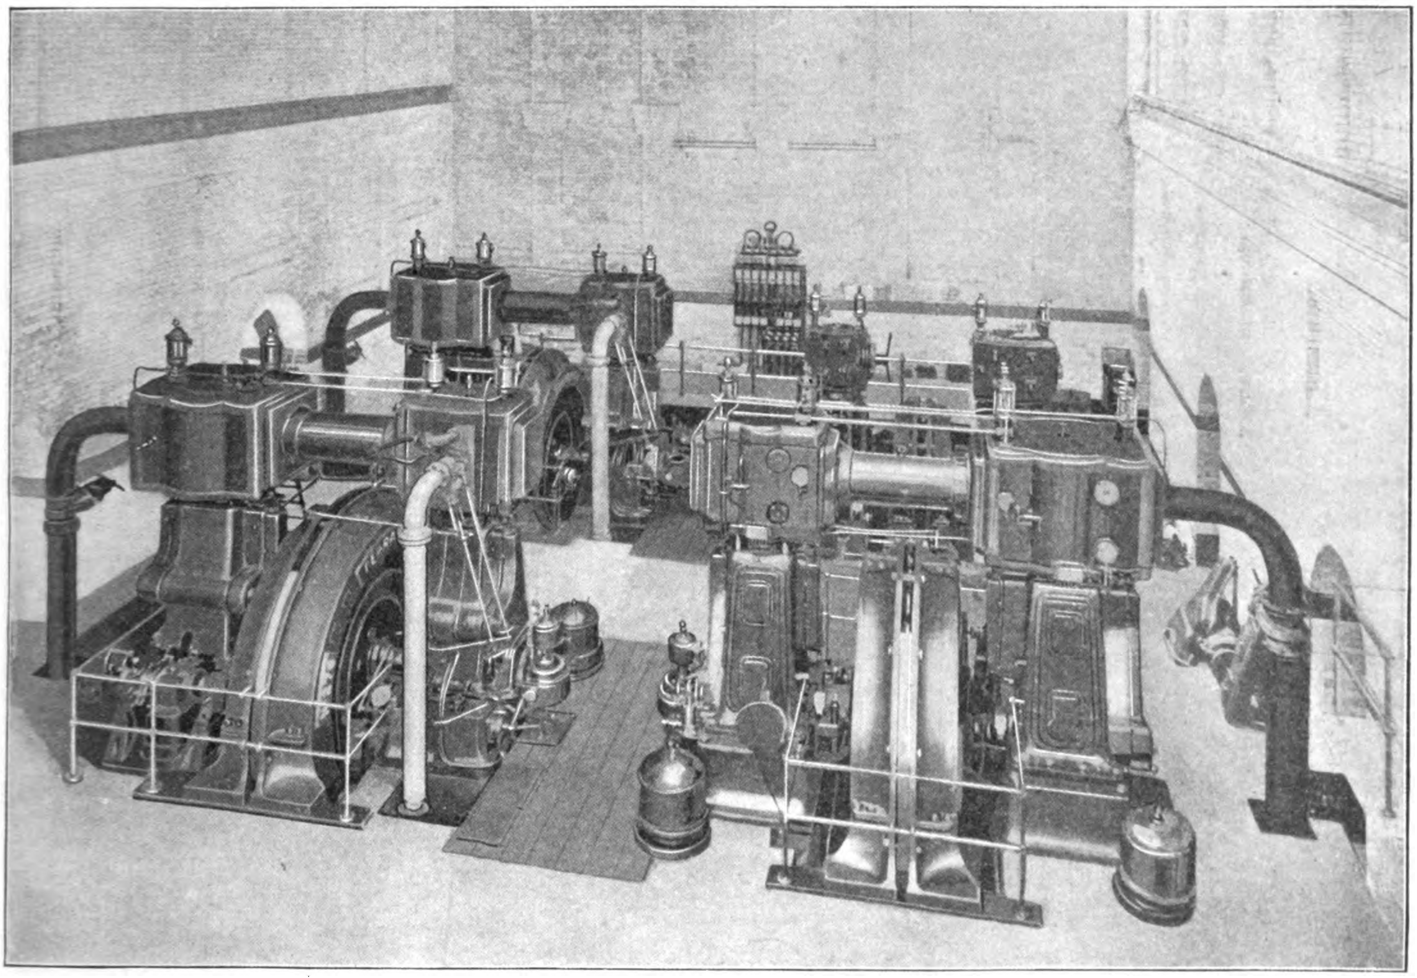

FIG. 1.—VIEW OF SMALLER GENERATING SETS, TAKEN FROM THE ENGINE-ROOM CRANE.

plans for a station of enormous capacity, which should be able to supply current for lighting on the same scale as the large gas corporations.

The Grosvenor Gallery high-tension distribution was at 2400 volts, but the new station, at Deptford, eight miles away, was to supply a 10,000-volt distributing system, an unheard-of proposition, and, to most engineers of that day, preposterous. The plan was widely denounced and its failure almost universally predicted, but Ferranti persisted and brought to a successful consummation the enterprise so freely criticised, and the 10,000-volt distribution is still an accomplished fact, the current being carried in the special concentric cables designed by him for this station. Ferranti alternators of 10,000 horse-power were under construction for this station, and well advanced, in 1889; but the directors, losing faith in the scheme on account of its mammoth scale, decided that they should not be completed.

The borough of West Ham, in London, possesses a central station in which the running machinery, both engines and alternators, were designed by Mr. Ferranti and built by his firm. The most interesting part of the installation is the new type of large high-speed vertical compound engine which Mr. Ferranti has built on new lines and containing many original ideas which involve departures from ordinary practice. On the continent of Europe and in the United States high economy has usually been obtained by the use of low-speed Corliss or other form of trip-valve engines. In England, on the other hand, most of the electric lighting work has been done by means of small high-speed engines entirely enclosed, and running with but very slight wear, almost without attention. Mr. Ferranti has combined to a great extent the advantages and strong points of both systems in the engines which are in use at the West Ham station.

There are in this station six direct-connected engine-alternators; a small one of 200 horse-power, three of 400 horse-power each, and two of 2000 nominal horse-power each, but capable of furnishing 2500 horse-power. One of the striking features of the latter machines is the small amount of space occupied; the ground area is only 20 feet by 16 feet, and the height above the engine room floor is 17 feet. This, of course, involves high rotative speed, and the engines run at 250 r.p.m.

The alternator armature has the coreless strip winding, such as was used in the Deptford machines; or, rather, there is a core in the coils, but not of magnetic material, being built up of bronze strips cast into a shoe at the inner end and insulated by strips of asbestos to prevent the circulation of eddy currents. The diameter of the armature is 14 feet, so that the peripheral velocity is 11,000 feet per minute—a speed that most dynamo builders would not care to deal with—and, standing near it, it seems like a great buzzsaw turning within a circular guard frame. Both of these engine-generator sets are shown by Fig. 2.

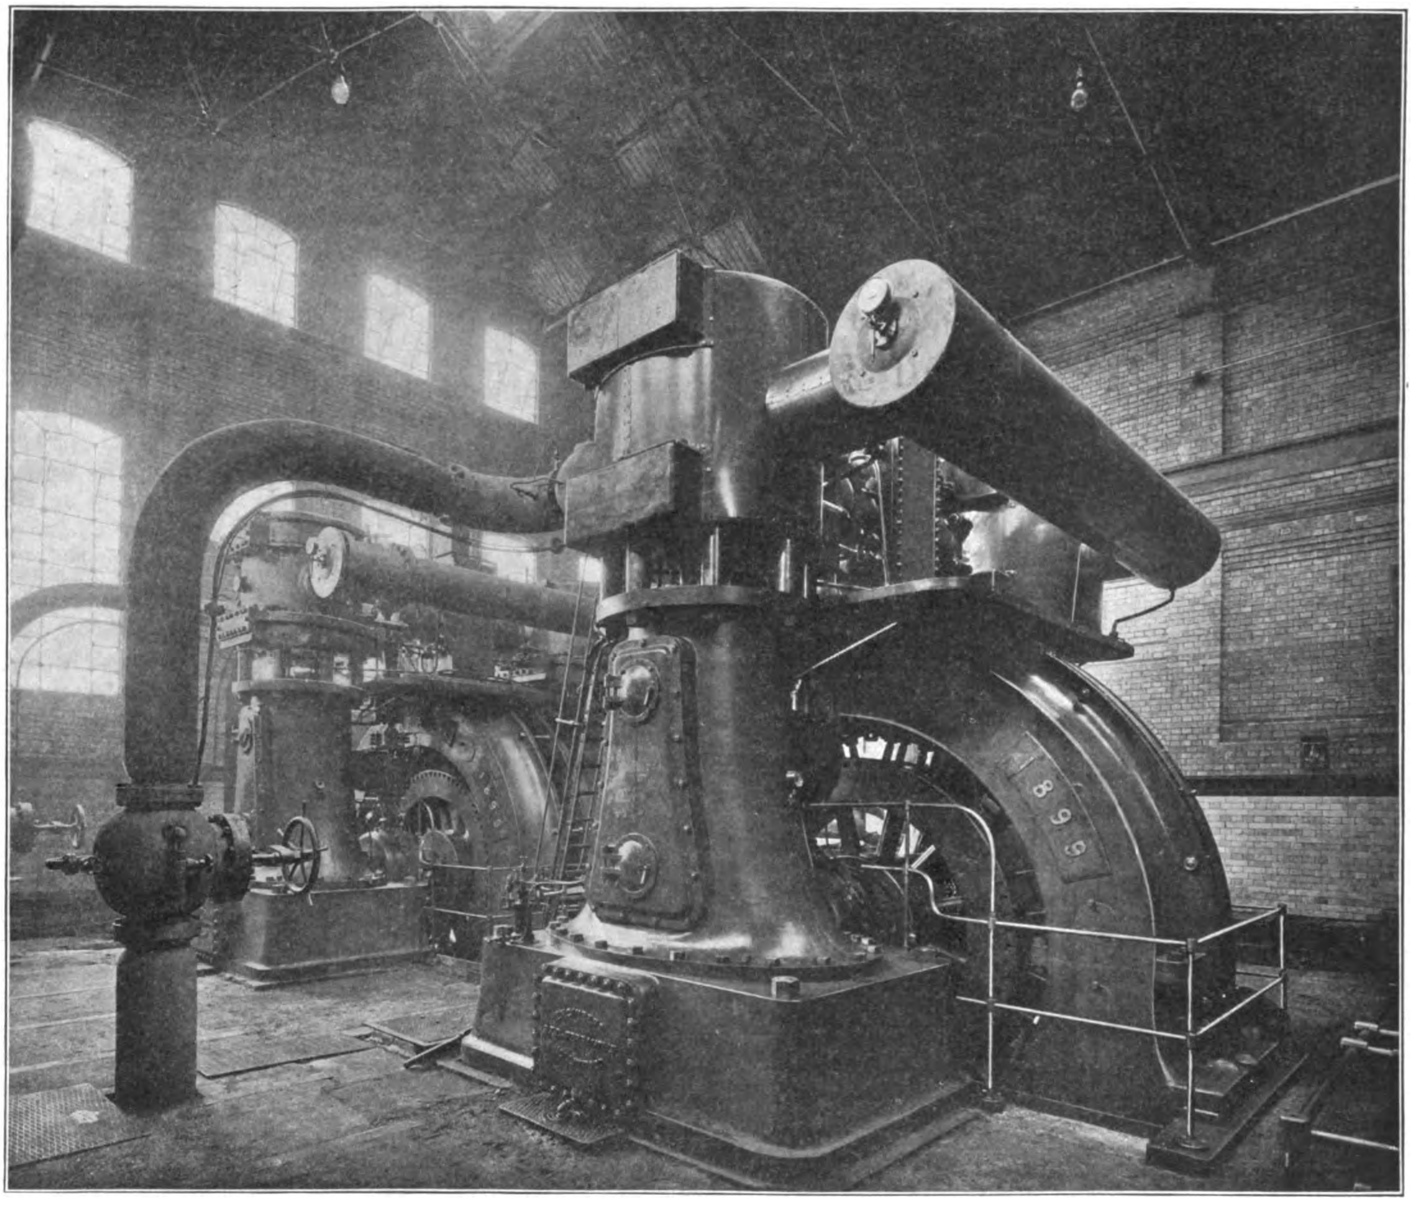

FIG. 2.—FERRANTI 2000-HORSE-POWER CROSS-COMPOUND ENGINES AND ALTERNATORS.

A radical change from ordinary designs is seen in the arrangement of the valve gear, which is enclosed in a chamber situated between the high and low pressure cylinders. No eccentrics are used for the valves, which are worked from a vertical shaft driven by bevél gear from the main shaft. This vertical shaft drives the exciter, which is a small bipolar Parker machine running at 750 r.p.m. A reduction of speed is made through a worm in the valve gear chamber, and the valves are moved by cams on a shaft which runs at one-half the speed of the engine. The whole of the valve gear is fitted in the valve box between the two cylinders of the engine. The box is closed by means of doors bolted and jointed in position, this construction enabling the valve gear to be entirely immersed in oil by filling the box containing it. This also acts as a reservoir for supplying the pumps which feed a relay governor with oil under pressure.

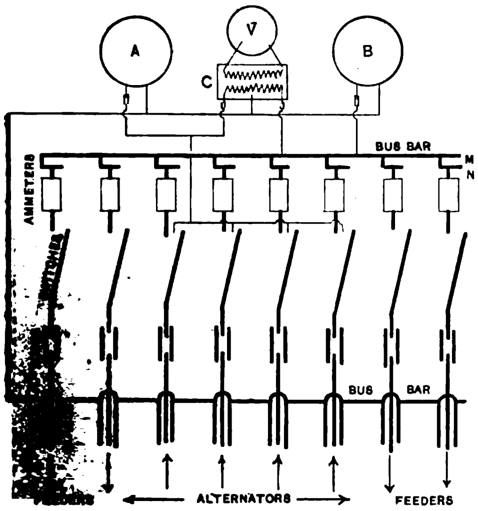

FIG. 3.—SWITCHBOARD DIAGRAM.

There are four valves to each cylinder, giving small clearance spaces. The valves are of the grid-iron type, and have double admission ports for travel in each direction. The exhaust valves have continuous travel, coming to rest at the end of the stroke, but the admission valves come to rest in the middle of each stroke, in which position the steam is cut off. A positive motion is given to the valve stems through rollers pressing against opposite sides of cams, where they are held in continual and firm contact. The cams are of constant diameter, and a variable motion of the valve is obtained by employing two cams, one fixed and one adjustable, whose relative position may be changed by the action of the governor. Variable expansion is used for both high and low-pressure cylinders. The connection of the valves is made by adjustable links, visible in Fig. 1, so that the valves may be very easily set, and if it is necessary to remove one of the cylinders, this may be done without interfering with the valve gear.

The speed of travel of both sets of valves is exceptionally low, notwithstanding the high speed of the engine; the maximum movement in each direction is only ⅝ inch, or 1¼ inches per revolution, giving a surface speed of 26 feet per minute. The engine may therefore be used with superheated steam, as is done at West Ham, where the working pressure is 160 pounds, and at the central station at Lambeth, where 200-pound superheated steam is used.

The speed of the engine is regulated very closely by a new form of relay governor acting on a spiral thread sleeve which varies the position of the movable cams relatively to the fixed cams on the vertical valve gear shafts. An emergency governor is also provided, which, in the event of an excessive rise in speed, will cut off the steam by a throttle valve. This governor acts through a lever on a movable fulcrum, and the valve may be closed by hand, should occasion arise, by pulling down the lever at this fulcrum.

Below the engine base on either side are oil reservoirs of enameled cast-iron, about three feet deep, the enamel being used in preference to having a metal surface on account of its communicating no impurities to the oil. Valveless rocking pumps on extensions of the crankpin force the oil through cloth filters in closed chambers in the engine base, then through oil pipes to the crankpins, main bearings, crosshead and slides, and the vertical valve gear shaft, providing forced lubrication to all running parts. The oil reservoirs are provided with cooling coils, through which cold water circulates, thus providing the bearings with a plentiful supply of clean, cold oil which contributes much toward the smooth running of the engine.

A special feature of the engine is the use of spherical self-adjusting bearings on cross-heads, crankpins and main bearings. The isolation of the valve gear serves not only to facilitate the erecting of the cylinders and pistons, but also the very practical end of keeping the gear and the oil in which it runs cool. The same idea is carried out in the lower part of the engine, for the columns are connected to the cylinders by short steel pillars which allow a free circulation of air beneath the cylinders and prevent the heat being transmitted to the columns and guides. Double glands are used, fitted with metallic packing, one on the under cylinder-head and the other on the top of the column, this arrangement being used to prevent the creeping through of oil or water. The columns entirely enclose the cranks and connecting rods.

The cylinder diameters are 28 inches and 51 inches, respectively, with a stroke of 21 inches. The combined efficiency of this engine-alternator set is between 86 and 87 per cent.

The alternator is in some points a departure from the more usual form heretofore seen, as special provision must be made for the very high speed at which it is driven. A heavy steel ring is pressed on the shaft over a split cast-iron hub, and steel radical bolts support the rim, which is in one piece and of cast iron. The bobbins in their bronze cradles are held by steel bolts insulated with sulphur. The armature is wound with copper strip ¾ inch wide, and the total air gap is 1½ inches, giving a clearance of ⅝ inch on each side between armature and pole-face. The e.m.f. of 2000 volts requires extra protection against sparking across, which is afforded by micanite caps covering the pole faces and extending a short distance back over the winding; this construction has been used for the last ten years on the 10,000-volt machines. The magnet frame may be moved back from the armature by means of screws, and runs over rollers in a cage on the base-plate. There are 24 poles on either side, giving, at 250 revolutions a minute, a frequency of 50 cycles.

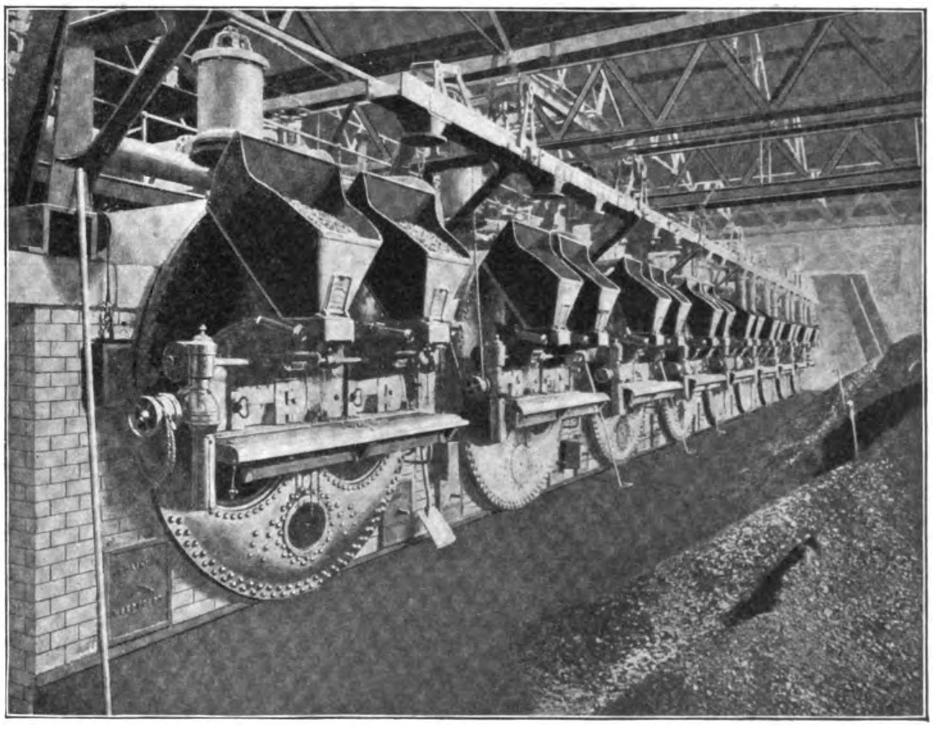

FIG. 4.—LANCASHIRE BOILERS AT WEST HAM STATION.

The West Ham electric light station

is before long to be removed to a new site near the river, where coal and water will be cheaper. It is at present located in one-half of a sewage pumping station, and the contrast is remarkable in passing from the powerful, high-speed Ferranti engines to a couple of pumping machines in the next room.

The switchboard is of the well-known Ferranti type, the instruments and switches being separated by a series of enameled slate partitions. Concentric cables are used for all circuits of distribution, with the outer main grounded; single-pole switches for the inner conductor are used on the board. These switches have double knife-blade contacts and a rapid oil-break. Below them are oil-break fuses in porcelain partitioned boxes, where the fuse is held under slight spring tension. When an overload causes a fuse to blow, the ends are immediately immersed in the oil, one on each side of the partition, effectually preventing any arcing. In order to renew the fuse, the box is withdrawn from the switchboard contacts.

Below the row of fuses are the handles of the resistance boxes for the exciter circuits, and a special form of switch for opening the alternator field circuits, short-circuiting them first across carbon contacts to prevent burning due to the field flash. Each generator and feeder circuit has an edgewise Ferranti ammeter at the upper part of the panel, and on the top are the bus-bars for the inner conductor of the cables. On a shelf of slate above the board are mounted the synchronizers and high-tension voltmeters, all being clearly indicated in the accompanying diagram, Fig. 3.

In the center of the switchboard is a double switch for the purpose of connecting the switchboard into one complete system, or by disconecting, to make two independent boards, as may be advisable when the load is heavy. When work is being done on a generator or circuit, the corresponding panel is locked in such a way that the switch cannot be closed, and the foreman in charge of the work can keep possession of the key until he is ready for the current to be switched on. An ingenious attachment to the main switch allows of placing it on a synchronizer contact before closing it on the alternator circuit, and, as soon as synchronism is attained, the switch may be pressed home.

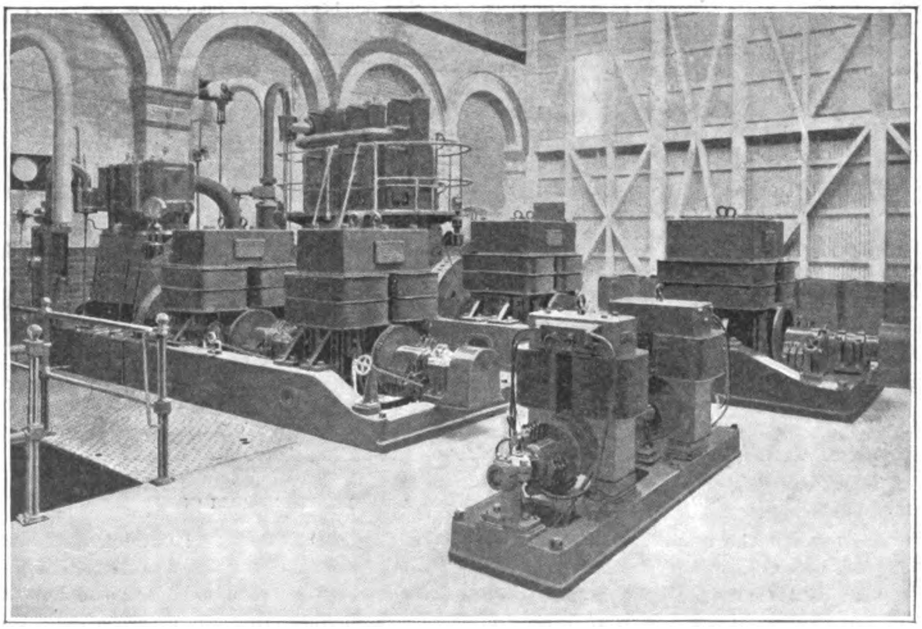

FIG. 5.—GENERATING ROOM OF THE GLOUCESTER MUNICIPAL STATION.

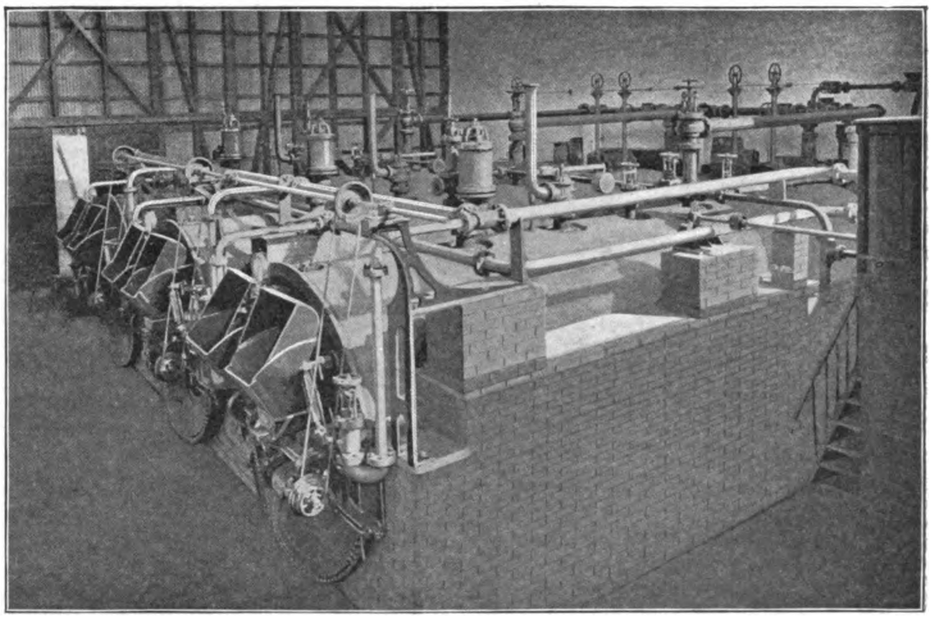

FIG. 6.—BOILERS OF THE GLOUCESTER MUNICIPAL STATION.

From the nature of the installation it is hardly possible to consider the boiler room and pumps altogether as part of the electric light station, since it was built as a combined pumping and lighting station, and the boilers and electric plant were added to as demand arose. At present there is 5400 horse-power of engines in use for electric lighting. At first nine Lancashire boilers of 300 horse-power each were put in, but Babcock & Wilcox water-tube boilers have been added to the plant. Fig. 4 is a view of the end of the boiler room containing the Lancashire boilers. They are fitted with mechanical stokers and a complete coal handling system.

The engines and electrical equipment of the station are thoroughly modern, and when they are removed to the new building they will have more fitting surroundings. There has not been much arc lighting done as yet, but a new departure is now being made in the addition of a Ferranti rectifier, which will probably soon be followed by several more of the same capacity—of fifty 12-ampere arc lights. General Electric alternating-current enclosed lamps were used, but the new system will have Brockle-Pell lamps and Ferranti rectifiers.

Features of Some Other English Plants.

At the Gloucester municipal station the boiler plant is similar to the old portion of the West Ham boiler plant. It consists of four Lancashire boilers, each capable of evaporating 6000 lbs. of water an hour. The boilers are 30 ft. long by 8 ft. in diameter, and the shells are built in seven sections of 13/16-in. plate. Fig. 6 gives a view in this boiler room. The boilers are fitted with Proctor mechanical stokers.

The generating plant consists of two engine-generator units, the engine of one set being of 500 h.p. capacity, and that of the other set being half this size. The larger engine drives two bipolar Silvertown dynamos, each capable of an output of 150 kw. at any e.m.f. between 440 and 500 volts, measured from outside to outside of the set—220 to 250 volts for each machine. The dynamos are shunt-wound with drum bar-wound armatures. The engine is a triple-expansion Belliss, with one high-pressure and two intermediate cylinders mounted above three low-pressure cylinders, and driving three cranks set 120° apart. It runs at 350 r.p.m. and is designed for 160 lbs. initial steam pressure. The smaller engine is a two-crank compound engine with one high-pressure and one low-pressure cylinder, driving cranks set at 180° apart. A single piston valve, located between the two cylinders, serves both of them. This engine will develop 250 horse-power at 380 r.p.m. under 130 lbs. steam pressure. It is direct-coupled to two Silvertown bipolar dynamos of 75-kw. output each, and these two, like the two larger machines, will give their rated output at any e.m.f. between 440 and 500 volts total, or 220-250 volts each. The engines were built by Belliss & Morcom, Limited, of Birmingham, which firm builds a large proportion of the central-station engines used in Great Britain. The engines are lubricated by a system of forced oil supply. Both of them run condensing, Blake & Knowles jet condensers being used.

The generators are supplemented by a storage-battery plant of 800 ampere-hours capacity, figured at a discharge rate of 80 amperes. There are 280 cells, and these are "floated" on the system, being charged during the light-load hours and assisting the dynamos during the heavy-load period. A booster set of the usual form is used in conjunction with the battery. This consists of a bipolar motor driving a dynamo of similar construction at 780 r.p.m.; the dynamo capacity is 100 amperes and 20 to 140 volts, and the motor takes current from the bus-bars at 220 to 250 volts.

The distribution is on the three-wire plan with 220 volts between the neutral and each outer wire. The feeders are underground cables laid in square cast-iron troughs, on wooden bridges, which are spaced at intervals of about 12 ins. After the cables are in place the trough is filled with bitumen, entirely enclosing them. Alongside of each feeder a small pilot lead-armored cable is laid directly in the earth; this serves to connect the feeding point with the voltmeter on the main switchboard at the station. The distributing wires are triple-concentric lead-sheathed cables, and these are laid in troughs like the feeders and surrounded by bitumen.

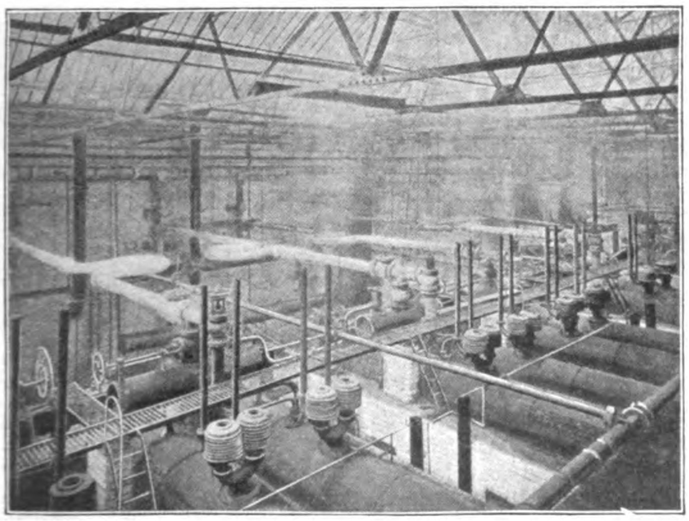

FIG. 7.—BOILERS IN THE GLASGOW STATION.

The arc lamps used for street lighting are grouped principally in series of nine across the outer wires of the system, a few groups of four lamps between the neutral and an outer wire being used. The lamps are of the Brockie-Pell single-carbon type, hung from ornamental goose-neck posts and arranged to be lowered for trimming and repairs by means of a winch in the base of the post.

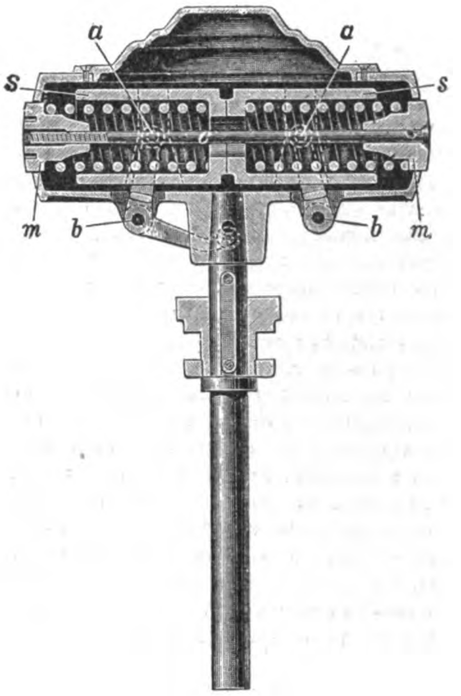

FIG. 1.—DETAILS OF HARTUNG GOVERNOR.

A feature of the plant is a garbage destructor provided for utilizing the refuse of the city as fuel. The garbage will not, of course, supply sufficient fuel to run the plant, but it serves to greatly lessen the coal consumption by supplementing the coal-fed boilers. This destructor has a capacity of 50 tons per day of 24 hours and is mounted under a Lancashire boiler 30 ft. long and 8 ft. 6 ins. in diameter.

The municipal plant of the city of Glasgow embodies a good many features of American practice and also retains a number of typically English features. In the engine room are found two Walker dynamos direct-coupled to a Ball & Wood vertical cross-compound engine; a Schuckert multipolar dynamo direct-driven by a Matthew Paul & Co. marine-type triple-expansion engine; two bipolar Crompton dynamos, of the same general type as the Silvertown machines in the Gloucester plant, direct-driven by single-acting vertical engines, similar in appearance to the Belliss engine; and two British Thomson-Houston multipolar dynamos of the circular-yoke type, driven by triple-expansion three-crank Belliss engines. The boiler room is equipped with Babcock & Wilcox boilers provided with chain-grate stokers. Fig. 7 is a view taken across the tops of the boilers and showing the arrangement of the steam pipes between the individual boilers and the horizontal header on the boiler-room wall. The engine room of this plant is a fair indication of the progress from the once-universal English practice of using bipolar direct-current machines toward the later American practice of using multipolar machines with circular yokes and radial magnet poles. It also illustrates the peculiar British custom of assembling in one engine room an aggregation of conglomerate types of engines and generators, which was referred to in the opening paragraph of this article.

A TYPICAL EUROPEAN ENGINE GOVERNOR.

Among other interesting engine parts shown at the recent Paris Exposition was the Hartung engine governor, illustrated by Figs. 1 and 2. As the illustrations show, the governor is very simple in construction. The weights, S and S, Fig. 1, are thrown outward by a centrifugal force against the resistance of the spiral springs shown in both engravings. The weights are connected by bell cranks, B and B, which support the weights in their position. A single adjustment nut, M, suffices to vary the tension of both of the governor springs as the rod, C, extends through the center of both springs and weights and terminates in a head similar in contour to the nut, M. Neither the weights nor the springs are attached in any way to the casing which surrounds them. The head of the nut and the extension head of the bolt fit rather snugly in circular openings in the wall of the casing, as indicated in Fig. 1, and these openings form guides for the springs, which prevent tilting. The governor is made by Herman Hartung, of Dusseldorf.

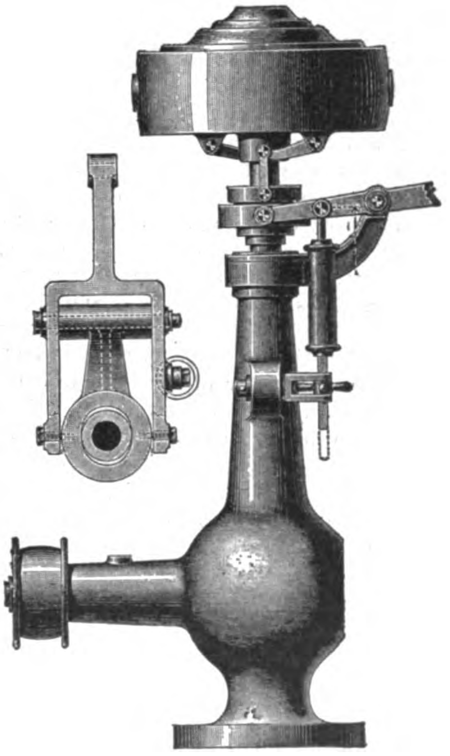

FIG. 2.—HARTUNG ENGINE GOVERNOR.

ELECTRICAL AND STEAM ENGINEERING IN THE NINETEENTH AND TWENTIETH CENTURIES.

ELECTRICITY IN THE NINETEENTH AND TWENTIETH CENTURIES.

BY A. E. KENNELLY, SC. D.

Standing within the portals of the twentieth century, and surrounded by electrical applications which have become a very necessity of modern civilized life, it is difficult to realize the condition of the electrical arts and sciences at the beginning of the nineteenth century. In the year 1801 there was not a single electric art, nor any utilization of this ever-present natural force. Franklin's lightning rod was certainly in use, but this was a device for preventing rather than utilizing electrical effects.

The eighteenth century developed the frictional electrical machine and a knowledge of the phenomena of high-tension electricity. In fact, comparatively little improvement has taken place in this direction during the nineteenth century. The frictional machines have made scarcely any advance in that time, and although the influence machines have improved in various ways, yet the improvement has been in degree rather than in kind, for Volta's electrophorous dates from 1775, and the influence machine was known in a variety of forms at the beginning of the nineteenth century.

In a similar manner, the science of electricity was practically circumscribed in 1801 to a summary of facts concerning high-tension electricity, and machines for producing it. Electrical measurements or quantitative relations were almost unknown. This was a condition consequent upon the intricate and recondite phenomena of high-tension electricity, apart from the limited number of students who expended efforts upon their study. It is doubtful whether in this year of 1901 we should possess any electrical measurements or any extensive quantitative knowledge concerning electricity if the voltaic pile had not been discovered. The difficulties in connection with the insulation, canalization and uniform supply of high-tension electricity are even now so great, that electrical measurements in connection with frictional or influence machines are vague, difficult and uninteresting. If all the electrical apparatus of Europe and America up to the end of the eighteenth century were collected together, we should be compelled to regard the collection from our present standpoint as an aggregation of interesting scientific toys, suitable for consoling the leisure and stimulating the imagination of secluded philosophers. Meanwhile, the average individual citizen of the eighteenth centnry regards electricity as a thing of danger, to be exorcised and avoided, which ran riot in thunder storms and was an uncanny spirit to be evoked by the magical power of wizard philosophers.

The complete revolution of popular feeling in the course of the nineteenth century which has made every modern citizen regard electricity as the force upon which he depends for the communication of intelligence from a distance and for the transmission of mechanical power from a distance, has been brought about in the main by two fundamental discoveries, namely, the voltaic cell in 1800 and the induction apparatus of Faraday in 1831. The electrical development of the nineteenth century is virtually an exposition of the development and use of these two instruments. Just as the eighteenth century may, from an electrical standpoint, be regarded as the era of development of high-tension electricity from the frictional machine, so the nineteenth century may be similarly regarded as the era of development of low-tension electricity from the voltaic cell and dynamo machine.

The voltaic cell gave an entirely new direction and motive to electrical investigation; it introduced a completely new set of ideas and a new terminology. The electric current was a conception which the spasmodic discharge of frictional machines and Leyden jars did not invite. It was, on the other hand, the natural suggestion of the phenomena attending the closure of the voltaic cell's electrical circuit. Upon the heels of the electric current came the electromagnet and electromagnetism, an instrument and a science which the frictional electric machine was not likely to reveal. From the electromagnet and electromagnetism came the electric telegraph in 1837, and forty years later, the telephone.

Great opposition had to be overcome in introducing the electric telegraph. The railroad itself did not have greater difficulty in making its first introduction to practical use. It was in connection with the railroads, however, that the electric telegraph first found employment in Europe, since the telegraphic announcement of the despatch and approach of trains was a recognized safeguard to the traveling public worthy of the initial expense on the aerial conductor. In the United States the telegraph was inaugurated in 1844 under Government appropriation by a bill which with difficulty passed through the Senate in the closing hours of its 1843 session.

Although the voltaic cell paved the way for the electric communication of intelligence, it was incapable of enabling electric transmission of power to be practically realized. The electric motor was indeed produced under its auspices and electric lamps were also produced with it, particularly the arc lamp. The cost of electric power from existing primary voltaic batteries is, however, mainly determined by the cost of metallic zinc, which, being obtained by metallurgical processes of reduction from zinc ores, is necessarily relatively expensive, and the cost of electric power from such batteries is upon any extended scale prohibitively great. The dynamo-electric machine, however, enabled electric power to be obtained at a cost not greatly in excess of the cost of producing mechanical power. It has been the development of the dynamo, the improvement in its efficiency and the reduction of its cost, which has led to the modern development of electric lighting and power transmission. The dynamo-electric machine is already so efficient in large sizes, that there is practically no room for very marked improvement in the future in this direction. We may always hope for improvement in cheapness, compactness, convenience and other good qualities of dynamo-electric machines, but in efficiency, the limitations to possibility have already been nearly reached. It is curious that unless all existing scientific knowledge is at fault, the possibilities that all futurity can offer in the direction of improving the efficiency of conversion from mechanical to electrical, or from electrical to mechanical power are limited to within the small compass of 4 or 5 per cent; whereas, with the existing heat engines employing fuel and which far antedate the dynamo-electric machine, the limits within which future improvements in efficiency can take place are from 70 to 95 per cent.

Accompanying the complete change in the attitude of public opinion toward electricity during the nineteenth century, attendant upon its gradual industrial utilization, has been a corresponding equally marked change in the attitude of electricity toward industry and daily life. The physicist and electrician of 1800 worked in an atmosphere as distinct from that of the work-a-day world as does the student of Sanskrit in regard to occupation, or the polar explorer in regard to location. At the present day, however, this isolation has completely disappeared, partly by reason of the fact that the general public has become slowly better educated in scientific matters, and has to this extent moved toward the physicist, partly because the applications of physics to industries are already so numerous, and partly because a large class of workers has of recent years been created and employed, generically classed as engineers and technologists, who occupy an intermediate position between the physicists on the one hand and the business men on the other, and whose duty it is to apply the laws of natural science to the purposes of the community. The result is that not only does almost every physical research have a direct bearing and value in technology, engineering and industrial affairs, but it is gradually becoming recognized that there is no better investment for public advantage than that in scientific or technological institutions, and that the specialized study of science is highly remunerative to the community at large.

The Twentieth Century.

The rate at which epoch-making discoveries are made mainly depends upon two conditions, namely, upon the aggregate amount of labor and investigation intelligently directed upon important problems, and upon the reserve of Nature's undiscovered forces, laws and capabilities. If, as during the early and middle ages of history, but little aggregate intelligent effort be directed to investigating the laws and resources of Nature, it is not likely that much return will be made in the discovery of new methods of controlling the forces surrounding us. Similarly, if it should be admitted that the resources of Nature available to humanity were already nearly exhausted, then it might be expected that but little further return in successful discovery could be obtained for even the greatest aggregate labor in search for new implements and processes. As for the effort, there never has been a period at which the total investigation and intelligent search for new means of harnessing and subjugating natural forces, was greater than at present, although much more total effort, and much better organization of the existing total effort could be, and doubtless will be, exerted. As for the latent richness of Nature's undiscovered wealth, while we have no knowledge of its amount, yet we have reason to suppose that it is yet practically unfathomed and untouched. Surely a mortal would be bold who should say that amid the forces on an enormous scale that surround us, the bounds to human utilization of them are already within sight. Only when the nature of gravitation, matter, energy and electricity in the earth and in the sun are clearly understood, will such a contention seem to be worthy of consideration. We may, therefore, reasonably expect that the rate of discovery, new means and methods of accomplishing human aspirations, will increase rather than decrease in the century to come.

The future progress of electricity and its applications in the twentieth century can only be estimated with reasonable accuracy on the unreasonable assumption that no new epoch-making discoveries will be made or that factors which are now at work in the development of the science and art will remain practically unchanged by new discoveries. As to what new discoveries will be made it is of course impossible to predict, and a single epoch-making discovery might revolutionize modern industry and crush every estimate of the most far-sighted observer. It is only possible to say what discoveries cannot be made without seemingly infringing the laws of nature as at present interpreted. Thus it is at present absolutely inconceivable that electrical energy for the production of light or power on a large scale could be obtained from any battery to which neither substance nor energy was supplied at intervals from without, because such a conception is contrary to the laws of the conservation of energy, which to doubt is to doubt the results of all accumulated human observations and experiences since the beginning of recorded time. On the other hand, to see by wire in the same manner that we now hear by wire with the aid of the telephone, is a perfectly reasonable conception, even though it may never be accomplished, and is not, perhaps, inherently more wonderful or improbable than the already accomplished hearing by wire might have seemed to intelligent persons at the beginning of the nineteenth century.

Moreover, the applications of electricity depend not only upon the progress of electricity and the electric arts, but also upon the contemporary sociological conditions, and unless the time is ripe for the reception of a certain improvement, the improvement itself is likely to lie sterile. Thus, at the present time, it is well known that it is practically feasible to communicate between railroad stations and moving railroad trains by electrostatic or electromagnetic induction, without any metallic contact between the moving train and the telegraph wires beside the track. But it is difficult to see how such a comparatively wonderful and certainly convenient capability can come into extended use, for the reason that the time which elapses between the stoppage of trains at successive railroad stations is not sufficiently great to make the services of a special operator on the train remunerative. If the same facility existed for communicating between stations on shore and ships at sea on long ocean voyages, it is highly probable that such a method of communication, if commercially practicable, would come into use.

Power Transmission and Distribution.

So far as concerns the long-distance transmission of electric power, the present tendency is certainly toward the production of higher electric pressures and the reduction of the cost of transmission. We may reasonably hope that the twentieth century will witness great achievements in the harnessing of such large water-powers as those at Niagara. Thus there are said to be about 7,000,000 of horse-power in the Niagara Falls, and with the exception of some tens of thousands of horse-power now utilized, or in course of utilization, the vast remainder is expended in the innocent but humanly utterly valueless result of warming the overflowing water about 1° Fahr. Although the falls are a very beautiful spectacle, their value to the country, and to the whole world, would be far greater if they were entirely removed and replaced by a dam and a vast area of wheel-pits for the local utilization and distant transmission of electric power. It is reasonable to expect that the distance to which such power could be economically transmitted will ultimately depend upon the cost of purchasing right-of-way and upon the length of line over which security from accidental break-down can be guaranteed, rather than on any purely electrical considerations of the cost of conductor. Only a few years ago a line pressure of 30 kilovolts was generally regarded as hopelessly impossible, while at the present time that voltage is coming to be regarded as only moderately high.

The electric distribution of power by stationary motors seems destined to make great advances not merely for use in mines and factories, but also for domestic service of every kind. In all large cities the tendency is to use muscular power less and motor power more.

Transportation.

In the use of electric power for transportation purposes it is reasonable to expect that not only will the suburban railroad transportation be conducted electrically, but also that high-speed passenger traffic between large cities may be conducted electrically. There seems to be no reason why passengers should not be carried on a specially constructed elevated structure, devoid of grade crossings, at any speed up to say 150 or 175 miles per hour, if electric motors are employed for the purpose and the rolling stock is designed accordingly. Although the cost of such an undertaking may seem almost prohibitive at the present time, yet the tendency is ever to increasing speeds in the face of the dictates of mere economy in transportation. Up to the present time electric transportation has been practically limited to dealing with the economic problem of making frequent starts and stoppages with the greatest convenience and least expense. It remains to show the capability of the electric motor to develop high speeds with the minimum weight and vibration where economy is of secondary rather than primary importance.

In the course of time, with improvements in automobiles of all kinds, it may be expected that horses will be banished from the streets of large cities and all urban transportation be carried on by mechanical means.

The progress of electric automobiles depends upon the development of electric-power storage. Under existing conditions, the leaden storage battery can only be successfully used for automobile propulsion within a relatively small running radius, and with the handicap of considerable weight, conditions which are likely to confine its principal use to city streets. If, however, the available energy per pound of storage cell could be largely increased, the convenience and simplicity of the electric automobile would give it immediate superiority over all existing mechanical prototypes. In view of the large amount of effort that has already been expended unsuccessfully in improving electric storage, a marked improvement in the apparatus would probably involve fresh discovery; but there seems to be no reason why such a discovery might not be made. It would indeed be remarkable if in the whole vast range of nature's combinative possibilities this particular possibility did not exist. A great practical improvement in electric storage would have a marked influence on many industries. It is even possible that large ocean steamers might be propelled by motors, deriving their power from stored electric energy. In order that this idea should be realized, however, the improvement in existing electric storage apparatus would have to be very great. There is certainly no immediate possibility, nor any future probability of introducing electric motive power to propel large vessels except with electric storage apparatus. In other words, it cannot reasonably be advantageous to replace the mechanical transmission of power through shafting from steam-engines to propeller by electric transmission, using the engines to drive a dynamo and a motor to drive the propeller.

Electric Lighting.

In electric lighting there is room for an enormous improvement in the efficiency of conversion from electric power into light. At present the incandescent lamp only converts about 5 per cent and the best arc lights about 10 per cent of the power they receive into radiant energy which affects the eye as light; or, in other words, these instruments waste respectively about 95 per cent and 90 per cent, mainly in radiant energy that the eye does not perceive. It is conceivable that nearly all this waste might be avoided or that nearly all the energy delivered electrically to the electric lamp might be converted into light, even though this result may never be accomplished.

Electro-Chemistry.

In the direction of electro-chemistry we may expect great advances. This is at present a youthful electrical industry, and yet it has developed so rapidly as to absorb the production of the elements aluminum, hydrogen, magnesium, potassium, sodium and silicon, as well as the compounds carbide of calcium and carborundum. Moreover, by electro-chemical methods large quantities of caustic potash, caustic soda, potassium chlorate and calcium chloride are produced, not to mention the refining of metals and the extraction of metals from their ores. We may expect the production of the electric furnace and the electrolytic vat to increase in quantity and in importance from year to year.

The possibilities of synthetic chemistry, including electro-chemistry, are so wide, without transgressing the limitations seemingly set by natural law, that any great discovery in this direction might appreciably alter the established order of productive agencies. There are already a few substances, such as madder, at one time fairly extensively cultivated, the cultivation of which has been practically arrested by the development of cheaper manufactured equivalents of synthetic chemistry. It is reasonable to expect that the growth of chemical sciences and arts will still further invade the territory of agriculture. Even now it is possible to manufacture alcohol by a series of processes involving electro-chemistry and starting with calcium carbide, although it does not seem that the synthetically manufactured product of the laboratory has yet competed with the product of the sun's chemistry in the open fields. It is conceivable that food products could be manufactured artificially cheaper than they are produced in the field or in the sheep and cow, with the aid of sunshine; but such a step might be feasible long before it would be commercially possible.

As to whether we may hope to obtain the energy of coal by electrical means without the intervention of the steam engine, it is impossible to conjecture. It is not at all probable that the energy could be obtained electrically from a non-conducting substance like coal, and the problem therefore narrows to the extraction of the chemical energy of coke. The solution of this problem would practically involve electro-chemical discovery, and appears to lie beyond immediate existing means. Even if it could be accomplished on a large scale, however, the process might be unremunerative or economically impossible. It is certainly reasonable to expect that improvements will be effected in the yield of energy obtained from coal, but whether that improvement will be effected by chemical, electrical or thermodynamical means, remains to be ascertained.

Telegraphy and Telephony.

In telegraphy we can hardly look for much improvement in the ordinary Morse system as operated by hand. That system would seem to have been already reduced to its simplest elements. It is in the direction of automatic telegraphy that we must look for future improvements in land telegraphy. It would seem reasonable to expect that with the aid of mechanical transmitters and receivers long circuits between large cities could be worked remuneratively at very high speeds and correspondingly reduced rates in such a manner as to enable the traffic on those circuits to replace the postal service, within certain limits.

In submarine telegraphy it would seem almost impossible greatly to increase the speed of manual transmission over the long cables already laid; or, in other words, a large increase in the speed of manual transmission over existing cables would involve some new discovery. There is room, however, for improvement in the methods of automatic submarine telegraphy, whereby the limits of speed in transmission may approach more nearly those seemingly set by fundamental physical laws. Means may be found for constructing new long submarine cables in such a manner as to enable much higher speeds to be obtained from them.

In the direction of wireless telegraphy it is reasonable to expect that the distances to which wireless messages can be transmitted may be greatly increased, and means developed for preventing the interference of separate messages. While it is not likely that wireless telegraphy will take the place of wire telegraphy on land, to any considerable extent, yet on the ocean, as a means of communication between ships, or between ship and shore, the system should find much utility. It may be hoped that in time all important light-houses may also become Hertz-ray houses for the transmission of invisible beams to vessels in the neighborhood, through fog, and beyond the bend of the horizon due to the rotundity of the earth. It is conceivable that such a system, sufficiently improved, would enable communication to be maintained with distant vessels for hundreds of miles from shore.

In telephony we may fairly expect a very great extension of the system in all large cities. Moreover, the distances to which telephony will be commercially extended will probably be considerably increased. Large business offices will be supplied through several telephone lines and the business of the officers will in a large measure be conducted by telephonic conversation with distant points. The ramification of the telephonic system to houses of all kinds should continue until the difficulty of obtaining telephonic communication with any particular subscriber offsets the advantage of an increasing number of subscribers. In other words, the more perfect the telephonic system in its details of operation and facility for affording communication, the greater the number of subscribers who can be induced to take part. There is no reason why eventually nearly every building for business or residence, except the smallest, should not possess telephonic communication.

It is also reasonable to expect that not only the number, but also the magnitude, of electrical undertakings, will increase in the century to come. The magnitude of industrial and engineering enterprises is at once a measure of the civilization and of the education of the period to which they belong, since not only are mutual confidence and co-operation required in corresponding measure, but also a corresponding acquaintance, by experience and knowledge, with those laws of nature under which the enterprise is conducted. So long, therefore, as civilization advances there can only be expected a continued increase in the magnitude and scale of enterprises of every kind, including those utilizing electricity. In view of the active part which electricity seems destined to play in the future, the twentieth century must be expected to offer greater interest and development in electricity and in electrical applications than the century which has just closed. There never has been a time in the past when the electric science was so closely associated with the electric arts as now, and the connection between the two seems likely to become more intimate and more beneficial as the car of time rolls on.

A CENTURY OF PROGRESS IN STEAM ENGINEERING.

BY A. F. NAGLE, M. E.

How did the beginning of the nineteenth century find the steam engine, what have a hundred years done for it, and what remains for future generations to accomplish? The object of this article is to discuss these questions in such manner as to enable a busy engineer to obtain a general grasp of the development of the steam plant during the century, leaving him free to search in historical books for more detailed information.

At the beginning of the nineteenth century the steam engine was working under 10 to 15 lbs. steam pressure and making from 10 to 30 revolutions per minute; it expanded steam from three to four times and was aided by both jet and surface condensers. It required the consumption of from 9 to 10 lbs. of coal an hour to develop one horse-power. To-day we can use steam of any desired pressure; reciprocating engines are running at from 100 to 300 r.p.m., making from 600 to 900 ft. piston speed a minute; they can be made to expand steam to any extent desired, which may be 40 times, and the economy has been brought to almost one horse-power per pound of coal per hour. It is not presumptuous to say that very little more remains to be done.

In its mechanical parts and functional elements the steam engine was complete at the beginning of the last century, but as a machine for converting the latent or potential power of coal into useful work it was not only a crude apparatus but the laws under which it worked were unknown. While the heat from burning coal was used to make steam, no scientific knowledge existed as to the measurement of this heat. In a general way it was known that it required about six times as much heat to evaporate water into steam as to bring it to the boiling point, yet no exact data existed on this point. The term "British thermal unit" (B. T. U.) had not been thought of.

Practice preceded science, and the engineer was left for many years to grope along as best he could, designing engines mechanically better and better, but with no scientific knowledge to guide him in a definite line of improvement. Watt had observed the rapidity with which steam condensed in the presence of a colder substance; his first experiments showed that three times as much steam was condensed on entering a cylinder as was required to fill it, so he very logically provided a separate vessel for a condenser. The rapid escape of heat by radiation and condensation was recognized as a fact to be avoided, but no scientific knowledge existed of the laws that governed it.

The nineteenth century has disclosed complete and perfect analyses of the laws which govern steam-engine design and construction, and it only remains for the engineer to apply these laws to meet his special requirements. Moreover, the steam engine has profited by the general advance in mechanical skill during the century. How much it itself has contributed to this improvement it would be difficult to determine. Metallurgy, forges and foundries could never have attained the magnitude and economic production they have but for the power that steam gave to them. At the beginning of the century the designing engineer was handicapped by the crude state of the mechanic arts in the construction of his conception. To-day he can have anything he is able to pay for; materials of the finest quality and workmanship of the most refined character are at his service. In a general way, the advance has been from unreliable cast iron to a definitely-known quality of steel. Then, nothing was known of the chemical or physical properties of metals; to-day, foundries, forges and steel works are all guided by scientific experts in their productions. In short, from guesses, steam engineering has passed to mathematical certainties during the nineteenth century.

While the engineer and mechanic have been busy in the workshops, the scientist has likewise been busy in the laboratory. During no century of the world's history has the human mind delved so deeply into nature's secrets as in the one just closed. Probably the first suggestion that there was some definite relation between work and heat was made just prior to the birth of the century, by Count Rumford, who, in 1798, discovered that the heating of the metal of cannon by the boring tool had some definite relation to the power exerted by the lathe. In a crude way he determined that about 630-foot-pounds of work were expended for every pound of water heated one degree. Until the thirties of the nineteenth century nothing further was done in this field, when Joule determined the mechanical equivalent of heat to be 772 foot-pounds. (Prof. Rowland, of Baltimore, subsequently found the value of 778 to be more exact.) As chemistry had demonstrated the indestructibility of matter, so physicists began to find that nature's forces were also indestructible; although a manifestation of force in one form might disappear, it reappeared in the form of heat, and vice versa. This law of the conservation of energy gave a sound basis for the study of the various laws of heat as applied to the steam engine, and there came to be established a standard of economy which theory describes as perfect; the nearness of practical results to this standard, called thermal efficiency, was an indication of what was accomplished and served as a guide to future improvements.

Steam Generating Plant.

Before proceeding to the discussion of the engine itself, it will be proper to divide the subject into its two main processes, namely, the generation of the steam in the boiler, and its use in the engine. So far as the writer is aware, no records exist of the separate performance of the boilers and engines of early periods. Mine-pumping engines gave the best opportunity for ascertaining the useful work done by engines, and the coal consumed gave a rough measure of economy. From this came the term "duty" of an engine, which means the number of foot-pounds of work done per 100 lbs. of coal burned. This is a comprehensive term in that it eliminates all intermediate processes and losses and expresses broadly the amount of work obtainable for a given expenditure of money. The earlier attempts at pumping by steam gave a "duty" of about 3,000,000 or 4,000,000 foot-pounds. Before Watt improved the engine a duty of about 6,000,000 or 7,000,000 had been obtained. Watt brought this to nearly 20,000,000. To-day we obtain 150,000,000!

There is no reason to doubt, judging from the construction employed in the early part of the century, that the boiler was not so inferior an apparatus as the engine, in comparison with present practice. A big tea kettle is not a very bad steam boiler, and that is what the early steam boilers were. It is safe to say that the best steam-generating apparatus of to-day, including a good furnace, water or fire-tube boilers, and economizers, will not show a reduction in coal consumption, for an equal quantity of steam generated, of one-half over what was accomplished in 1800. If we apply the term boiler efficiency to the ratio between the heat converted into steam and the potential heat contained in the coal, I should say that this efficiency might have been from 40 to 45 per cent a hundred years ago. To-day we obtain at the best from 80 to 90 per cent, but a general good result is from 60 to 70 per cent.

Let me call attention to the several elements that go to make up this improved economy. First, we have a little better furnace; second, the boilers themselves are of better design for the utilization of heat; third, economizers placed in the path of the escaping gases are new and have added something to the plant efficiency; fourth, superheaters are attached to boilers, but contribute more to the economy of steam in its passage through the engine than to direct boiler economy. While these are elements which go to improve fuel economy, far greater progress has been made in boiler design and materials to secure greater safety and durability. From 10 to 15 lbs. pressure in 1800, boilers are now made to stand any pressure the engineer may choose to carry. No single standard form has been developed during the century, but a great number of designs are still competing for supremacy. It can, however, be safely said that for special purposes, peculiar types are practically of established forms. But each form, or type, is an excellent apparatus, and presents no probable prospect of any material improvement.

Considering for the moment the efficiency of a modern first-class boiler plant in terms of water evaporated from and at 212° per pound of combustible, 13 lbs. have been obtained where no economizer was used; with an economizer this would probably have been increased to 13½ lbs. As the heat in 1 lb. of combustible is only sufficient to evaporate 15 lbs. of water, the thermal efficiency would have been $\frac{13.5}{15} =$ 90 per cent. Can we look for any material improvement over this splendid accomplishment? So far as converting the potential heat in the coal into actual heat of steam, we have obviously reached very near to perfection.

Utilization of Steam.

What do we accomplish in converting this steam into useful power? The best record to date is nearly 23 per cent, which was accomplished by the Nordberg pumping engine. This corresponds to nearly one indicated horse-power per pound of coal per hour. The more general good practice, however, is from 2 to 3 lbs. of coal per hour per indicated horse-power. Still, this is an enormous advance over the best practice of 1800, which was about 9 lbs. per hour per indicated horse-power. It is a curious fact that this tremendous gain in economy is not due to the discovery of a single new principle in nature in addition to what was known in 1800; the discovery of scientific laws has merely enabled builders to make more intelligent application of forces already familiar. At the beginning of the century, as previously stated, boiler construction was so inferior that only about 10 lbs. gauge pressure could be safely carried; and although the compound engines of Hornblower and Woolf were known, yet in the imperfect state of the mechanic arts no better result was obtained with them than with the single-expansion cylinder cutting off at about one-third stroke.

TABLE I.

Theoretical steam per I.H.P.-hour with no clearance, no leakage and no condensation; based on 2 lbs. back pressure absolute.

Expansions.	25 lbs. abs.	100 lbs. abs.	200 lbs. abs.	300 lbs. abs.
3	20. lb.	....	....	....
4	19.5 lb.	....	....	....
6	14.8 lb.	11.8 lb.	....	....
8	14.1 lb.	10.8 lb.	....	....
10	13.7 lb.	10.2 lb.	9.50 lb.	....
15	....	9.26 lb.	8.52 lb.	....
20	....	8.78 lb.	8.00 lb.	7.70 lb.
25	....	8.46 lb.	7.65 lb.	....
30	....	....	7.37 lb.	7.08 lb.
35	....	....	7.20 lb.	....
40	....	....	7.07 lb.	6.74 lb.

By means of formulas accessible to anyone who chooses to study the subject, it is easy to compute what high steam pressures and large expansion make possible. Ignoring clearance and loss by radiation and condensation, and assuming the vacuum to be within 2 lbs. of perfect, Table I will serve to show what relations exist between steam pressures and the number of expansions. It will be observed from this table that if Watt had but 10 lbs. steam pressure in his boilers, and expanded that steam three times, there was a theoretical consumption of steam of 20 lbs.; while to-day, with 185 lbs. boiler pressure, expanding 20 times, there would be required but 8 lbs. We can therefore make the comparisons given in Table II.

TABLE II.

Year.	Steam pressure in boiler.	Number of expansions.	Coal per hour per I.H.P.	Water evaporated per lb. of coal.	Pounds of steam per hr. per I.H.P.	Theoretical of last column.	Ratio of last two columns.
1800	10 lbs.	3	9.	5.5 lbs.	48.5	20	41%
1900	185 lbs.	20	1.4	12.0 lbs.	12.0	8	67%

As the steam jacket was used by Watt, aside from the increased steam pressure and greater number of expansions now practiced, we have effected a saving in having less clearance space, less leakage, due to better workmanship, and less radiation, due to better exterior coverings. These items go to make up the ratios in the final column of Table II, showing that in 1800 only 41 per cent of the theoretical possible was realized, while to-day we realize 67 per cent. It is possible to reach closer to perfection than we have done, but the general conditions of life are such that only in special circumstances can we afford to pay for a plant giving extreme economic results, and hence while 1 lb. of coal per hour per indicated horse-power is attained in a few cases, the average consumption remains nearer to 2 lbs. and more. The loss from condensation is still quite great, but is being reduced to some extent by the use of superheated steam. There is a possible saving of 15 to 20 per cent by superheated steam over saturated steam; and a more general application of superheat is the most probable line of improved economy open.

Mechanical Details.

It is impractical and would be unprofitable to go over the numerous minor constructions which have come and gone during the century, but a few which have remained may be mentioned, as well as such as are new and likely to remain as long as the steam engine is the principal prime mover. The gravity or pendulum ball governor that Watt applied to his engines is still used by many engine builders, and when used in connection with a liberating valve gear is a very good governor. The Porter governor and shaft governors are new, and are necessitated by valves and valve gears offering considerable resistance. High-speed spring governors were born during the century, and are likely to remain in use for certain types of engines. Shaft governors are of modern design and have attained a high degree of efficiency, with great power.

The D slide valve, which is said to have been made in the shops of Boulton & Watt at the beginning of the century, is still in service, but has been shorn of much of its chief drawback by being balanced by back-pressure plates. The rocking valve erroneously bearing the name of Corliss is a product of the century, and retains its successful position notwithstanding the onslaught made upon it from time to time by inventors of substitutes. Probably the greatest improvement in valves during the century has been the piston valve, and it will doubtless continue in use.

Valve gears are legion in number, but the variable cut-off controlled by the governor is the striking improvement of the century. The poppet valve used by Watt continues to be used on large vertical engines, and more particularly on steamboats. Lifted by a cam operated by an eccentric, it was necessarily a late cut-off mechanism, but a striking improvement was made in 1841 by Fred. Sickels, who cut in two the valve rod so that the valve could be freed from the lifting cam and allowed to drop to its seat at any period of its upward (and later, the downward) stroke. Variable cut-off was also obtained by the link-motion of George Stephenson in 1829 on his famous locomotive, the "Rocket."

The cutting off of steam was first effected by a sliding plate on the back of the main slide valve, thus closing the port in its opening motion. The point at which this cut-off occurred was for many years adjusted by hand and has always been so adjusted on marine engines, but in 1826 James Whitelaw, of England, is said to have controlled the point of cutting off by the governor. In this country this form of cut-off was used for many years until the Corliss type superseded it. In 1851 Corliss made a round-seated valve in place of a flat-seated one. The rocking motion of this valve was favorable to the application of the beautiful type of valve gear known as the wrist-plate motion, invented by Corliss. Then he took the Sickels liberating valve-stem feature and the governor-regulating feature already known, and made the handsome engine known by his name.

The pioneer in the construction of the high-speed engine was Chas. T. Porter, who brought out the Porter-Allen engine in 1861. It was a four-valve engine, the valves being balanced by moving between two parallel surfaces; the exhaust valves were moved by a fixed eccentric, and the steam valves through a half-link whose block was shifted by the governor.

Rotary Engines.

About the middle of the past century innumerable inventions were made in so-called rotary engines, but they are nearly all obsolete now. Most of these inventions have their origin in a mistaken notion that there is a loss of power in a crank engine; and others attempt to economize in space, gain in rotative speed, and still maintain as good steam economy as is obtained in a crank engine. The utter failure in the latter feature is rarely offset by the success of the first two. In their analysis, all these rotary engines are really crank engines with the pistons attached directly to the crank, but substituting sliding blocks in the cylinder for connecting rods outside of it. The true rotary engine of the century, and one not yet fully perfected, is the steam turbine, which has been so greatly developed by Mr. Parsons. The principle of action is that of an impact water wheel. It is worth while to put on record the latest official test of this engine, and this is accordingly given in Table III. Here is truly a new development of a very old principle. The performance of the engine is now equal to the best reciprocating types, with greater possible improvements before it. If the same degree of success shall be obtained in the steam turbine as has already been realized in the water turbine—and there is no good reason known so far which would prevent this—an efficiency of 90 per cent would be obtainable. This would mean that the steam consumption would be reduced to approximately 7½ or 8 lbs. per horse-power-hour. It is not unreasonable to predict that for electrical uses this type of engine may become a standard form in the near future.

TABLE III.

Parsons Steam Turbine. Direct-Connected to Polyphase Alternator. Speed 1500 r.p.m. Steam pressure 162 lbs. Superheat, 26° Fah.

Kw.	I.H.P.	Steam per Kw.-hour.	Steam per I.H.P.-hour.
1190 (over-load)	1860	19.3 lbs.	12.35 lbs.
995 (full load).	1550	20.1 lbs.	12.86 lbs.
745 (¾ load)...	1195	22.2 lbs.	14.21 lbs.
500 (½ load)...	781	25.4 lbs.	16.26 lbs.
246 (¼ load)...	384	33.8 lbs.	21.63 lbs.

Friction, field not excited, about 6 per cent of full power. Speed regulation between full and no load 3.6 per cent.

Surveying broadly the century's progress of the steam engine, it has been due more to the development of the mechanical arts, for which the century has been noted in so many other fields of human effort, rather than to any great invention or discovery in science. As to its future, it can safely be said that no scientific discovery will be made which will change its status as a prime mover, nor will any great invention affect its position, but we shall continue to apply the skillful work known to the art to a more general practice, and thus bring the average nearer to the highest. An eminent engine builder once said to me: "Mechanical engineering is not what it should be, but what people are willing to pay for." And if I may predict for the coming century, it will be one whose people will be willing to pay for better engines and will, consequently, be provided with them.

The Independent Telephone Exchange at Atlanta, Ga.

BY E. E. CLEMENT.

Many of the independent telephone companies are turning to the multiple switchboard, following the example of the Bell companies. The arguments advanced for and against the multiple switchboard, and the defects of the old-style transfer or divided central boards, are fairly familiar to all telephone men. It is not intended in this article to take up the broad question of multiple vs. trunking, but merely to set forth the main features of a large modern telephone exchange in which the trunking principle has been successfully used throughout, and which is probably as good an example as can be found of its kind.

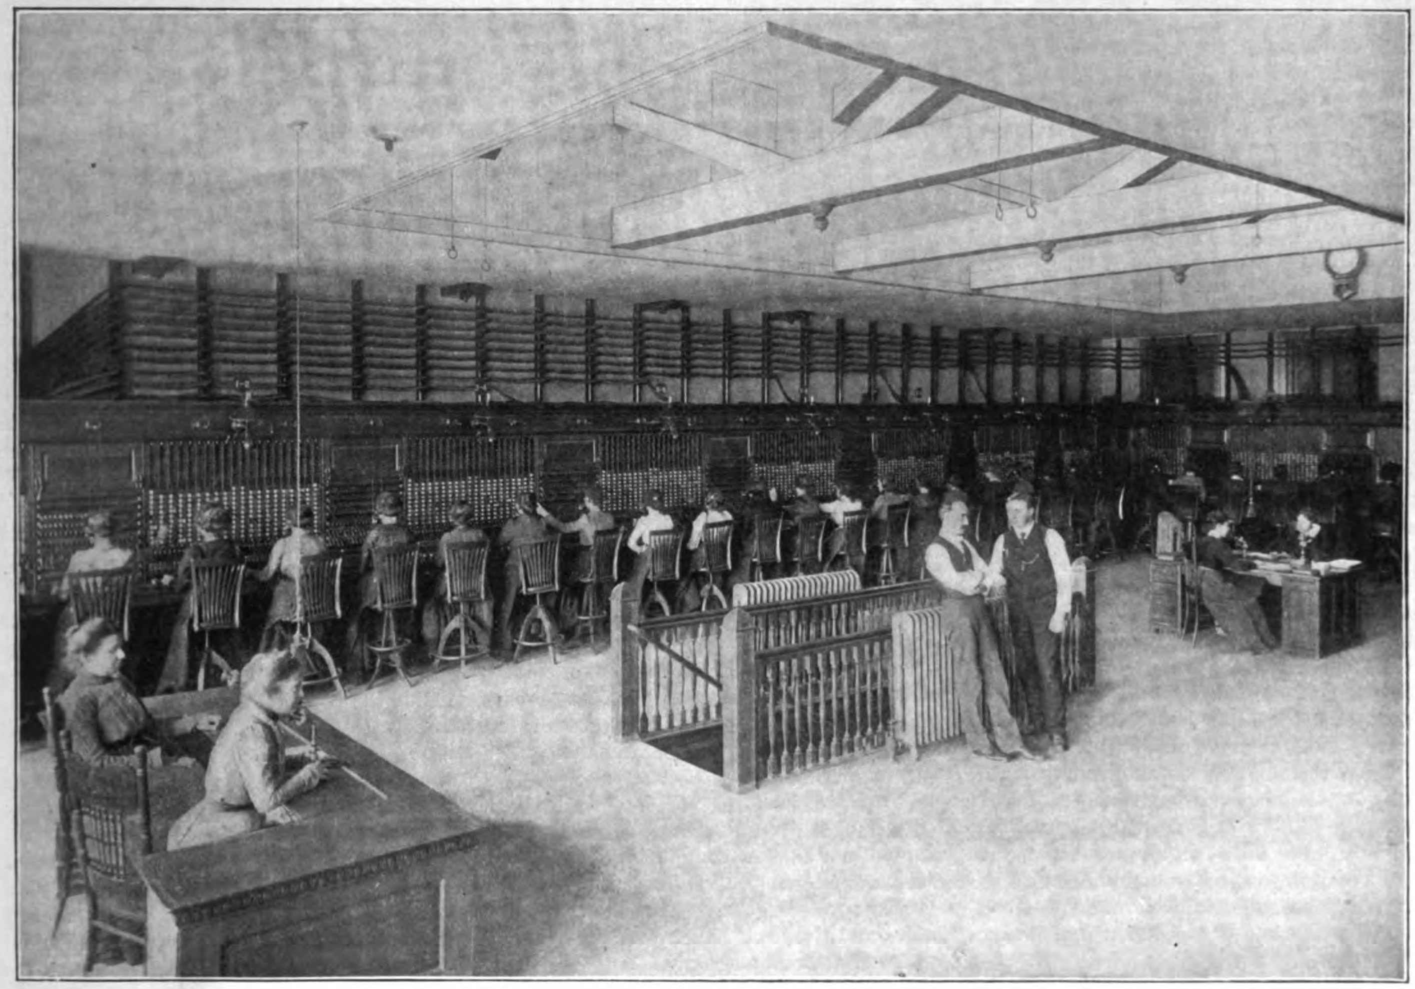

FIG. 1.—THE OPERATING ROOM OF THE ATLANTA INDEPENDENT TELEPHONE EXCHANGE.

The Atlanta company, after much preliminary work and calculation, decided to install a 2000-line board, with an ultimate capacity of 4000 lines, in its main building. As the work progressed, however, it was found that several boards would be required in other parts of the city, and the plans were slightly changed so that now the main exchange is equipped for 3000 subscribers, with additional facilities in case they are needed, bringing its capacity up to the original figure of 4000. The construction work and the installation of the exchange were carried out by the Atlanta Standard Construction Company, while the manufacture, erection and installation of the apparatus were under the personal supervision of Clement & Gharky, Philadelphia, under whose patents it was manufactured. (All of these patents are now the property of the Sun Electric Manufacturing Company, of Philadelphia.)

The Atlanta system is essentially an underground system. There is one long overhead line starting in the suburbs and passing about the city and out for about twelve miles, and an extension like perhaps half as long giving access to certain groups of subscribers who could not be economically reached otherwise, but most of the subscribers during the past year have been served through the cables. All of the main cables are 120-pair, lead-sheathed and paper-insulated cables of standard type, made to rigid specifications and drawn into the ducts by the John A. Roebling's Sons Company, of Trenton. The conduits are of terra cotta, in four-duct and six-duct units; the main trunk conduits have sufficient capacity for over 4000 lines. The distributing poles are of locust, averaging 50 ft. in height, and provided with square platforms strongly framed with iron, and wooden terminal boxes containing double rows of terminal strips with protective devices. Wherever practicable within the city, conduits were run and the cables taken directly into the basements of buildings to be served, distribution being then effected by means of small terminal boards and interior cables.

At the exchange building all cables enter through the front foundation walls, passing into a cable vault beneath the entrance door and extending back some 25 ft. From this vault a vertical brick shaft passes up to the second floor, into a large room over the main entrance, where the distributing and cross-connecting boards are located. This cable shaft is located about 20 ft. back from the front wall, and between it and the latter is a second vertical shaft which carries the switchboard line cables up to the third floor, where they pass directly onto the wall brackets or hangers shown in Fig. 1 over the top of the switchboard. The arrangement of rooms in the main building is as follows: On the first floor are the general offices, with a private office opening therefrom; a large back room, storeroom and instrument room. On the second floor, the whole depth of the building on the right-hand side is taken up by the operators' sitting room, dining room and retiring room; the front room on the left-hand side contains the distributing and cross-connecting board and power plant. The entire third floor is occupied by the operating room; the operating room is entered by a central stairway; the switchboard extends down two sides of the room and across the rear end, and all the rear windows are hermetically closed.

Fig. 2 shows the power room, with its switchboard, and one side of the combined cross-connecting and distributing board. The cables enter at the right-hand side from beneath and pass under a false floor, being brought up in rows along the sides of the distributing-board frame. The latter is an iron structure formed of angles and tees forming a cage with cross-bars overhead of iron pipe carrying vertical pins 5 ins. in height arranged in rows; each pin has a sleeve of hard fiber slipped over it to prevent short-circuits or crosses in case the insulation on the jumper wires should break. The cage has two partitions inside, and each of these is faced with hard-wood panels, as are also the two sides and the back. Each cable is brought up to the foot of the panel and there fitted with a pot head, the wires from which are formed up and led to rows of pairs of brass terminals passing through the panel. On the outside of each panel is a corresponding row of fuse protectors on porcelain bases, to which the cable wires are connected.

From each fuse block a continuing pair of wires is threaded back through the panel and up the inside face to the top of the frame, where it is led along between the parallel rows of pins to its appropriate terminals on the rear face of the board. This whole rear face is covered with small brass terminal connectors having binding screws to facilitate the changing of jumpers, the latter being threaded through in each case and being connected on the face of the panel. The switchboard line cables are 52-pair interior cables, and start from the inside of the rear face of the cross-connecting board, thence passing down under the false floor and across to the right-hand side in the picture, where the front of the switchboard cable chute is just visible near the ladder shown. Each cable has its terminal wires formed up and threaded through one side of the panels to the connectors.

It will be seen from this description that distribution and cross-connection is accomplished in the simplest possible manner and without the slightest confusion. Instead of a tangled mass of jumper wire there is a symmetrical set of leads on the top of the iron frame, accessible either from beneath or from above, and separated by the rows of pins into regular intersecting avenues, rendering it very easy to trace any particular connection and change or remove the same if desired. Walking inside the cage, one finds three little chambers with good head room and plenty of elbow room; all cable and wire connections being on the inside of the panel in orderly fashion, and everything perfectly accessible.

To one walking around the outside of the cage the sides or faces present only an array of terminal protective devices and brass connectors, each bearing the number of its line or switchboard wire as the case may be. By removing the protective devices, which are held in spring clips and are very compact (having fuses of the Maxstadt type), the terminals are left open for testing both ways, and an instantaneous connection can be effected by means of a small wooden handle with two pairs of terminals, connected by a four-conduct-

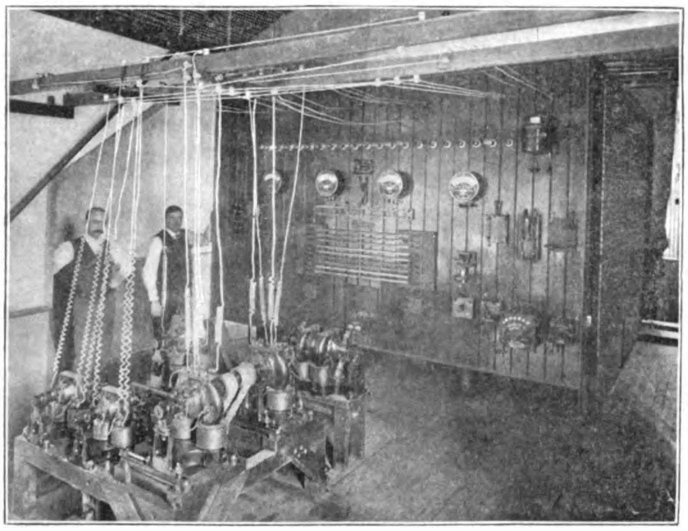

FIG. 2.– THE POWER ROOM.

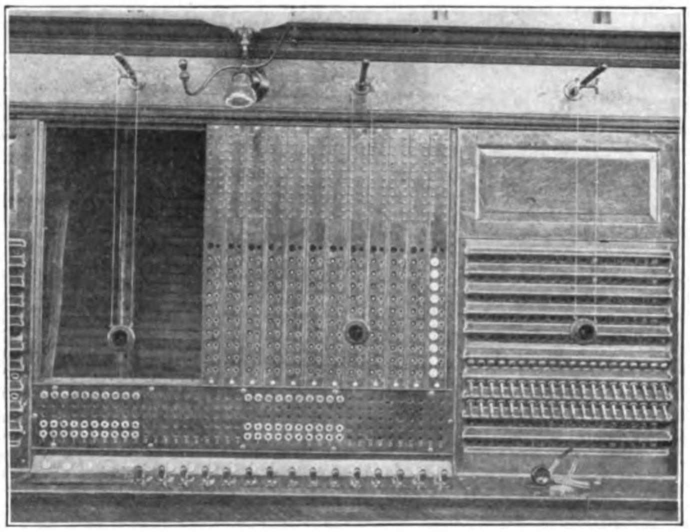

FIG. 3.—ONE SET OF PANELS.

or flexible cord to a permanent test table at one side of the room. This is not shown in the illustration, as it is behind the board on the left.

Across the front of the distributing cage, which would otherwise be open, and with about 4 ft. intervening, is the power switchboard, carrying voltmeters and ammeters, underload and overload circuit breakers for the charging machines, and all the main and local switches, starting rheostats, test ringer, wattmeter, etc. This board also has an iron frame, of pipes, angles and tees, and, like the distributing and cross-connecting cage, is strongly braced in every direction. In the photograph it is shown with temporary wooden panels, the picture having been taken when the exchange was first put into operation and before the slate panels had been received.

The power plant shown in the foreground of Fig. 2 was put in in the face of serious difficulty, to meet existing conditions. The only available source of electrical supply at the time was a 500-volt direct-current circuit. A 5-h.p. 500-volt Crocker-Wheeler motor was installed, belted to a countershaft hung on the under side of a heavy wooden platform which carried all the machines. From this the two charging machines are driven, either being capable of running independently, of course. A second or reserve motor was afterward added, and the entire arrangement proved to be fairly satisfactory pending the completion of 110-volt lighting mains by the local electric light company. In addition to this set of machines a water motor was provided in the basement with a ringing generator connected to it and wired to the power switchboard, to serve in case of failure of the 500-volt current, the storage cells having sufficient capacity to tide over any ordinary interruption. These batteries are Chloride accumulators of 500 ampere-hours capacity, and they are arranged in tiers on shelves, protected by an enclosing casing with glass doors.

There are duplicate sets of cells, one set being charged while the other is discharged, changes in connection for charging and discharging being made by means of the gang switches shown in the middle of the switchboard. This arrangement was made very simple to avoid blunders, one set of switches being always up and the other down. Twenty-six cells are employed in each set, the voltage of the signaling current on the lines being about 32, sixteen cells being therefore required for this service, and the balance furnishing current for the operators' transmitters, certain local switchboard circuits to be referred to and the lamp signals.

Passing now to the main operating room, which is shown in Fig. 1, it will be noted that the cables from the distributing board, coming up at the left of the picture, are taken from the top of the chute on to cable hangers or brackets supported on vertical hardwood studs secured along the walls, 25 ins. apart. The switchboard is divided into sections of three "positions" each, and there are three struts to each section, a pair of cables being let off from every third strut, beginning with the lowermost pair, and across the top of the board to the connecting terminals. The chute through which the cables pass up to the operating room is provided with doors on each floor, so that it can be opened for its entire length; and the same arrangement is followed with the chute through which the line cables pass up from the vault in the basement to the distributing board, perfect accessibility of every part of the line, either individually or in all its cable, being thus secured.

The arrangement of this switchboard is in many respects novel, and after over a year of continuous service it has proved itself to be eminently satisfactory. The board is divided, as just stated, into sections of three "positions" each. Two of these "positions" are taken by "A" operators, who answer all calls and initiate trunk connections; the third position being taken by a "B" operator, whose sole duty is to complete trunk connections according to instructions received from the "A" operators. This "B" operator does not ring, nor talk to any subscriber except when the line wanted is busy. Her sole work is to insert plugs, and the "A" operator does the rest. When the work is very light, all but the "B" operators can be dismissed, in which case these operators take up the work on the adjoining "A" panels; in order that they may do this, switches are provided on the right and left of each "B" panel, as shown, to connect the head circuits together.

Fig. 3 shows a section of three "positions" in course of erection, with parts removed to exhibit the inside construction. The most striking feature of the board to one not familiar with these systems is the enclosed gallery of ample dimensions which passes all around it, and is perfectly clear of cables or other obstructions. In Fig. 3, behind the left-hand transmitter, will be seen a continuation of one of the struts, referred to in connection with Fig. 1, bored to receive the horizontal members of a trunk cable frame. The trunk cables run along the wainscoting of the wall, where they are not only out of the way but absolutely open and accessible all the time, being arranged in an orderly fashion like the line cables of Fig. 1. They cross the floor of the gallery under short sections of false flooring raised 3 ins., these being loose so that they can be lifted when necessary.

At every third strut along the wall a pair of line cables is led off and taken across the top of the board to the front behind the moulding, where they pass down through the roof, the braided covering is removed and the wires are formed and laced to come down to the inside ends of the terminals on the top of the vertical strip. The eleventh pair of terminals on each strip and the eleventh opening in each case shown unfitted with a line unit, are "extras." These openings are normally plugged. In each section of the switchboard there are twenty vertical line strips, carrying normally two hundred line units. The first and tenth, and the eleventh and twentieth strips, however, each carry an extra unit the same as a line unit, wired to the chief operator's desk for one and the trouble operator for the other. The "A" operators call the chief the same as they would a subscriber, her desk being fitted with a row of annunciators consisting of plungers which also serve as keys, and which, when depressed, put her telephone set into circuit.

Each line unit is carried on a yoke secured to the back of the strip, the relay being of tubular form, and the lamp fitted in the front end of the tube. This is closed on the outside by a bull's-eye of translucent material, shown in the right-hand strip in Fig. 3, the bull's-eyes being removed from the other strips in that engraving, leaving the lamps exposed. Below the line strips the trunk panel is fitted with jacks and order keys. The panel is shown in Fig. 3 bored for the full equipment for 4000 lines, but with jacks for only 1000 installed. These are plain open-circuit jacks, each connected to its individual trunk line leading to some particular "B" section. In actual service it was found that two trunks from each "A" to each "B" operator was sufficient, giving four on each double "A" panel that lead to the same operator. The order keys at the top correspond, of course, with the pairs of trunks, the order circuits being separate from the trunks. The trunk and order-circuit cabling is wired on the trunk panel before it leaves the factory, and the connections are at one end, where the cable passes down the leg of the board and thence under the floor to the rack in the rear of the gallery.

Directly below the trunk panel and extending across each double "A" section is a signal panel, and directly in front of this are the "operators' strips," being a series of units composing the horizontal table. Each of these strips is of five-ply wood veneered on its surface with black fiber and carrying a pair of plugs and a combination key. The calling plug of each pair has a switch in its seat which, as long as it is not in use, connects the operator's head 'phone to the corresponding cord. No listening key is required, therefore, for as soon as the operator has inserted the answering plug in response to a call she is already on the line.

The combination key has two functions; in one position it connects the generator to ring, and in the other position it connects the corresponding signal lamp back of the plug to act as a supervisory signal, leaving it connected until the called subscriber answers, when it is automatically thrown off. This key, the plugs, and the plug seat switch are all wired in grooves in the edges of the strip before it leaves the factory.

The "B" section on the right of Fig. 3 consists essentially of a cast-iron panel in two parts, made in "stair-steps," and drilled through with rows of holes for the plug seats and "B" signals. The former are plain plug seats, tubular in form, held in place by a shoulder on one side of the iron and a nut on the other. The latter are plungers which serve both as push buttons and as signals. The row of these in front of any "B" operator represents all the "A" operators in the exchange, and when one pops out it means that the corresponding operator has come in on a trunk leading to one of the two plugs below it. This signal is only intended to guide the eye, for it is operated by the "A" operator having pressed her order-key on the trunk panel for this particular "B" operator, and as soon as she has done that she has crossed her talking circuit with that of the "B" operator and gives the order orally for the connection; but the visual signal is found to be useful in many ways.

If several trunk signals came in at the same time, the orders would be confusing to the "B" operator receiving them, but by a simple arrangement of the circuit these signals are made non-interfering; a "lock-out" mechanism prevents more than one signal coming in at a time, so that no confusion can result. At the same time, if the "B" operator happens to be busy or inattentive and misses an order, the signal shows her which operator called, and she can ask for the order to be repeated by simply depressing the plunger to its fullest extent, as this crosses her talking circuit with that of the corresponding "A" operator.

The wiring on the rear of the "B" sections, as well as the management of the cords and weights of the trunk plugs, is simplified by inverting the plugs; this also gives an opportunity to use long cords, which permit the trunk plugs to be used over a large part of either of the two adjoining "A" sections, as indicated in Fig. 4.

There are some novel features about the operators' suspension sets. In the first place the transmitters are suspended by bare conductors, which pass over insulated sheaves. This allowed the size of these conductors to be reduced so that they are almost imperceptible, and do not obscure or confuse the view of the board. The sheaves are carried on a sliding support, which is locked in position by the weight of the transmitter, the operator being thus able to adjust her transmitter up or down, inward or outward, by merely raising it in her hand. An automatic switch is provided, operated by a stop clamped on the cord so that when the transmitter is pushed all the way up by a retiring operator the battery is cut off. The head 'phone is plugged in on a jack underneath the table in the ordinary way.

Having described a few of the main features of the board, its operation will probably be now understood. Although no reference has been made to it, the reader has probably inferred that the board works with a central battery. This is true only as to signalling, however. Local batteries are used at the subscribers' stations. The subscriber calls by removing his receiver from the hook. This act closes the battery circuit and current flows through one coil of his relay, which closes the lamp circuit. The "A" operator, receiving the signal, inserts the answering plug of a pair, and being already on the end, is enabled at once to ask "number." If the number wanted is on her own section she inserts the calling plug in the jack of the line wanted and pushes the knob of her key in one direction at one operation. This connects the lamp signal corresponding to that pair of plugs, and a reverse motion of the key rings up the subscriber. The previous insertion of the answering plug connected the line relay in a bridge circuit, presenting high impedance to talking current but permitting the battery current to pass neutrally and retire the signal.

The supervisory signal, however, remains lighted until the called subscriber answers, and it is therefore unnecessary for the operator to "listen in." As a matter of fact, she has no means of listening in after the connection is made. When the called subscriber answers, the supervisory signal disappears, and a clear through circuit is established between the subscribers, with no branches or coils, and only one pair of cord contacts, interposed.

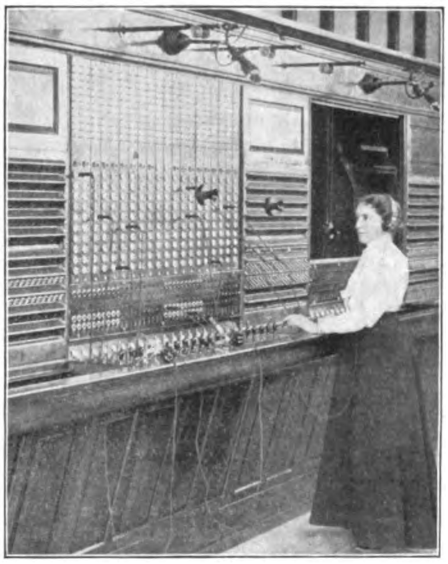

FIG. 4.—TRUNK PLUGS CARRIED OVER.

Either subscriber can control his own lamp signal by moving his switch hook, and when both have hung up their receivers both line lamps are lighted for clearing out. If one lamp only should light, it would either be a sign of trouble or indicate that one subscriber had neglected to hang up his receiver, the operator then taking the usual steps to apprise him of that fact.

If the wanted line is not within reach, the "A" operator inserts the calling plug in the jack of a trunk leading to the desired section, at the same time pressing the corresponding order-key and repeating the number to the "B" operator, and pulling the knob of her combination key as before. The "B" operator takes the proper trunk plug and inserts it in the desired jack. The instant she has done so a circuit is completed for the supervisory signal in front of the "A" operator, who is thereby informed that the connection is complete and proceeds to ring. There need be no delay in the "A" operator's work, because of a slight delay in the completion of the connection; for the lighting of that lamp always means the same thing—that is, she is to ring, and the order cannot be lost, for the "B" signal will bring the "B" operator back on the order circuit if she has missed it. When the subscriber answers, the supervisory lamp goes out, and when the conversation is finished the clearing-out signals are received at both ends as before.

In case a line is busy, that is, if the "B" operator finds a plug already in the jack, she speaks directly to the calling subscriber through the trunk wire, informing him that the line is busy, and in hanging up his receiver he gives the clearing-out signal; or should he neglect to do so the "B" operator can directly inform the "A" operator of the fact.

This system is provided with an arrangement of multiple trunks, instead of the simple trunking described, where trunking between exchanges is to form a considerable percentage of the business. For this purpose a set of busy signals are used in addition to the supervisory signals shown. The desk at the left-hand side of Fig. 1 is a monitor's desk, fitted with listening keys only, so that the monitors can listen to or talk with any operator or the chief. In the complete designs, where conditions permit it, this desk is also fitted with a distributing board for all the operators' circuits, and "on and off" keys giving control of the individual operators, battery connections, to insure economy. The chief operator's desk is also fitted with a limited number of special line units, whereby habitual "kickers" among the subscribers can be accommodated by the chief herself.

One of the most interesting points about the Atlanta installation is the provision of automatic tests for almost all troubles. In case of grounds or crosses on the lines the troubles report themselves at once; in case of a subscriber leaving his receiver off the hook or of a supervisory relay failing to work, a white or a red lamp lights, as the case may be; and generally it may be said that this system makes the trouble man's work easy.

In an article of this kind it is manifestly impossible to go into all the details of construction and of the circuits of a large exchange. It will perhaps be not out of place to say that all of the features described herein are substantially covered by patents or by claims in applications that are the absolute property of the Sun Electric Manufacturing Company. This switchboard, and others that have grown out of it, are the results of long-continued original work, in which special care has always been taken to avoid encroaching on the rights of others, and the same care exercised to insure self-protection.

The service possible with a system of the kind described is very rapid, as a year's experience has demonstrated, approaching within one second average time of that possible on the most modern multiple boards. The expense of operating, taking everything into consideration, is almost the same, and the following advantages are perfectly apparent: Lower cost of installation; absolute simplicity of parts and of circuits; perfect accessibility of every part of the apparatus and of the wiring, from the cable heads up; proper apportionment of the weight and bulk of cables and racks where they belong, around the walls of the exchange and not on the switchboard; interchangeability of parts; and finally, the possibility of almost instantly being able to take out any part or any aggregation of parts in the entire exchange, without exception, and to replace it by another, without interruption of the service.

ANNUAL MEETING OF THE ENGINE BUILDERS' ASSOCIATION.

The Engine Builders' Association of the United States held its annual meeting on December 4 at Sherry's, corner Fifth Avenue and Forty-ninth Street, New York City. Three extremely interesting papers were read before the meeting, one by Mr. H. C. Ebert, of the Westinghouse Company, on "Inter-relations Between Engine and Generator Builders"; one by Mr. E. J. Armstrong, of the Ball Engine Company, on "Economy Guarantees of High-Speed Simple Engines," and the other by Mr. H. G. Reist, of the General Electric Company, on "Some of the Requisites of Modern Lighting Generator Sets."

Mr. Ebert, in his paper, stated that as purchasers continued to express a strong preference for direct-current apparatus his paper would deal specifically with the subject of the so-called engine-type generating sets. He proceeded to point out that when a consulting engineer makes the specifications for the generators and engines he usually designates an engine which will closely correspond with the generator in capacity, speed and regulation, but when the selection of an engine to drive a certain size of generator is made by the purchaser himself an engine is invariably obtained which in these three important features does not match the electrical part of the outfit. It is in such cases, he said, that both engine and generator builders find great difficulties. There should be uniformity in rating engines with regard to the overload capacity of the generator to be driven. It should be noted that what would be considered ideal regulation for a direct-current installation would not be satisfactory with alternating-current power generators. If the governors on two engines driving alternators tend to give different speeds, say 500 and 525 r.p.m. respectively, no matter with what regularity the engines may run the two alternating-current machines will not operate satisfactorily in parallel; the one which runs at the higher speed carrying all the load.

There would seem to be no good reason, he continued, for dissension or disagreement if the builder who is to furnish the engine and the one who is to furnish the generator will acquaint each other with the general terms of their contract with the purchaser, so far as those terms relate to characteristics held in common by both the generator and the engine. Mr. Ebert strongly commended the work of the committees on "Standards for Direct-Connected Generating Sets," appointed by the American Society of Mechanical Engineers and the American Institute of Electrical Engineers, and predicted as a result of the joint labors of these two committees the elimination of many minor troubles which are now experienced.

He outlined the Westinghouse Company's practice in direct-connected generator outfits, which included calling the attention of the engine builders to the magnetic attraction between the field magnet and the armature core and stating on the drawings the amount of magnetic pull which may be expected should the armature become decentralized. As this unbalanced magnetic pull acts at right angles to the shaft and may be in any radial direction parallel with the plane of revolution it should be carefully considered, not only with regard to the shaft diameter but also the strength of the foundation, sub-base, and housings on the main bearings. The connection between the outboard bearings and the sub-base should be particularly rigid. In one or two instances wherein this magnetic attraction was not taken into consideration by the engine builder the result was the almost total destruction of both engines and generators.

Mr. Ebert also stated that Westinghouse engine-type generators for both direct-current and alternating-current power work were designed to be connected to the engine in any one of the following four ways: First, the revolving element of the generator may be pressed and keyed on an extension of the engine shaft, the engine builder furnishing the shaft, keys and outboard bearings; second, the generator may be self-contained and include the shaft, shaft keys, outboard bearing and half of a flange coupling for bolting to a similar half coupling on the end of the engine shaft or side of the flywheel; third, the revolving part may be designed with a flanged extension for direct connection to the flywheel, the shaft on which this revolving element is pressed or keyed may or may not be a part of the engine shaft; fourth, machines of 850 kilowatts and over can be built with bosses on the spider arms for bolting direct to an extension on the engine flywheel. In any case the Westinghouse Company provides the necessary gauges and templates to enable the engine builder to properly fit the connecting parts of the engine.

Mr. Bird, of the Ball & Wood Company, said that pressing on armatures was a great inconvenience, and that it was not always clearly understood who should do the work, the engine builder or the generator builder. He said that his company's practice was to bore a hole in the end of the shaft of a uniform size and to use a stud bolt to insure a fit. Mr. Ebert expressed approval of this practice, and suggested that its general adoption would probably be welcome to electrical manufacturers. Regarding the question of overload capacity, Mr. Ball agreed with Mr. Ebert that this question was a serious one; the electrical engineer, he said, was largely to blame for making some plants unnecessarily costly and frequently preventing a would-be purchaser from putting in a plant because of the high cost imposed by the practice of encouraging the purchaser to ask for a larger overload capacity than his actual need justified. Mr. Ball suggested that there should be a limit placed on the overload capacity to be specified. Mr. Ebert said that this would probably adjust itself, that the Westinghouse Company had already reached a point of refusing to agree to more than 50 per cent overload capacity, and were doing all they could to keep down the demand for excessive specifications in that direction.

Mr. E. J. Armstrong, in his paper on "Economy Guarantees," pointed out that the matter of economy does not always receive due consideration. An engine that runs smoothly, noiselessly and reliably will have friends and purchasers whether it uses much or little steam. He had no desire to advocate improvement in economy to the neglect of other essential qualities, but he believed that many engine builders have only an imperfect idea of the capability of their own engines. He thought that if the subject was amenable to a greater extent to mathematical treatment the case would be different, but in spite of the marvelous advancement in science at the end of the century, he believed that the exact formula for the economical performance of the steam engine had yet to be written. In view of the fact that the steam used by an engine often costs as much per year as the engine itself it would seem that the purchaser might consider steam economy as of first importance and price as a bad second; yet, even a small difference in price or a personal preference will decide a purchase without raising the question of economy at all. A difference of 10 per cent in steam consumption between two engines might easily place the more wasteful one in the position of being too expensive, even as a gift, for installation, but there is no doubt that there have been and still are even greater differences than this between engines that are sold on equal terms. Mr. Armstrong expressed the belief, however, that this condition of things would be brought to an end in the early future. For years, he said, there had been an increasing tendency among purchasers to raise the question of economy, and engine builders must recognize and prepare to meet a demand for definite guarantees and performances.

It is not usually practical to test engines of small size after installation; the expense is disproportionate and the difficulties in the way of obtaining accurate results are great. The liability to error and the impossibility of running preliminary tests make it unsafe to make close guarantees which are to be demonstrated in this way. The proper place to test an engine is on the shop testing floor. The question of penalties for failure to meet the terms of contract is considered quite onerous by engine builders, but if not provided in the contract, the only penalty is the non-acceptance of the engine; and as this is often impracticable because of lack of time, there is a good chance that the guaranty is not worth anything. Definite penalties at least have the effect of protecting those who really make their guarantees in good faith and with a knowledge of what they can do. There is nothing wrong about it from the purchaser's standpoint. There is one feature of the situation that is manifestly unfair and calls for remedial action. Better economy costs money. It may not actually cost more to build a high-duty engine than a wasteful one, but it costs a good deal more to learn how and to keep up the standard afterward. It costs money to tune an engine up to meet a close guaranty, and testing engines is an expensive business at the best. There should certainly be an addition to the price when guarantees are required. Mr. Armstrong suggested that all duty guarantees should provide for their fulfillment on the shop floor test before shipment and should always be considered as an extra, it being optional in all cases with the purchaser to accept the proposal with or without the guaranty. If the guaranty does not mean anything, it should not be made. If it does stand for something it costs a good deal and is worth to the customer all that he is likely to be asked for it.

Mr. H. G. Reist, in his paper on "Requisites of Modern Lighting Generator Sets," pointed out that it is not possible to adopt absolute speeds for engines which are used to drive alternating-current generators direct, because of the various frequencies employed in different classes of work, and because the generators must be built with a number of poles that is divisible by four. Mr. Reist proceeded to explain the relation between the frequency of the circuit and the revolutions per minute of the generator, and argued that by a careful selection of sizes it would be feasible to keep down the number of designs to a great extent and thus facilitate the duplication of the designs adopted. The General Electric Company had given considerable thought, he said, to the selection of a range of sizes, and had concluded that if the units adopted were of such size that each one was 50 per cent larger than the one below it there would be a sufficient number of large machines to meet all requirements. Mr. Reist said that this conclusion had been sustained by practical application of lines of generators and motors with the sizes spaced approximately according to this plan. This method of determining the sizes, he admitted, necessitates giving some of the machines odd ratings, but this would occur in any case with either the engine or the generator, as one is rated in horse-power and the other in kilowatts.

Referring to the operation of direct-driven alternators in parallel, Mr. Reist stated that all engines designed for this service should not have an angular deviation from absolutely uniform speed of more than $\frac{5}{P}$ degrees of a cycle, P being the number of poles on the machine. The principal trouble experienced in operating alternators in parallel, he said, is due to the variation in speed of the prime movers, which causes hunting and the exchange of wattless currents between the generators.

Mr. Stett suggested that it would be well for dynamo builders to specify more exactly just what would be required of the engine in regard to the speed variation in each case. Mr. Stett also brought up the question of getting plans more promptly from manufacturers so that the engine builders could have more time on their work. Mr. Ebert said that if no special designs were called for, the plans could be given quickly, but many special machines had to be built and they naturally were hindrances to getting out the plans promptly. Mr. Wood made a motion that the committee from this association should meet similar committees from other associations concerned and take the matter up thoroughly.

At the close of the executive session, Mr. W. M. Taylor, of the Chandler & Taylor Company, extended an invitation to the association to meet next year at Indianapolis, and the invitation was accepted. In the evening a dinner was served at Sherry's, which was thoroughly enjoyed by about 35 members and guests of the association.

Abstracts from Foreign Contemporaries

An Arc Lamp with a Nernst Effect.—An interesting description of a Bonhivers arc lamp recently appeared in the "Zeitschrift fuer Beleuchtung." The two carbons of the lamp approach each other at an angle somewhat less than 180°, and in close proximity to a block of refractory material which is brought to a very high temperature by the arc, and radiates a light of a quality similar to that of a Nernst lamp. The refractory material of which the block is made consists of 52 per cent of burnt clay, 26 per cent of raw clay, 12 per cent of powdered quartz, and 10 per cent of boracic acid.

Luminous Electric Radiators.—The accompanying engraving, Fig. 1, taken from the London "Electrician," illustrates the latest pattern of Dowsing electric radiator. The apparatus consists of a bright copper framework resembling somewhat an open firegrate, and containing four incandescent lamps having candle-shaped bulbs. The copper sheet back of the lamps serves the double purpose of a reflector and a radiator, the construction of the apparatus being such that a current of air can pass up behind this sheet and out into the room.

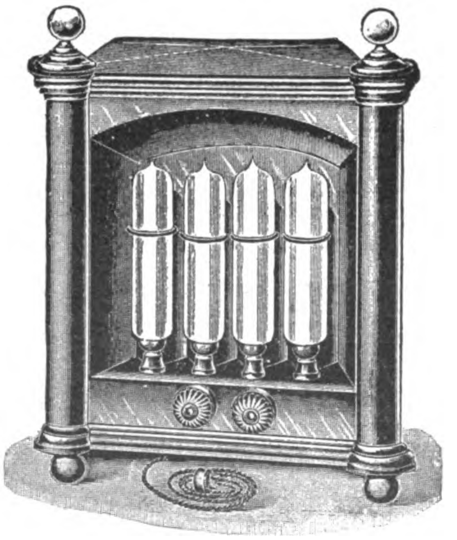

FIG. 1.—LUMINOUS RADIATOR.

Reflector Incandescent Lamps for Street Lighting.—A recent issue of the London "Electrician" has an illustrated description of a rather interesting type of incandescent reflector lamp which is used for street lighting. Fig. 2 herewith illustrates an ordinary gas lantern equipped with two of these lamps. As the illustration shows, the bulb is shaped somewhat like the familiar McCreary shade, and the upper half serves as a reflector by reason of a silver deposit on the outside of the bulb, which is protected from the action of the weather by a coating of copper deposited directly on the silver film.

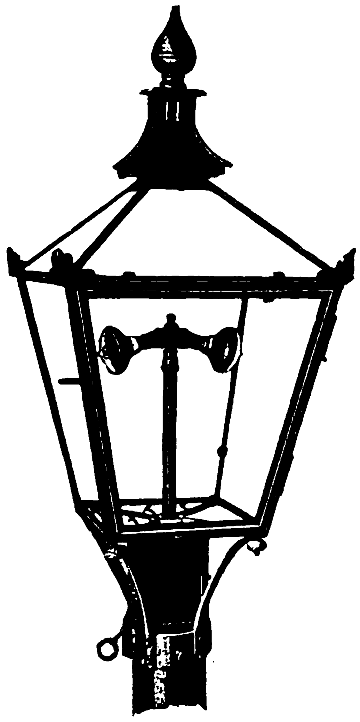

FIG 2.—STREET LANTERN.

Surface Contact Railway Systems.—In recent issues of London electrical papers there has been published a description of the Schuckert surface contact system, which has been in successful use on some of the railway lines in Munich since the summer of 1899. The road-bed is provided with a central row of contact studs with automatic switches for connecting these studs with the live feeders when the car is over the studs, and disconnecting them when it has passed. Fig. 3 is a diagram of the car connections, and Fig. 4 a general scheme of the system. There is no mechanism beneath the road-bed proper, the contact stud switches being grouped in sub-surface pockets along the side of the track. The cars are provided with skates, of course, which make contact with the track studs in the usual manner. The electromagnetic switches, as an inspection of Fig. 4 will make clear, are so arranged that a shunt circuit from the last stud already in contact with the skate energizes the relay which connects the next contact stud ahead of the skate with the feeder circuit. Following behind the skate is a short-circuiting brush which sweeps both the contact studs and the rails. (The rails are used as a return conductor, as in the case of an ordinary trolley system.) The object of the short-circuiting brush is to prevent any of the studs from being left alive. In the event that the release mechanism fails to act after the skate has left the stud, the short-circuiting brush comes along and connects the stud with the rails, putting on a dead short-circuit which throws an automatic circuit-breaker in series with the stud. The total cost of the installation is said to be about twice as great as the ordinary trolley system with steel poles, and about 1-3 of the cost of a consolidated conduit system.

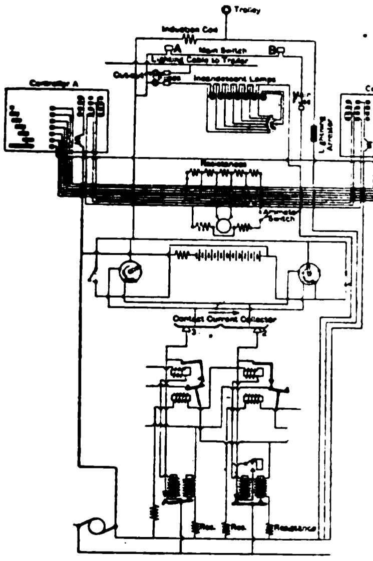

FIG. 3.—SCHUCKERT CAR DIAGRAM.

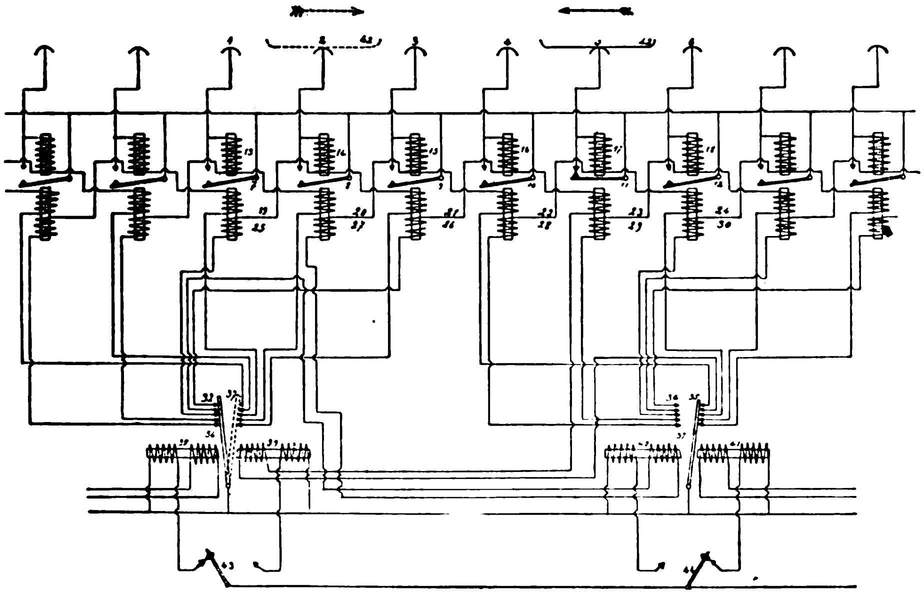

FIG. 4.—DIAGRAM OF SCHUCKERT SURFACE-CONTACT RAILWAY SYSTEM.

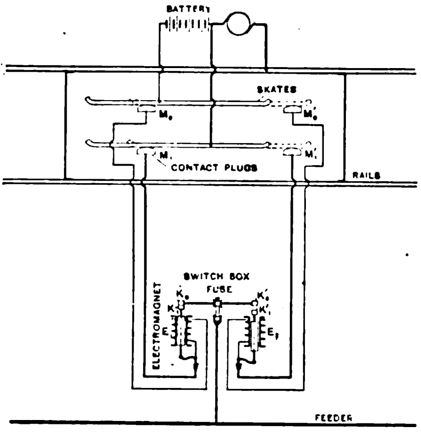

FIG. 5.—HELIOS SYSTEM.

An illustrated description of the surface-contact system of the Helios Company, which is somewhat similar to the Schuckert system described above, is illustrated in the "Elektrotechnische Zeitschrift." This system includes contact studs or knobs between the rails and skates on the cars, exactly like the Schuckert system, except that there are two lines of contact studs and two skates on each car. There are also distributor boxes at intervals along the side of the road-bed containing relay switches which connect and disconnect one line of contact studs with and from the feeders. The electro-magnetic switches, however, are operated by a storage battery on the car. The connections are shown in Fig. 5; one set of contact studs, M_0, is for the storage battery and relay connection, the electromagnetic switch being restored by a spring when the battery skate breaks the connection under the car.

Motors for Machine Shop Service.—In a long serial on the driving of machine tools by individual motors, which appeared in recent issues of the "Elektrotechnischer Anzeiger," O. Lasche, discussing the arguments which have been advanced against individual motors, says that comparing the current consumed by individual motors with that taken by motors which drive groups of machines, the group system shows better economy only when all of the machines are deliberately run at the same time under maximum load. In practice, however, where the load does not average anything like its maximum value, it has been proved by experience that individual motors are more economical. Regarding the first cost of equipment, Mr. Lasche, taking as an example an installation of 61 machine tools, estimates that the first cost of the plant with individual motors (assuming that the building has already been erected) is only 2.3 per cent higher than the cost of the group system. And where the building has not already been erected this advance will be reduced by reason of the fact that the individual motor system does not require a building with such strong walls as the other.

A New Storage Battery Plate.—A peculiar type of Plante or formed storage battery plate, which constitutes the positive electrode of the Omega storage battery, is described by P. Weber in a recent issue of "Centralblatt fuer Accumulatoren und Elementenkunde." The plate consists of a central web of zigzag cross-section, as shown in the lower part of Fig. 6, on each side of which are provided wings which constitute the positive plates. The object of this arrangement is to allow the plates to expand in any direction so as to avoid buckling. The process of forma-

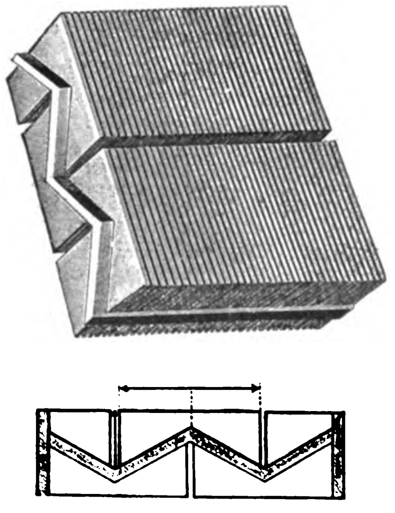

FIG. 6 —OMEGA BATTERY PLATE.

tion is not described; the author states that a special process is used which requires only three days' time for forming and which does not involve the use of any chemicals that can subsequently prove detrimental to the battery.

Direct Current vs. Polyphase Currents.—A general comparison of direct and three-phase currents for plants of medium size was made by H. A. Earle in a paper read before the Manchester section of the British Institution of Electrical Engineers recently. Mr. Earle made the usual comparison of copper required for transmission lines and pointed out the disadvantages of polyphase motors for use where speed regulation is required. He also alluded to the exaggerated bugbear of commutator trouble, showing that the objection to the commutators of direct-current motors in surroundings where sparking might cause an explosion was entirely overcome by the modern wholly-enclosed direct-current motor. The paper contains an interesting comparison of direct-current and polyphase motor efficiencies. Mr. Earle made tests of a large number of both types of motors and plotted the results in the shape of a curve. The principal results are given below:

EFFICIENCIES.

Brake H.-P......	3½	6	10	25	50	100
Direct current..	82%	85%	86%	91%	92%	92%
Polyphase	75%	80%	84%	88%	90%	91%

Regarding the railway motors, he pointed out that while polyphase motors appeared especially suitable for long lines of railway where distances between stops are considerable, such a system is unsuitable for use in towns where frequent stops and a variable rate of speed are required. He did not point out, however, one of the strongest disadvantages of the polyphase system for railway traction, viz., the lack of interchangeability between a system of this sort and the prevailing direct-current system, which would prevent the cars of one system from operating on the tracks of the other.

Induction Motors as Generators.—In a translation of a paper read by Mr. Maurice Leblanc before the Societe Internationale des Electriciens, which recently appeared in the London "Electrical Review," is described an induction machine designed for use as a generator. The machine has practically two distinct stators mounted concentrically about a single shaft, as represented in Fig. 7, where CC is one stator and EE the other. The laminated stator core, CC, is provided with a single-phase primary winding. On the shaft are mounted two distinct laminated cores, DD, and FF, bar-wound after the fashion of ordinary induction motors except that the windings of the two cores are interlinked, as shown by the diagram, Fig. 8. The stator core, EE, is provided either with several exactly similar circuits angularly displaced with reference to each other, as in the case of an ordinary polyphase induction motor, or a continuous closed-circuit winding, such as would be used for the stationary armature of a direct-current revolving-field machine. The functions and operations of the various parts are as follows: The winding of the stator, CC, is excited in the usual manner and induces alternating current in the rotor winding on the core, DD. This winding delivers current to its duplicate winding on the core, FF, which in turn induces currents in the windings on the stator core, EE. The machine obviously requires no sliding contacts or collector rings whatever, and its speed for a given frequency is only one-half that of a generator of ordinary construction.

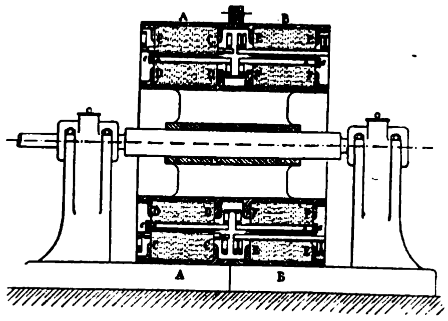

FIG. 7.—LEBLANC INDUCTOR ALTERNATOR.

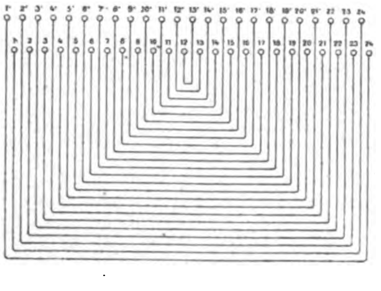

FIG. 8.—ROTOR CONNECTIONS.

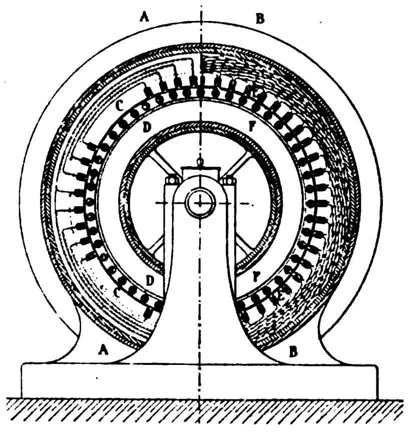

FIG. 9.—SIDE VIEW OF ALTERNATOR.

Electrical Central Station Service.—At a meeting of the Glasgow section of the Institution of Electrical Engineers, W. A. Chamen read a paper on "Electricity Supply," in which he advocated the use of low-tension direct-current, generated on a site within the area of supply, if possible, and supplemented by a small amount of high-tension apparatus in order to reach remote distribution points. If it is impossible to obtain a supply within the area of distribution at a reasonable price and with railway accommodations, then a high-tension system with the generator station outside of the distribution area is the next best argument. Mr. Chamen favors a three-wire system of distribution with 500 volts between the outer wires, as this would allow the use of a uniform maximum e.m.f. for both lighting and traction. He stated that in Glasgow, where such a system is used, 250-volt incandescent lamps of as low as 5 and 6 candle-power have been in use for over fifteen months without failure. The efficiency of the lamps is 5 watts per candle for the sizes named; 4 watts per candle for 8-c.p. and 16-c.p. lamps; 3½ watts per candle for 32-c.p. lamps; and 3¼ watts for 50-c.p. lamps.

Regulation of Rotary Converters.—It is well known, of course, that the direct-current e.m.f. of a rotary converter cannot be regulated by adjusting the field strength of the machine. The method usually employed in this country for regulating the direct-current voltage is to insert an induction regulator in the alternating-current leads, and by means of this vary the alternating-current e.m.f. impressed at the collector rings. The method used by the Allgemeine Elektricitäts Gesellschaft of Berlin for this purpose is described in a recent number of the "Elektrotechnische Rundschau." Fig. 10 herewith illustrates diagrammatically the arrangement. On the same shaft with the converter armature is mounted an ordinary alternator armature, R, wound for the same number of phases as the converter armature and connected in series between the alternating supply and the converter armature windings. The auxiliary armature, R, rotates within a field magnet, M1, having the same number of poles as the field magnet, M, of the converter, and excited from the same source. It is obvious that the auxiliary machine acts merely as an alternating-current booster. It is also evident that the fields and armature windings of the two machines must have fixed relations with each other in space in order that the phase relations may be symmetrical. If it is desired to have the rotary converter compounded so that the direct-current e.m.f. will rise as the function of the load, the field magnet of the auxiliary machine may be provided with only a heavy wire winding connected in series with the direct-current load, just as the compound coils of a direct-current generator are connected.

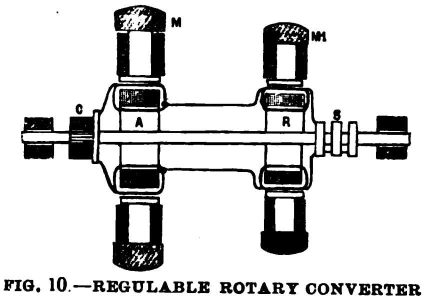

FIG. 10.—REGULABLE ROTARY CONVERTER.

Electric vs Steam Locomotives.—In a paper recently read before the British Institution of Electrical Engineers. W.

Langdon discussed very conservatively the relative merits of the electric locomotive and the steam locomotive for trunk line service, basing his comparisons on three-phase transmission between generating stations and rotary convertor sub-stations for the electric system. Taking the 50-mile Midland railway between St. Pancras station (London) and Bedford, and assuming a motor efficiency of 85 per cent, a transmission efficiency of 90 per cent, a conversion efficiency of 84 per cent, and a distribution efficiency of 87 per cent, Mr. Langdon showed that the cost of working with electric locomotives would be 14.04 cents per train-mile, as compared with 17.85 cents per train-mile for steam locomotives. He pointed out that in the case of the adoption of electric traction by a company already established and using steam locomotives, the additional expense due to the change would unavoidably prove for some years an addition to the company's capital charges, but that for a new company it would not be necessary to take into consideration the interest of the entire additional outlay necessary for the electrical plant, because there would be considerable saving in first cost in other directions.

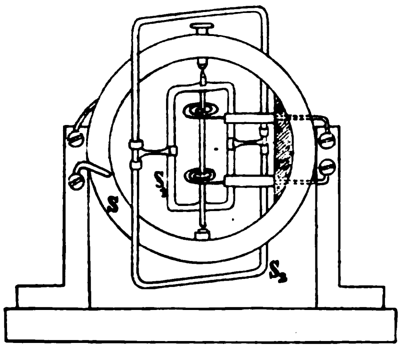

FIG. 11.—ASTATIC WATTMETER.

An Astatic Wattmeter.—The "Elektrotechnische Rundschau" recently published a description of a new Hartmann & Braun astatic wattmeter for use on direct-current and alternating-current circuits. Fig. 11 herewith, which has been reproduced from the journal mentioned, indicates the principle of the apparatus. The current coil, S, is fixed to the framework of the meter, and there are two potential coils, S1, and S2; the inner one mounted on pivots, as shown, and the outer one supported by struts from the inner coil. The two potential coils are connected in the usual manner common to all astatic instruments, so that the current circulates in opposite directions through them, nullifying the effect of the earth's magnetic field. As the arrangement shown by Fig. 11 involves some difficulties in practical construction, the coils of the actual instrument are made up as in Fig. 12, which shows three potential coils, one of the fundamental pair being divided into two sections.

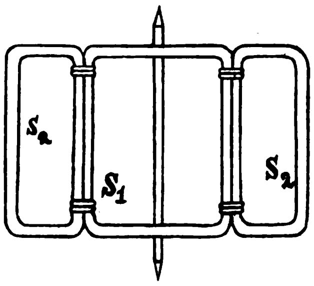

FIG. 12.—WATTMETER COILS.

Some Recent Electrical Patents

Insulating Knob.—Several forms of knob insulators have been devised, the object of which has been to provide a means for attaching wires to the knob without the use of separate tie wires. One of the most recent devices of this sort is illustrated in Fig. 1. The body of the insulator knob is of the ordinary shape, but the portion below the groove is extended on one side into a lip, or hook, A, the function of which is made clear by the engraving. Patent No. 660,271.

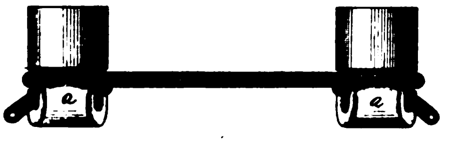

FIG. 1 —INSULATOR KNOB.

Distribution System for Rotary Converters.–It is well known that when two or more rotary converters or synchronous motors are supplied from one distribution system there is a liability to hunting, which is greater if the natural periods of oscillations of all of the machines are identical, as would be the case if the machines were all of one size and type. With a view to obviating this tendency to hunting, E. J. Berg, of the General Electric Company, has devised the arrangement shown diagrammatically by Fig. 2, in which the supply generators are represented by A, the step-down transformers by T, the rotary converters by R, and the direct-current mains, which are fed by the rotary converters, by E B. The alternators supply bus-bars, D, in parallel in the ordinary manner, and from these bus-bars individual feeders, E, F and G are carried to the respective transformers. At the transformer end the feeders are cross-connected by means of equalizing wires, C, C, C, of extremely low resistance. It is the provision of these equalizing wires which is expected to overcome the tendency to hunting, the inductive character of the circuit acting to oppose the interchange of wattless currents, and the low resistance of the conductors serving to equalize the electromotive forces of the machines. Patent No. 666,483.

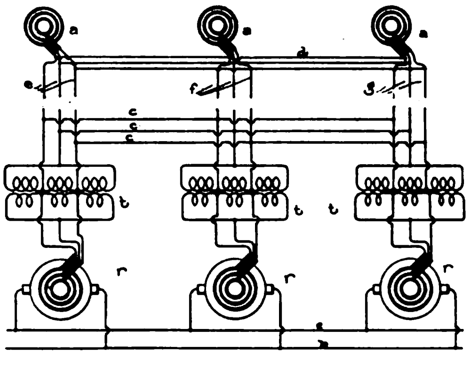

FIG. 2.—ROTARY CONVERTER CIRCUITS.

Alternating-Current Distribution.—It is frequently desirable in the operation of polyphase alternating-current systems, for the purpose of balancing, to transfer portions of the load from one phase to another of the system. A simple method of accomplishing this has been patented by E. M. Hewlett, of the General Electric Company, and is illustrated diagrammatically by Fig. 3. In the diagram, 4 represents a three-phase transformer supplying mains, 1, 2, and 3, of a three-phase circuit, from which are tapped off two-wire single-phase branches, 13, 14 and 15. Each of these single-phase branches is controlled by two single-pole double-throw switches, which enable the operator to connect any single-phase branch to any pair of the three-phase mains. In the diagram, branch 13 is connected between mains 1 and 2, and throwing the upper switch over to the left would connect it to mains 1 and 3, as branch 14 is connected; branch 15 is connected to mains 2 and 3. Patent No. 660,815.

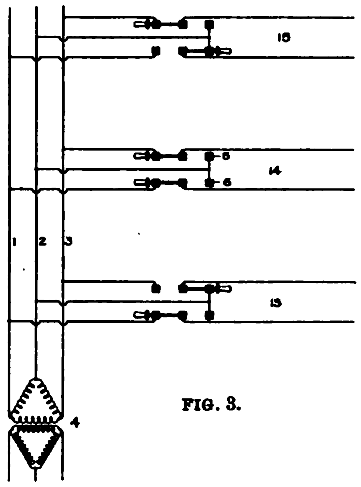

FIG. 3.

Arc-Lamp Carbon-Holder Contact.—The advent and widespread adoption of the enclosed-arc lamp seems to be responsible for the employment of the upper carbon fed from a stationary tube, sometimes without any upper carbon holder and sometimes mounted in the end of a thin tube sliding within the stationary tube. A disadvantage of this construction is the difficulty of making contact between the carbon and the stationary part of the lamp without retarding the feeding of the carbon or rendering it uncertain. With a view to overcoming this difficulty the device shown by Fig. 4 has been patented by George E. Stevens and assigned to the General Electric Company. The engraving is almost self-explanatory. The carbon, G, is mounted in the end of the carbon tube, H, containing a plug, A, on which are mounted four spring arms carrying rollers in their bifurcated ends. The spring arms tend to press the rollers outwardly through the slots, H′, in the movable tube into contact with the wall of the stationary tube, F. The object in extending the movable tube, H, up beyond the rollers and cutting slots in its wall, through which they protrude, is to restrain the outward movement of the spring arms when the carbon tube is removed from the guiding tube in order to facilitate the replacement of the carbon tube by the trimmer. A lug, F^1, is provided at the upper end of the stationary guiding tube, F, to limit the upward movement of the carbon tube, H, and prevent the rollers from passing the upper edge of the stationary tube and hanging up the carbon. Patent No. 659,711.

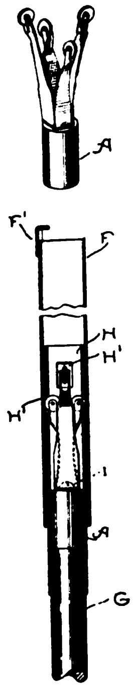

FIG. 4.

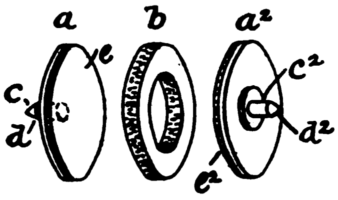

FIG. 5.

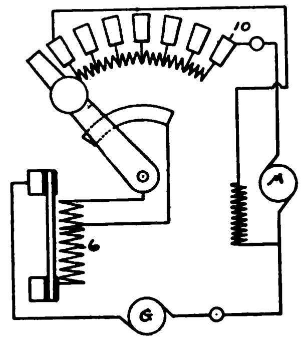

FIG. 6.

Telephone Transmitter.—A patent has been issued to George B. Perkins for a granular-carbon telephone transmitter in which the current-varying device is constructed as shown by Fig. 5, where *a* and *a2* are thin metal discs each having a pointed spindle, *c* and *c2*, projecting from the center at right angles to the disc. A thin disc of carbon, *e*, is attached to the opposite face of each plate and covers the whole surface. Between the two plates is mounted a ring, *b*, of felt or similar material, which forms a chamber for the granulated carbon. One face of the felt ring is cemented to one of the carbon discs, *e*, and the granulated carbon is poured into the chamber formed by the center of the ring. Then the other carbon disc, *e2*, is cemented to the face of the ring, *b*, completely enclosing the granulated carbon. When the button is thus assembled one of the pointed spindles enters a seat in a small metal button in the center of the transmitter diaphragm and the other spindle enters a similar seat in an adjusting screw by means of which the pressure is regulated. Patent No. 659,691.

Motor Starter and Circuit-Breaker.—One of the objections which has long been urged against the use of circuit-breakers instead of fuses as protective devices for electric motors is that the circuit-breaker must be set to withstand a current flow which is considerably beyond the maximum ability of the motor in order to prevent opening the circuit by the rush of current which occurs when the motor is started up. Time-element circuit-breakers have been proposed to meet this difficulty, and are used in other cases, but have not come into use in connection with motors of ordinary size because of their expensive construction. Fig. 6 represents diagrammatically an arrangement which has been patented by W. M. Scott for the purpose of obviating the difficulty. The circuit-breaker winding is indicated by 6, the motor being indicated by the letter M, and the generator or source of current by G. The circuit-breaker coil is shown divided into two sections, one of which is cut out by the rheostat lever until the contact brush has reached the final contact button, 10, at which time the motor is presumed to be running with normal current, and the whole circuit-breaker coil is thrown in. This arrangement evidently raises the limit at which the circuit-breaker will be thrown until the rheostat arm reaches the running position, when the point of operation for the circuit-breaker is lowered by reason of the added winding. The patent describes other methods of accomplishing the same end, such as shunting the circuit-breaker coil until the rheostat arm reaches the running position. Patent No. 661,196.

◆

NEW BOOKS.

High-Speed Steam Engines. By Wm. Norris and Ben H. Morgan. London: P. S. King & Son. Cloth, 150 pages, 5½ x8½ ins.; 115 illustrations. Price, $2.50.

The character of this book, with the exception of a short introductory section on the development of the high-speed engine, is entirely descriptive. The leading types of British engines are well described and the text is adequately illustrated. The section on American high-speed engines is sadly deficient. Ten pages are devoted to the Westinghouse engine, two-thirds of which might have been logically occupied by descriptions of some of the representative engines that are not even mentioned, notably the McIntosh & Seymour, Erie Ball, American Ball and Skinner. The descriptions of the American engines that are given are not at all comprehensive, with the exception of the Westinghouse and Ideal engines, which are very fully treated. As an exposition of English practice, however, the book is extremely creditable.

Engine Tests. By Geo. W. Barrus, S. B. New York: D. Van Nostrand Company. Cloth; 335 pages, 6 x 9 ins.; 146 indicator diagrams; 1 chart. Price, $4.

This book is a fitting companion to Mr. Barrus' "Boiler Tests," being of precisely the same character. The book contains records of results from more than a hundred tests of engines and a full explanation of the methods employed in making the tests. The list of engines tested includes every type commonly used, from the simple non-condensing single-valve kind, of 25 horse-power, to four-valve compound and triple-expansion engines of 1000 to 1500 horse-power. Besides the tests for steam consumption there are two extremely instructive chapters on Valve Setting and Steam-Pipe Diagrams, both profusely illustrated by indicator diagrams. The book is almost indispensable to steam engineers who are even casually interested in steam-engine performance.

Electrical Units for Boys. By Arthur A. Kent. Lebanon, N. H.: Kendrick & Davis. Paper; 32 pages, 3 x 3½ ins. Price, 10 cents.

This is an elementary little pamphlet written for the benefit of boys who are interested in electricity. The scope is restricted to an explanation of the fundamental electrical units and a short discussion of magnetism and small electric motors.

◆

NOTES.

Trolley Mail Cars.—In Grand Rapids, Mich., all mails are transported between the railroad stations and the post-office on trolley cars, and these electric mail cars also constitute traveling mailing stations, a letter box being attached to the guard of the front platform of each car. When anyone wishes to mail a letter he simply stops a passing car and drops the letter in the box. The system has been found of great advantage in cases of urgent letters directed to remote parts of the city and mailed too late for the last regular collection by carrier.

Electric Railway Development in Connecticut.—The electric street railway track mileage of Connecticut has increased from 100 miles in 1890 to 500 miles to-day. Then there were 15 horse railways in the State, and to-day there are 33 individual street railway corporations, and these have absorbed some 50 smaller roads. There is a continuous trolley line from Westchester County, N. Y., along the Sound shore to Branford, and branch systems have been built up the Naugatuck Valley northward for 20 miles, to New Haven, and up the Hartford line to New London. Cross-country lines connect these systems and gridiron practically all of the most important sections of the state. It is scarcely necessary to explain that electric traction is responsible for these developments.

Electric Railway Up Mont Blanc.—An electric railway to the summit of Mont

Blanc is projected. The plan which is favored contemplates starting a line from Les Houches on the Savoy side, 11 miles below the summit. It is proposed to provide twelve stations, each fully equipped with every convenience for travelers. The project includes a power house on the river Arve, which now furnishes power for the electric road up Mont Saleve, on the edge of Geneva.

Northwestern Electrical Association.—The ninth annual convention of the Northwestern Electrical Association will be held at Hotel Pfister, Milwaukee, Wis., beginning on the morning of January 16. Papers will be read on subjects of particular interest to central station engineers, and the hotels and railroad companies have made special rates, for delegates to the convention. Complete particulars regarding rates, etc., may be obtained from Mr. James Wolff, 320 Dearborn Street, Chicago.

Another Moving Stairway for the Manhattan Elevated Road.—The Manhattan Elevated Railway Company has installed a second escalator or moving stairway in its system, the new escalator being located at the 23d Street station of the Sixth Avenue road. There are 32 steps and the machine moves at 72 ft. a minute, at which rate its capacity is 4500 passengers an hour. It can be speeded up to 90 ft. a minute, giving it a capacity of 7500 passengers an hour. The apparatus was installed by the Otis Company.

The Riker Motor Vehicle Company Absorbed.—The Electrical Vehicle Company has bought up the entire capital stock of the Riker Motor Vehicle Company, which was its most formidable competitor, and has bought also from Mr. Riker personally all his foreign patent rights, the Riker Company having owned only the United States patents. The Riker plant at Elizabeth, N. J., will be continued. This deal puts the Electric Vehicle Company in a much stronger position than it previously occupied, Mr. Riker's patents being of a very important character and his experience most valuable.

A Point in Central Station Working.—The policy of the St. Joseph (Mo.) Railway Light, Heat and Power Company of selling exhaust steam for heating purposes recently developed an interesting point in central station operation. The company's station is located on the Missouri river, where condensing water is easily available, but the plant is run non-condensing and the exhaust steam is sold for heating purposes, although the income from this service is just about sufficient to pay for the additional coal required to run non-condensing instead of condensing. The question was naturally asked why it would not be better to save the additional coal handling and simplify the distributive system of the company by running condensing; whereupon it developed that by supplying exhaust steam for heating to large buildings, the company could also get the contract for lighting, whereas if the heating service was not supplied, the large buildings having to put in a boiler and pumping equipment for heating purposes would naturally add an electric lighting plant. During the summer months the engines will run condensing. This point is one well worth notice by central station managers similarly situated.

A Much-Traveled Cat.—According to a contemporary, an ambitious cat recently sprang into the fly-wheel of a large engine in a refrigerating company's power plant, and as the engineer could not shut down, the animal was compelled to stay in the fly-wheel for two hours and a half. When the engine was finally stopped, the cat was found alive, having traveled about 73 miles in a circle. It is not stated what sort of geometrical figures the cat described upon attempting to walk after being released from its peculiar imprisonment; it is safe to assume, however, that that cat's appetite for pi is permanently satisfied.

Underwriters' National Association.—At the the annual meeting of this Association held in New York on Dec. 11 and 12, some important decisions were reached regarding changes to be made in the National Code for 1901. A motion to change the limit of low-tension circuits from 300 to 550 volts was carried at the first session. During this session, also, a long discussion took place on the advisability of grounding one of the wires in low-tension circuits, in which numerous authorities were quoted; and prominent electrical engineers spoke in its favor. The resolution was finally adopted to allow the grounding of one wire in every low-potential circuit, but making it optional with the installing engineer.

The committee on slow-burning insulation reported on a new style of insulated wire, and recommended its optional use for a year with the present form. The new style reverses the positions of the slow-burning and weather-proof layers. One layer of the latter is placed next to the copper and two layers of the braid containing the approved slow-burning compound surrounds it. The resolution offered to make both of these wires comply with the requirements was passed. Much work was reported by the committee on the carrying capacity of aluminum wire, and the results of a long series of tests show that insulated aluminum wire has a safe carrying capacity 84 per cent that of similarly insulated copper wire of the same size, while bare aluminum wire has only 77 per cent the capacity of the corresponding size in bare copper. These figures will be incorporated in the new code.

Prof. Puffer, chairman of the sub-committee on "The Carrying Capacity of Aluminum Wire," submitted a table, given herewith, showing the relative safe currents for aluminum and copper wires of various sizes, both covered and bare. The figures for aluminum were calculated graphically from the results of a great number of tests made on different sizes of aluminum wire, the part of the table referring to copper being taken from that already published in the code. Considering the present impracticability of using aluminum wire for interior work, however, and the fact that the figures showed a percentage relation, it was decided to merely state this percentage. A note to the present table for copper wire will, therefore, be added, to the effect that covered aluminum wire has 84 per cent the carrying capacity of covered copper wire and bare aluminum 77 per cent of bare copper. It will be noticed from the column headed "Smoking Copper" that copper wire becomes hot enough to smoke when carrying about three times its safe current. Prof. Puffer also made a report on automatic rheostats in which he pointed out large room for improvement and advocated the adoption of severer tests by the manufacturers.

A great number of break-down and short-circuit tests have been made on fuses during the year and many exhibits were made of fuse blocks that had been rendered unsafe by the blowing of the fuses. The mica-covered cut-out was strongly condemned as a fire hazard. The difficulties in getting a fuse block which could not be improperly fused were discussed, and it was the general opinion of the speakers that some form of enclosed fuse was the nearest approach to the solution of this problem. For small currents, some form of plug cut-out, similar to the familiar lamp socket fuse plugs of the General Electric Company, were recommended. The spacing of break distances in switches and fuse blocks gave rise to some discussion. As they stand in the code at present the required distances for fuses is considerably less than for switches. After quite a little discussion, they were allowed to stand as now printed.

The New Year.

When a large number of widely separated persons independently render almost precisely identical opinions on any particular subject it is entirely legitimate to conclude that the opinions are well founded. Hence, one may feel justified by the remarkable coincidence of expressions published elsewhere in this number in expecting that the year just born will be a most progressive and prosperous one for the electrical and allied industries. It is little short of astonishing to note how very slight is the deviation from unanimity of opinion as to the prospects for the coming year, with less than half a dozen exceptions, the letters which are abstracted on pages 57 to 60 reflect a most sanguine feeling regarding the business outlook. We cordially congratulate all concerned upon the optimistic state of affairs and trust that everybody's "great expectations," unlike those of poor Pip, may be fully realized.

Impending Developments.

The extremely interesting and instructive discussions in this number of electrical and steam engineering in the two centuries which have just met leaves little to be said. There have seldom, if ever, been published any synopses of the development and status of the two great branches of applied physics so comprehensive as these, and no student should fail to read both articles carefully.

Predictions are always rash and seldom fulfilled; besides, the practical man, for whom this paper is published, is much too busily occupied with solving the everyday problems of the present to clutter his mind with hypothetical and more or less visionary deductions, but a brief consideration of impending progress may not be uninteresting or supererogatory. Of the several recent developments in applied science which are not yet matured, the Nernst lamp and Marconi telegraphic system appear the most promising, so far as the immediate future is concerned. It is impossible to hazard an opinion as to the ultimate future of the Nernst lamp; such an attempt would be reduced to the worthless level of a mere guess. It seems reasonable, however, in view of the steady progress that is being made in Germany, to expect that the Nernst lamp will soon become a most important factor in lighting practice. It is not visionary to suppose that the glower will eventually be made sufficiently substantial to put the operation of the lamp on a basis commercially practical in every sense of that term. The lamp being electrolytic in action, it is not well suited for direct-current service; consequently, it will constitute a powerful ally for alternating-current enthusiasts, and it is not unlikely that its perfection will mean the abandonment of arc lighting for ordinary purposes. Wherever direct-current service is considered preferable, however, the arc will doubtless remain supreme.

The Marconi system of telegraphy, or some progeny of it, may ultimately render worthless the existing land and submarine lines, but nothing thus far developed indicates that this stage of perfection is imminent. That the system has an important field is perfectly obvious; but while the limitations of its scope cannot be described now with the slightest degree of certainty, it seems evident and rational that there are and always will be such limitations and that the abolition of metallic conductors is a very hazy contingency. And the application of the Hertzian principle to telephony is still more indefinite; the delicacy of telephonic apparatus is such that its reliable operation by non-directive ether waves or stresses or whatever one may term them would not seem to be ordinarily practicable.

In "heavier" electrical engineering the alternating-current motor represents the most recent advance and about the only mechanism having extensive possibilities of development. What is needed in order to round out the alternating-current system is a motor that will start efficiently under load from standstill, run efficiently at various speeds and be devoid of a fractional power factor. The production of such a machine will be a tremendous achievement, but greater things have been done before.

American and English Central Stations.

At the present rate of approach toward common ground it will be only a comparatively short time before a comparison of American and English central station practice will fail to reveal any divergence beyond unimportant details. Many of the rigid lines of demarcation which formerly separated the ideas of the engineers of the two countries have been considerably softened and not a few of them have been entirely obliterated. It requires but a small effort of memory to recall the day when the Edison type of direct-current dynamo, so magnificently developed by the Hopkinsons, was the almost exclusive central station standard in England. To-day, a considerable number of bipolar machines are in use, but the allegiance of British engineers is being steadily transferred to the multipolar type which has for several years ruled here; a type, it is only fair to state, that is not American in origin, although it is so in point of highest development. Alternating-currents are slowly but surely gaining ground also in England, as are enclosed-arc lamps. On the other hand, comparatively high potential three-wire distribution (220—250 volts on each side) which has been in use across the Atlantic—well, it may be more considerate to omit dates—has begun to make a discernible impression in this country. The gradual convergence of the two lines of practice is noticeable also in many incidental features which it is unnecessary to enumerate.

In steam work there are not such well-defined indications of destined conformity. The English central station almost universally employs vertical high-speed engines, usually provided with throttling governors, whereas horizontal engines of moderate speed are used in a large majority of American plants and regulation by varying the point of cut-off is the invariable practice. Mr. Ferranti, whose progressive ideas and sound practice make him a colossal figure among designers of both steam and electrical machinery, has made use of variable expansion for engine regulation, but his engines are notable exceptions to British practice. The differences between English and American engines seem rather unaccountable in view of the similarities between the practice in Continental Europe and that in the United States.

Inductance and Reactance.

These two terms, judging from the letters which are received at this office (and cheerfully answered), seem to be greatly confused in the minds of many students; and when one considers the changes that have been made in electrical terminology during the past few years this is not very surprising. However, if the beginner will commit to memory the fundamental fact that inductance is a cause and reactance an effect, it will be easier to distinguish between the two terms. A coil or a loop of wire is possessed of the property of inductance, whether current be passing through it or not. The extent of this property depends upon the number of turns of wire in the coil, and the magnetic conductivity of the medium which is encircled by the coil. A coil of 50 turns, for example, wound about a soft-iron core, has very much greater inductance than a coil of the same number of turns without any iron core; and a coil of 10 turns on a core has much less inductance than one of 50 turns on the same kind of core.

Reactance, on the other hand, is the direct result of inductance, without which it could not exist. The reactance of any electrical circuit is the product of its inductance, the number of times the current flow is reversed per second, and a constant. The measure of inductance is the henry, and its symbol is usually the letter "L." The measure of reactance is the ohm, like that of resistance, and it is usually represented by the letter "X," but a coil has no reactance until a current passes through it and the rate of flow is varied. Representing the number of complete reversals per second of an alternating current by the letter "N," the formula for reactance is: $6.28 \times N \times L = X$, and this shows more plainly than any lengthy explanation could do the direct relation between inductance, L, and reactance, X.

Another term which contributes to the confusion of a beginner is reactive e.m.f. The value of this is obtained by multiplying the reactance, which is expressed in ohms, by the current flowing in the circuit, just as one obtains the drop in a direct-current circuit by multiplying the resistance by the current. The reactive e.m.f. is induced by the magnetic lines of force which are created in the coil by the passage of current through it; these lines are "cut" by the wires of the coil exactly as the line of force passing from the field magnet of a dynamo to its armature are "cut" by the conductors on the armature core. This phenomenon was formerly termed self-induction, but the term has been practically abandoned, notwithstanding its excellent explanatory character.

Electric Railway Car Control.

A recent court decision awarding $4000 damages to a woman for injuries caused by a fall due to a sudden spurt by the car on which the complainant was a passenger naturally tends to impress upon thinking persons the fact that there is room for improvement in the present method of controlling such cars. It is scarcely necessary to point out that the corybantic evolutions which a motorman devoid of delicate sensibilities may (and usually does) compel standing passengers to perform are not irremediable accompaniments of the present system of railway car control. It is, of course, entirely a matter of volition on the part of the motorman whether he shall accelerate his car gradually and allow "strap-hangers" a fighting chance to reach home intact, or whether his manipulation of the controller and brake handles be such as to impart to the car the traveling characteristics of a kangaroo and to enforce acrobatic transpositions upon unfortunates who have to stand. If the patrons of a railway line were all centipedes, or had even an extra pair of legs each so that they might stand in quadrature, so to speak, jamming the controller handle from zero to the fifth notch with a single graceful sweep might be innocuous pastime; under existing anthropological conditions, however, only an unusually agile monkey or jack-rabbit is entirely safe in a car driven by a careless motorman.

As noted above, the present system of car control does not necessarily entail the abrupt jerks and disconcerting stops which one constantly sees practised. It renders them possible, however, and a great improvement would be wrought if the traction companies could be made to realize the importance and practicability of removing the rate of acceleration and retardation from the motorman's control. There are several ways of accomplishing this which it would be superfluous to suggest to well-posted engineers. The rate of acceleration is automatically controlled now in some electric train systems, and there is at least one form of power brake available which takes care of the rate of retardation to a sufficient extent to prevent the dangerous "stone-wall" stops that appear to be one of the special joys of a certain class of motormen. The only excuse that is apparent for the retention of the clumsy hand-brake and the use of unchecked controller mechanism is the extra expense involved in providing semi-automatic in place of purely manual apparatus. Until such time as the railway companies avail themselves fully of the engineering facilities and resources at hand it might be advisable for passengers to provide their clothes with rubber linings which can be blown up to form enveloping air cushions just prior to entering a car.

DESIGN FOR A 75-LIGHT DYNAMO.

BY CECIL P. POOLE.

The accompanying sketches illustrate the salient features of a dynamo designed to maintain 75 16-c.p. incandescent lamps at 110-120 volts. The field magnet is of the familiar radial-pole type with circular yoke, and is provided with a partial "shrouding" on each side somewhat similar to the practice observed by the Crocker-Wheeler Company. The principal object of this shrouding is to give the machine a rather more finished appearance than it would have without it, and if any reader who may undertake to build the dynamo prefers to leave off this web it may be done without affecting the operation of the machine.

Fig. 1 is an end view of the field-magnet frame minus the coils and journal boxes. Fig. 2 is a plan view of the frame, which shows the arrangement of the projecting feet that support the journal pedestals, and Fig. 3 is a sectional view on a line through the center of the field-magnet structure. In order that the design may be available to a larger number of readers, cast iron has been adopted as the material for the field magnet instead of cast steel, which, of course, is the usual modern practice. The only machine work necessary on the field magnet is boring out the pole faces and tooling the seats for the journal pedestals, all of which must be done at one mounting of the magnet frame in order to insure accurate alignment between the armature chamber and the journals. Fig. 4 is a section of one magnet pole and the corresponding part of the yoke, taken on the line C-D of Fig. 1, and Fig. 5 is a cross-section of a magnet core taken on the line A-B in Fig. 3.

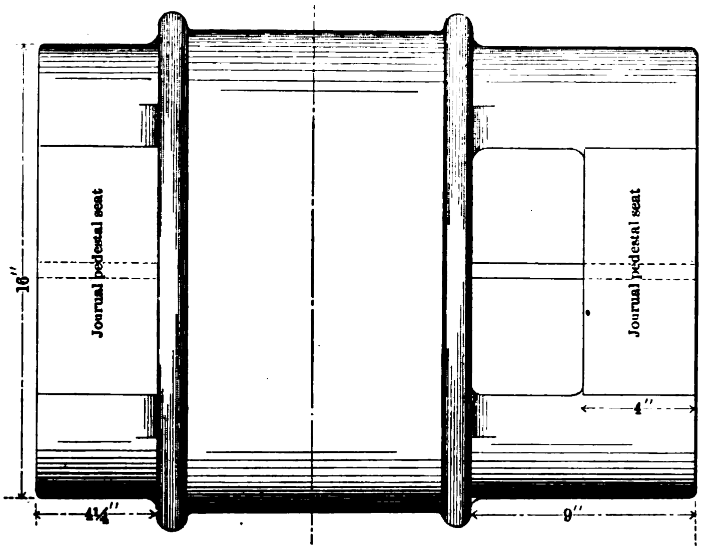

FIG. 2.—PLAN VIEW OF MAGNET FRAME.

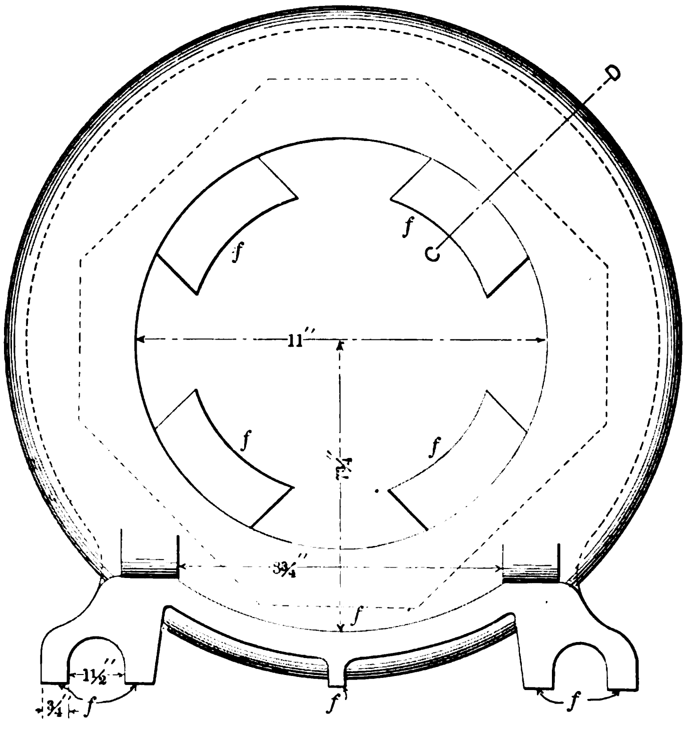

FIG. 1.—END VIEW OF FIELD MAGNET.

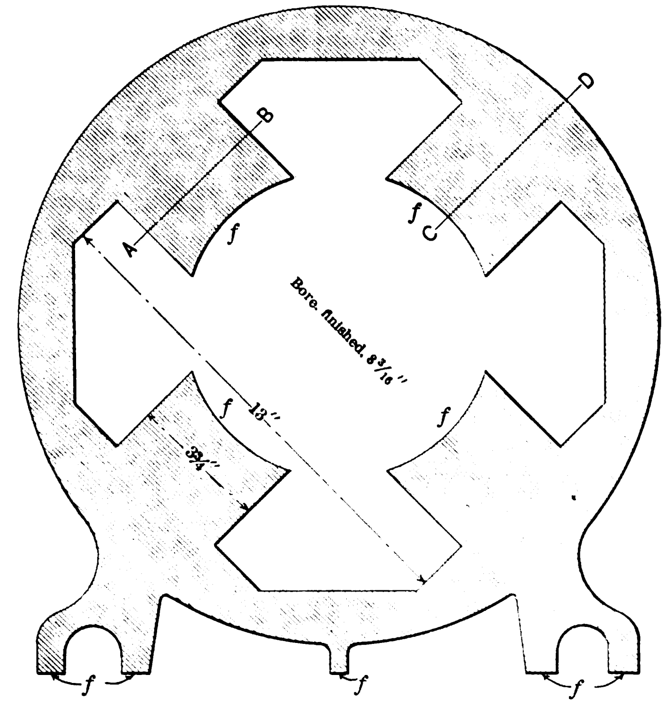

FIG. 3.—TRANVERSE SECTION OF FIELD MAGNET.

The dimensions of the magnet, which are not shown in the drawings, are as follows:

	Ins.
Extreme diameter of shell	17
Extreme diameter over the ribs	18¼
Distance between ribs	9
Thickness of each rib parallel with shaft	1
Total plan length of field-magnet frame from outside to outside of journal pedestal seats	24½

Figs. 6 and 7 are sectional views of a journal box and pedestal, the former being an axial section and the latter a transverse section. The section of Fig. 6 is taken on the line J-K of Fig. 7, and the section of Fig. 7 is taken on the line H-I of Fig. 6. As the sketches plainly show, the bearing is of the oil-ring variety, with a circular reservoir, and the sleeve is perfectly straight, this type being much easier for an amateur to construct than a self-aligning bearing. If ordinary care is taken in cutting the seats of these pedestals and in turning off their bases, the bearings cannot fail to come in alignment without any special provision in the way of a swiveling bushing. The pedestals and journal boxes are of cast iron, of course, and the bushing may be made either of solid brass or of a thin seamless brass tube babbitted. On the inner end of one journal box a seat ½ in. long should be turned for the brush-holder yoke. Only two sets of brushes are required, and these must bear upon the commutator exactly one-fourth of a circle apart. The brush yoke, therefore, may be of the V type in preference to the ordinary straight arm which is used on bipolar machines. Returning to the bearings, the oil rings will be 2½ ins. in diameter, inside, 5/16 in. wide parallel with the shaft, and ⅛ in. thick, measured radially.

Fig. 8 shows the shaft and a sectional view of the armature core and supporting drum. This drum is a simple cylinder, *d*, 8 ins. in diameter outside when finished, and provided with a flange, *g*, at one end, which carries at its outer edge a drum or barrel, *b*. The function of this barrel is to support the projecting ends of the armature coils. The discs are mounted on the drum, *d*, and clamped in place by means of a ring, *r*, which carries a barrel, *b*, exactly like the one on the flange of the core drum. These flanges project 2¼ ins. from the core discs. The ring, *r*, may be secured to the drum, *d*, by means of six 3/16-in. machine screws. The dimensions of the different parts of the shaft are marked on the sketch, as well as the principal dimensions of the armature core and spider; those which are not indicated are as follows:

	Ins.
Diameter of extension barrels.........	5¾
Diameter of core hubs, h..............	2
Extreme length of core drum from end to end of the hubs................	9¼
Diameter of core drums, d............	3
Radial thickness of drum wall........	⅜
Thickness of flange, g, and ring, r, parallel with shaft..................	½
Diameter of armature discs...........	8
Number of slots........................	40
Size of each slot.........................	¼ x 1.3

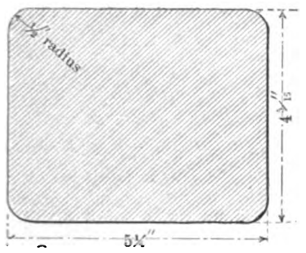

FIG. 4.—CROSS SECTION OF MAGNET POLE.

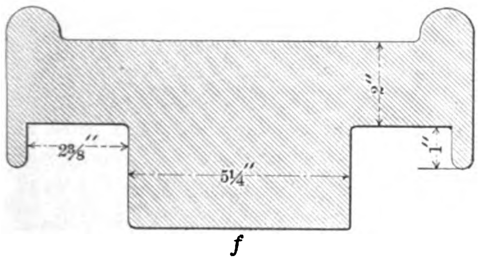

FIG. 5.—RADIAL SECTION THROUGH MAGNET POLE AND YOKE RING.

The commutator should be purchased from some of the standard manufacturers. Its extreme length along the shaft must not be over 4¼ ins. It must have 41 segments, and should be not less than 5 ins. in diameter. The width of the brush tread parallel with the shaft must be not less than 3 ins., and the diameter from tip to tip of diametrically-opposite connecting lugs must be 7½ ins.

The machine is designed for the use of carbon brushes, each set comprising two brushes ⅝ x 1¼ ins. The builder can exercise his own judgment as to the type of brush-holder to be used, but should remember that it is indispensable to have a reliable contact of low resistance between the brush and the holder. As noted above, there are only two sets of brushes, these being set "on the quarter," or 90° apart.

The field winding of the machine consists of four coils of No. 18 double cotton-covered magnet wire wound 14 layers deep and 46 turns long parallel with the axis of the core, giving 644 turns per coil. If the builder is able to put more turns than this without exceeding a depth of 11/16 in., so much the better, but the coil should not be deeper than this. The coils are connected up in the usual manner, so that the polarity of the magnet cores alternates, and a rheostat must be provided to regulate the field current. As in the case of the commutator, it is wholly inadvisable for an amateur to attempt the construction of his rheostat; consequently, no directions are given for this.

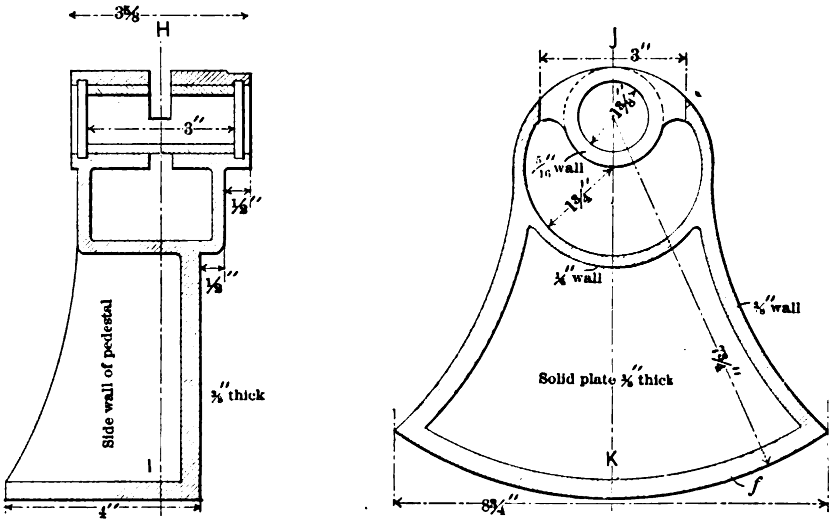

FIG. 6.—SECTIONAL VIEWS OF JOURNAL BOX AND PEDESTAL.—FIG. 7.

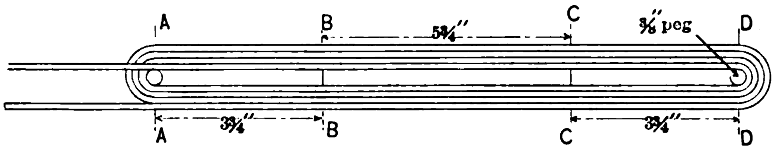

FIG. 9.—ARMATURE COIL BEFORE SHAPING.

Each field coil must be taped with two layers of German-linen tape wound through the coil shuttle-fashion, so that the tape crosses the wires at right angles. As in the case of the armature coils, each layer of taping must be wound with a half lap, varnished and thoroughly dried, i. e., the first layer must be thoroughly dried before the second layer of tape is put on, and then the second layer must be varnished and dried similarly.

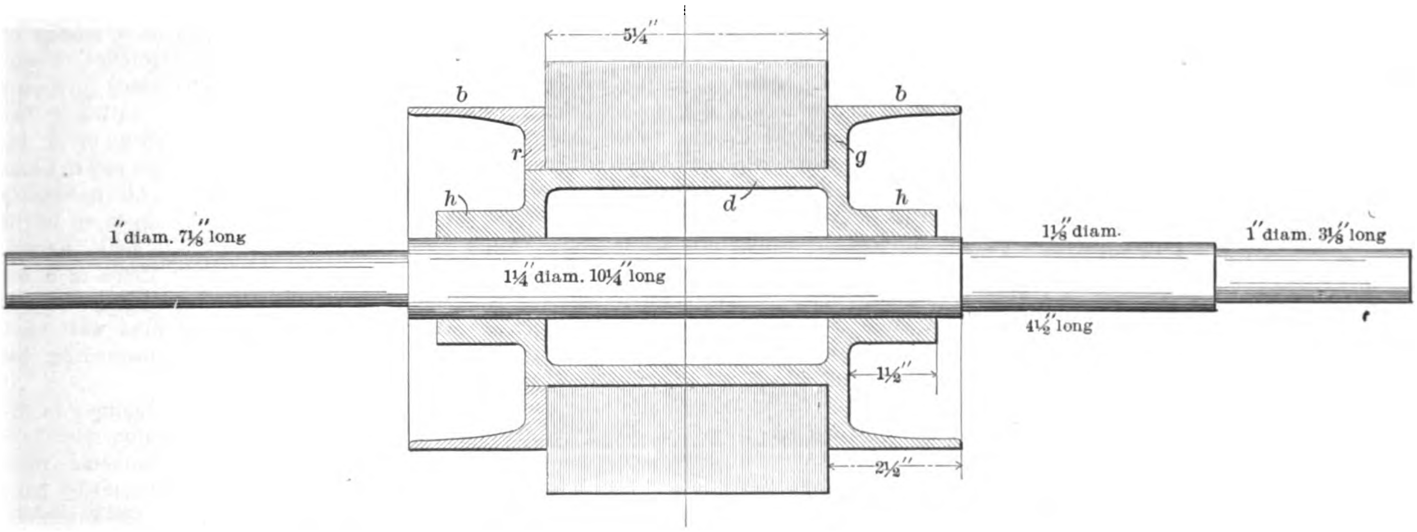

FIG. 8.—ARMATURE SHAFT AND AXIAL SECTION THROUGH ARMATURE CORE.

The armature winding consists of 41 coils of No. 8 double cotton-covered magnet wire, each coil containing 4 turns. The coils must be wound around two ⅜-in.

pegs, as indicated in Fig. 9, the four turns being wound one on top of the other, so that when the coil is finished it will present about the appearance shown in the sketch. The convolutions of the coils should be secured with fine linen thread at each of the bends; also at the two points indicated by the lines, B, C. Then the ends of the coil should be clamped from the points, A and B, outward, and the two sides pulled in opposite directions until the plan of the coil assumes the shape shown in Fig. 10. Then it should be carefully wrapped with two layers of German linen tape, each layer being wound with a half lap so that there will be two thicknesses of tape in each layer of four thicknesses altogether. Varnish each layer and bake the coil until it is thoroughly dry.

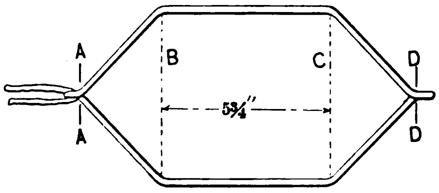

FIG. 10.—ARMATURE COIL, SHAPED.

The coils must be assembled on the armature core so that between the two sides of each coil there will be 10 teeth. It is absolutely imperative that all of the coils be wound exactly alike so that the starting ends of all of them will occupy exactly the same position at the bend of the coils. When the coils are all in place on the core they should be secured temporarily by two retaining bands of twine wrapped around the core at each end. Then the terminals should be carried to the commutator, all of the lower terminals being put in place first.

It will be found advantageous to lead the lower terminals to the left about 10 commutator bars instead of carrying them straight out to the nearest bar. Having put the lower ends in place in rotation, start at any convenient place with the upper ends, carrying the first one around to the right and inserting it in the commutator segment which is 20 spaces from the segment containing the under end of the same coil. In other words, between the two segments to which the terminals of any coil are connected there must be 19 other segments. This is illustrated by Fig. 11, which shows the terminals of one coil connected to the commutator. After the ends have been soldered in, a binding of No. 18 tinned-iron wire should be put around the center of the core, and another binding of either strong cord or thin brass wire should be put around the projecting ends of the coils near the ends of the supporting barrels. All of the binding wires must be wound on fiber strips not less than 1/64 in. thick.

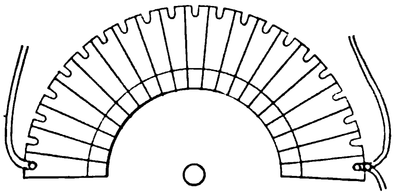

FIG. 11 —TERMINALS OF ONE COIL IN PLACE.

The principal data applying to the machine are as follows:

Armature speed	1500 r.p.m.
Normal armature current	43½ amperes
Drop in armature winding	4 volts
Normal exciting current in field winding	3¼ amperes
Magnetic density in field magnet cores	47,000
Magnetic density in air gap	36,000
Magnetic density in armature teeth	109,000
Magnetic density in armature core	70,000

POINTS ON INSULATION TESTING.

BY FRED P. WOODBURY.

There are two methods of testing the insulation of electrical machines commonly in vogue. The first is simply a measurement of its resistance and, like all such measurements, may be accomplished either with the bridge or by the voltmeter method. Such a measurement of resistance is of value in determining the general condition of insulation, but it may not show a weak spot of small area. It is an excellent method for determining if there is dampness in insulation that is otherwise good.

The second method of testing is to subject the insulation to a high potential. This is a sure test, but must be carefully and properly done, or serious injury to the insulation may result. It should always be borne in mind in testing insulation of apparatus that the object in view is not to determine the extreme limit of pressure it will withstand, but to ascertain if it is strong enough to withstand continuously the maximum voltage to which it is likely to be subjected, and be as nearly puncture proof as possible against any static charge that may seek a ground through its medium.

Voltage subjects insulation to a mechanical strain just as truly as does steam within a boiler tend to force it open. The folly of testing a boiler until the plates begin to shear will be apparent to anyone. For the same reason it is unwise to subject insulation to a pressure beyond its limit of elasticity. A case illustrating this point which came under the writer's observation was that of a purchaser of some 10,000-volt transformers who stipulated that the manufacturer should test the insulation with 45,000 volts (between the primary winding and the iron) for fifteen minutes continuously, while hot. The transformer stood the test, though the leakage increased greatly as it progressed, thus permanently weakening the insulation. A far more rigid and less injurious test would have been to apply 55,000 volts for two or three seconds.

It is evident from the foregoing that while the test should be severe enough to give an ample margin of safety above the working voltage, it should not approach very near to the probable break-down point of the insulation. In testing with alternating current the potential should be applied gradually. It is well to place the high-potential leads of the testing transformer in position first; then close the circuit in the low-tension primary with resistance in series, which should be cut out until the desired voltage is obtained between the high-tension leads. The resistance should be cut in again before the circuit is opened. It is desirable to have the primary circuit lightly fused. The highest voltage should not remain on for more than three or four seconds. In using direct current for testing, enough resistance should be put in series to prevent an abnormal flow of current in case the insulation should break down.

The tests should always be made when the insulation is hot, as it is then more likely to show any weakness.

The necessary strength of insulation varies more with the class of work the machine must perform than with the working voltage. Thus, for example, a 500-volt street-railway motor should stand a test of at least 3,500 volts (alternating current) between the frame and winding, while if a railway generator will stand 2,000 volts it is sufficiently well insulated. Stationary motors or generators of 200 volts or less should stand 1,000 volts, and 600-volt machines should have a test of 1800 or 2000 volts.

Alternating-current generators of 1000 volts should be tested with 5000 volts, and machines of 2000 volts output should stand 8000 volts. Transformers of 1000 volts primary voltage should be tested with 6000 volts between coils, and also between primary and iron; 4000 volts is an ample test between the low-tension secondary and the iron.

The insulation tests of large high-tension power-transmission transformers vary greatly, sometimes reaching 120,000 volts. Care should always be exercised to see that the insulation to be tested is normally dry; a good machine may be needlessly injured just for the want of a little "drying out."

A SIMPLE RAILWAY SIGNAL SYSTEM.

BY E. C. PARHAM.

Signal systems are, as a rule, used on single-track trolley roads as a means of blocking cars out of the stretches of single track in between switches or turn-outs as they are more commonly called. The signal is generally in the form of an incandescent lamp, which shows red to block a car; and white, or not at all, to signify that the track is clear. If the lamp in the signal box at the approach to a single track shows red, it means that there is a car somewhere on that stretch of track and that all approaching cars must wait until the line is clear before proceeding beyond the signal.

Some signal systems are manual in operation and others are automatic. On manual systems, every conductor must leave his car and throw the signal by hand if it is to be thrown at all. On automatic systems, the signals are operated by some interference on the car itself or on the track, or by insulated sections in the trolley wire or rail. Nearly all such systems involve the use of electromagnets to operate switches or throw targets. Lightning seems to take a fiendish delight in playing destructively with these magnets, so that automatic signal systems employing electromagnets are not very generally adopted.

There are several conditions that every signal system should fulfill; it must be simple, cheap, reliable, of substantial construction, and well protected from thieves and the weather. Up to the present time the best systems are compromises between these several conditions. The one that most successfully meets all conditions is the "telephone dispatch" system, in which there is a telephone in a locked box at every turnout. These telephones connect with a central office presided over by a regular train dispatcher, who pegs the cars and sends out his orders the same as on a steam road. Every conductor upon arriving at a switch, rings up central, reports his train number and gets his orders. The telephone dispatch system is not cheap enough for some roads and is not necessary on others where the train speeds are low.

There is no system so much used nor is there any that gives more general satisfaction than a simple arrangement of incandescent lamps that can be installed by any line-man. Fig. 1 is a diagram of the connections for an 8-lamp signal system, and Fig. 2 shows the actual arrangement of the lamps. In Fig. 1, K1 and K2 are two simple three-way tongue switches, such as can be quickly and cheaply made in any machine shop. One of these switches is placed at each end of the stretch of single track to be protected and the two switch tongues are connected by means of a wire (this can be a No. 10 or No. 12 iron wire) strung on the line poles, and including two red lamps, Ra, Ra. Each switch has a trolley contact, 2, and a ground contact, 3, each wire leading up to the trolley wire has two lamps in series with it, marked Wa and Wb, and each ground wire one lamp, marked Rb, Rc. Each switch then is connected to two red lamps and two white ones.

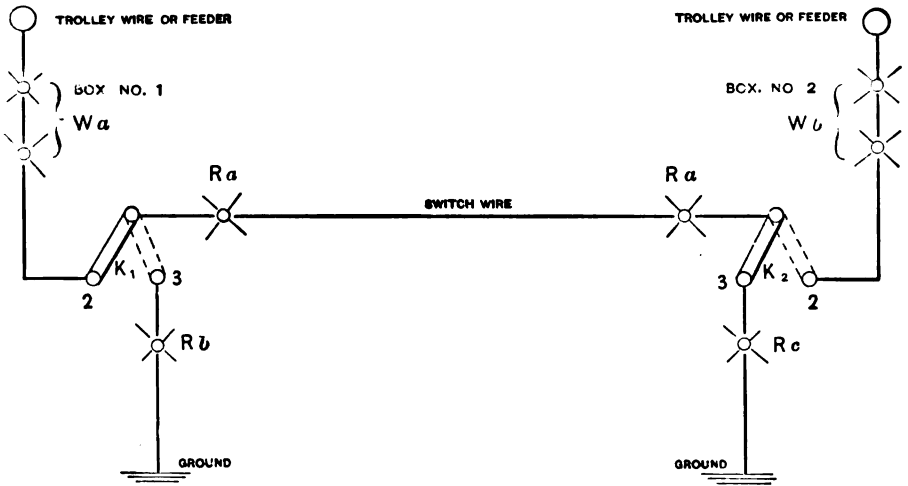

FIG. 1.—DIAGRAM OF CIRCUIT FOR ONE BLOCK.

When the two switch tongues are in the full line position, the two white lamps Wa, and the red lamp, Ra, light in the No 1 signal box, at, say, the west end of the single track; and only the two red lamps, Ra and Rc, in the No. 2 box at the east end. If the two switch tongues are in the dotted position, the lamps get current from the No. 2 trolley connection and the two white lamps, Wb, and the red lamp, Ra, light in the No. 2 box, while the two red ones in the No. 1 box light. If both of the switch tongues are thrown onto the No 2 buttons, both ground lamps are cut out and all of the other lamps being connected only to the trolley, are also left dark. Also, if both tongues are thrown to the No. 3 blocks on their respective switches, none of the lamps can light.

Fig. 2 shows a form of signal box. It has two parts, an open part for the white lamps and a closed part for the red ones. The white lamps are on top and outside, but are protected by a hood and cages (the latter not shown); the lamp-sockets are of the protected weather-proof type. In the door and two sides of the box are set panes of glass; if the glass is red, the lamp globes are all ordinary white ones. The signal box is kept locked and every inspector has a key. Inside of each box two extra lamp globes are kept. The trolley and ground blocks of the three-way switches should be at least 7 ins. apart to avoid short-circuits; the lamp in the ground wire lessens the chances of such a mishap. The closed part of the box need have no lining save a coat of thick shellac, such as comes out of the bottom of a shellac pot. The switch handle protrudes through a slot in the bottom of the box; this handle must always be at the extreme right or left when the system is in service; never in an intermediate position.

The only likely source of trouble in such a box is due to open circuits caused by loose connections, broken wires or broken lamp filaments. To minimize the chances of any such troubles, all connecting wires should be of flexible cord and all connections soldered. With these precautions the system can be made almost absolutely reliable, if instead of one lamp two lamps in multiple be used in each case and the ground, trolley and signal wires all be run two in parallel, or made of flexible wire. Such a signal box gives much better satisfaction if, instead of being hung on one of the regular line poles where it is subjected to all of the jarring and vibrations that the line suffers, it is clamped to a short post of its own. The connections should be inspected after each storm. The inside of the box should be kept clean and the handle should not be allowed to get loose so that it may be released by jarring

The system is operated as follows: Say that a conductor approaching the No. 1 signal box finds all lights are out; this means that the tongues of both switches are on the same blocks of their respective boxes. It further means that if the lights are in good working order and are, therefore, not out on account of a fault, some car passing out of the block has extinguished them and the line is therefore clear. The conductor, before allowing his car to proceed, throws the switch to the opposite position from that in which he finds it. If it rests on the No. 2 or left-hand side of the box the tongue at the far end of the block also rests on the No 2 side of the signal box there, or the lights would burn. By throwing the tongue to the No. 3 side of the No. 1 box, that box will show two red lights, Ra and Rb, and the No. 2 box will show one red light, Ra and two white ones, Wb.

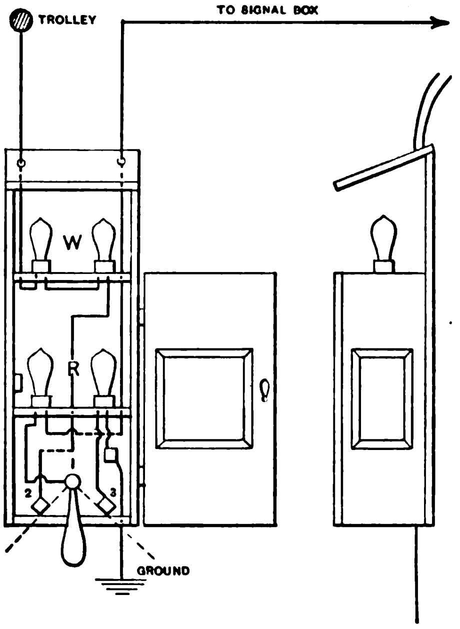

FIG. 2.—A SIGNAL BOX.

No matter what may be the positions of the two switch tongues, if the lights are out, throwing either of them to the opposite side will light a red lamp in both boxes and block the road in between those two boxes and no second car is supposed to enter the block until the signal lights are out. On passing out of the block the conductor opens the block behind him by throwing the No. 2 switch tongue to the opposite side, thereby putting out the lights on the block he has just run through. The next stretch of single track constitutes a second block; it is protected by two more signal boxes which must be operated in the same way.

It is very amusing sometimes when two cars approach an open block from opposite ends at the same time, to see a conductor rush over to the box and get the red light against him just as he is going to give it to the other fellow.

INTERIOR TELEPHONE SYSTEMS.

BY W. S. HENRY.

SMALL SWITCHBOARD SYSTEMS.

When the number of telephone stations exceeds about twenty, depending more or less upon the frequency with which the telephones are used, it is not a very good plan to use an intercommunicating system. It is better to connect each telephone directly with a centrally-located switchboard, at which an operator is usually required to make the necessary connections between the various stations or "subscribers," as it will be convenient to call them. Automatic switchboards requiring no operator may be had, but up to the present time they do not seem to have made much headway, probably owing to their complicated mechanism and greater liability to get out of order than the manually-operated switchboards.

For a small system not exceeding fifty or seventy-five stations, and especially when there is no experienced electrician to look after it, the switchboard should be made as simple and durable as possible. For this reason it does not seem advisable to use complicated combination listening-and-ringing keys, nor self-restoring drops. The boy or girl who generally attends to such a board, sometimes, in addition to other duties around the office or factory, usually has plenty of time to make the necessary connections.

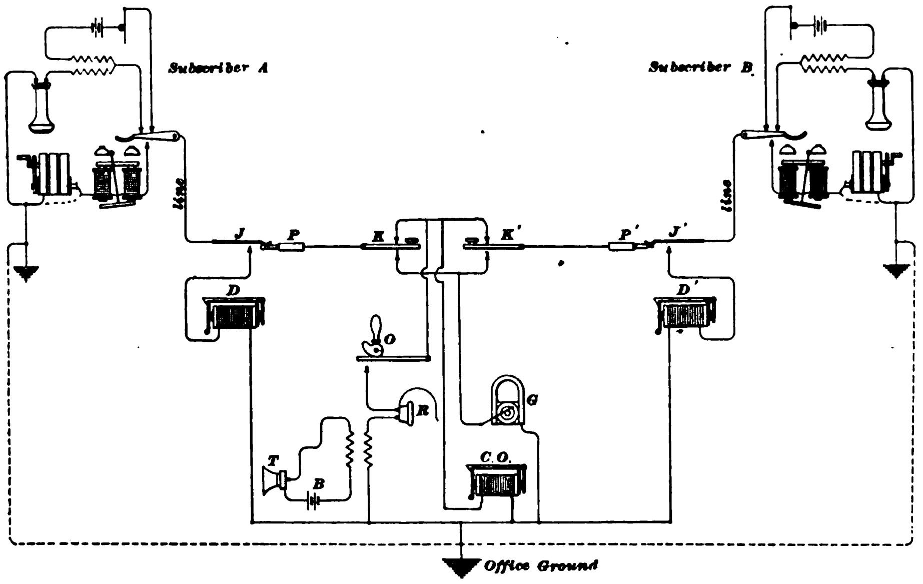

FIG. 1.—DIAGRAM OF SIMPLE SWITCHBOARD SYSTEM.

While common-battery or central-energy systems would seem to be the ideal plan for an office or factory where the distances are short, still, unless very well designed and cared for, such a system does not always give as good service as it should. Separate batteries at each station, merely for operating the transmitters, have some advantages. Such an arrangement, with automatic signalling, whereby the central office can be called up by simply removing a subscriber's receiver from the hook-switch, seems in the present state of affairs—considering the fact that the Bell Company probably owns the most desirable patents on common-battery systems—to be about the best, and since it has proved satisfactory for large town exchanges, it should certainly be satisfactory for factories and office buildings.

Although the writer hesitates to recommend dry cells for use at the subscribers' stations, nevertheless they are now being used successfully by a few companies. They have the advantages of being very cheap and requiring no care, which is not true of wet batteries. On an average they will last about nine months in telephone service, and after that they are still good for a year or more in ordinary bell circuits where they are only in use for a few seconds at a time. A dry cell should never be used in a telephone circuit after it falls below three-fifths of a volt, for it will no longer hold out for long conversations. It is a waste of time and money to attempt to recharge dry cells; they can be bought for twenty cents or less apiece; in very large lots they have been bought as low as fourteen cents. Disregarding first cost, a good wet cell is much preferable to any dry cell.

All new switchboards, no matter how small, should be wired for complete metallic circuits; that is, two separate wires throughout for each telephone line. The switchboard should not be wired on a common-return plan, even if it is desirable to use the ground or one common wire as a return path from all the telephone stations. However, on account of its simplicity, a common or ground-return system will be described first, for it will enable the reader to more readily understand the succeeding descriptions of other systems.

The circuits of one of the simplest possible systems are shown in Fig. 1. In case a common-wire return is employed instead of a ground return, the connections are made as shown by the dotted lines, the ground connections at the telephone stations and at the switchboard being omitted. Two telephone stations, their connection with the spring jacks, J and J^1, as these switch devices are called; the annunciators or drops, D and D^1, and one operator's cord circuit are shown. The cord circuit consists of two plugs, P and P^1; two ringing keys, K and K^1; one listening key or cam, O; a clearing-out or call-off annunciator or drop, CO; a generator, G; a watch-case receiver, R, with head strap; a microphone transmitter, T; a microphone battery, B; an induction coil, and the necessary connecting wires. The same transmitter, T, battery, B, receiver, R, and generator, G, are used in connection with each one of the ten pairs of cord circuits that are usually provided for about each one hundred jacks on the board. It is evident that one operator who has charge of ten pairs of plug circuits would use the apparatus named on only one cord circuit at one time, and hence there is no necessity to duplicate them. One terminal of the receiver and one terminal of the generator have each ten branches, one leading to the under contact of each listening and ringing key respectively.

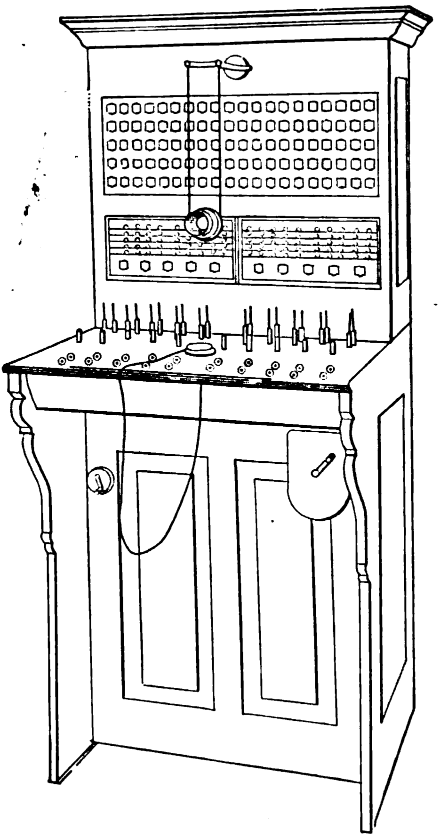

FIG. 2.—SMALL SWITCHBOARD.

The jacks, J and J^1, are usually located on the face of the board, the annunciators, D and D^1, above them, and the clearing-out drops below the jacks, each clearing-out drop being directly behind and in line with the pair of plugs with which it is associated. The plugs, when not in use, rest upright upon a projecting shelf or table in two rows, each front plug and the one directly behind it constituting a pair. As already stated, there are usually on small boards about ten pair of plugs for each hundred jacks. A switchboard with the apparatus arranged about in this manner is shown in Fig. 2. On the same shelf and in front of the plugs are the listening and ringing keys. The operator's transmitter hangs down in front of the board and the watch-case receiver is shown lying upon the shelf. Below the shelf on the right side is the hand generator. On a larger switchboard the generator should be run continuously by a motor.

On small boards it is not a bad plan to place each jack directly under the annunciator belonging to the same line, and in this case the annunciator is frequently designed and constructed so that the act of inserting the plug mechanically restores the shutter to its normal position. Such a switchboard is shown in Fig. 3. Instead of two separate ringing-key buttons, a cam is here used. Its normal position is vertical; when it is drawn forward the ringing generator is connected with the front plug; when it is pushed back beyond the vertical position, the ringing generator is connected to the rear plug or it may be arranged to ring out on only one plug, as will be explained later.

The system shown in Fig. 1 is operated in the following manner: Normally the plugs are not in the spring jacks as shown here. If subscriber A desires to converse with subscriber B, he turns the handle of his generator, thereby causing the shutter of the annunciator, D, at the central office to fall, thus notifying the switchboard operator that A wants to talk to some other subscriber. The operator inserts the plug, P, frequently called the answering plug, into the spring jack, J, that has the same number near it as that exposed behind the fallen shutter of the annunciator, D, and therefore belonging to the same line as the annunciator, D. The act of inserting the plug in the spring jack cuts the annunciator, D, out of the circuit. The operator then restores the fallen shutter by hand and pulls forward the handle of the listening cam, O. The operator and subscriber A can now communicate with each other over the following circuit: From receiver, R, through the listening key, O; the key, K; plug, P; jack, J; line; subscriber A's telephone, and back through the ground, or common-return wire, as the case may be, to the receiver, R.

The operator having asked and received the number of the subscriber with whom A desires to converse inserts the companion plug, P^1, of this pair into the proper jack, J^1. The insertion of the plug, P^1, in the jack, J^1, disconnects the annunciator, D^1, from the circuit. The operator may restore the listening cam to its normal position now or wait until later, after she has made sure that the two subscribers are properly connected by hearing them start their conversation. After inserting the plug, P^1, frequently termed the calling plug, into the jack, the operator depresses the ringing key, K^1, for a few seconds and turns the hand generator, G, at the same time. The generator current rings B's bell, passing from the generator, G, through the lower contact of the ringing key, K^1; cord and plug, P^1; jack, J^1; line; subscriber B's bell; the automatic shunt around his generator (represented by the dotted line), and back through the ground or common-return wire to the central-office generator, G. Thus subscriber B is called by the ringing of his bell.

When subscriber B, in order to answer the call, removes his receiver from the hook, the two subscribers, A and B, can communicate with each other over the following circuit: A's receiver; secondary winding of his induction coil; his hook-switch; line; jack, J; plug, P; lever and upper contact of key, K; upper contact and lever of key, K^1; plug, P^1; jack, J^1; line; B's hook-switch; secondary winding of his induction coil and receiver, and back through the ground or common-return wire to A's receiver. When the conversation is finished A and B hang up their receivers and one or both ring off—that is, turn their generator handles. Both should do so to avoid the possibility of neither doing it. This will cause enough current to flow from either subscriber's generator through the line, jack, plug, ringing key, and clearing-out drop, CO, to drop the shutter of the latter. This notifies the operator that A and B have finished their conversation and she then removes both plugs from the jacks and a weight under the table sliding on the plug cord pulls the plugs to their proper seat upon the table. The operator also restores the fallen shutter of the clearing-out drop to its normal position.

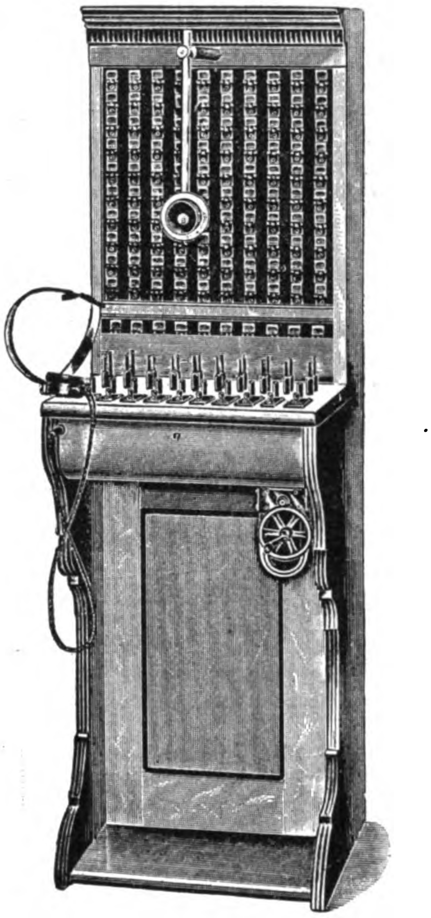

FIG. 3 —SMALL SWITCHBOARD.

It will be noticed that during a conversation the annunciators, D and D^1, are disconnected from the circuit, but that the clearing-out drop, CO, is always connected to the circuit while the conversation is taking place. The latter, therefore, forms a shunt across the talking circuit, since it is bridged from the cord circuit connecting the two jacks to the ground, or common-return wire. Hence, in order that no appreciable part of the talking current from one subscriber's instrument shall be shunted to the ground at the central office instead of passing on to the other subscriber's instrument, the clearing-out drop must be so wound as to present a very high impedance to the high-frequency talking currents and yet allow enough of the ringing current from a subscriber's generator to pass through it to drop its shutter. Such drops are usually wound to have a resistance of 500 or 600 ohms and should be iron-clad. That is, in addition to a soft-iron core the coil should be entirely surrounded by a shell of soft iron. Such a coil has such a very high impedance for the rapidly alternating talking currents that no appreciable part of these currents can get through it. However, the ringing-off current, which has a very much lower frquency, can readily flow through it and cause the shutter to drop.

Since the annunciators, D and D^1, are not connected to the circuit when the subscribers are talking, they can be made of any suitable resistance such that the subscriber's generators will operate them. They are usually wound to have from 80 to 100 ohms. If the annunciators, D and D^1, are wound to 500 or 600 ohms and made iron-clad like the clearing-out drop, CO, they could be permanently connected between the line and the ground or common-return wire and not arranged to be cut out upon the insertion of a plug in the jack. In this case they would both act as clearing-out drops as well as annunciators and no third clearing-out drop, CO, would be necessary. One objection to this arrangement is that it would put two annunciators across the talking circuit instead of only one; moreover the subscribers' generators would have to furnish twice as great a volume of current as in the arrangement here shown.

STARTING AND STOPPING DIRECT-CURRENT DYNAMOS OPERATED IN PARALLEL.

BY ALTON D. ADAMS

When two or more shunt-wound dynamos are to be started on a circuit not supplied from any other source, the switches for all of the dynamos may be closed before the start is made, and the dynamos allowed to build up and take the load as their speeds increase. In the use of this method it is necessary to place the rheostat levers at such positions that the dynamos will divide the load in suitable proportion, or else to adjust the rheostats continually as the magnet frames build up. If all of the dynamos are brought to full speed before the rheostat levers are moved from the "dead" positions, the dynamos may then be brought into action properly by simultaneous adjustment of all of the rheostat levers. Where a shunt dynamo is to be put into operation on a circuit with others already at work, the dynamo should have its terminal e.m.f. adjusted to just the voltage of the bus-bars and its main switch should then be closed. If the adjustment of pressure is exact, the newly-started dynamos will neither take nor deliver current when its switch is closed, and the rheostat may subsequently be shifted until the machine assumes its share of the load. As the dynamo begins to deliver current to the system, the rheostat levers of the other dynamos must be so shifted as to weaken their magnets, otherwise the voltage of the system will increase as the dynamos first in operation give up a part of their loads to the new machines and consequently have smaller internal losses of pressure. If several shunt dynamos are running in parallel and one is to be removed from the circuit, the rheostats of each dynamo should be adjusted until the one to be disconnected neither takes nor delivers current, when its main switch may be opened without changing the voltage of the system.

Two or more compound dynamos may be started on a circuit not previously in use, in the ways described for shunt machines, provided, of course, that the necessary equalizer connections are made. If a compound dynamo is to be started on a circuit where others are already in operation, any one of several methods may be followed. These methods vary as to the time at which the equalizer connection is made with respect to the making of the main positive and negative connections. According to one plan, the equalizer connection is made permanent on all of the dynamos. This arrangement leaves the series coils of all dynamos constantly in circuit, whether one or more machines are in operation.

To start an additional dynamo on a circuit where others are at work, all of the series coils being constantly in circuit, it is only necessary to so adjust the rheostat of the dynamos to be added to the circuit that its voltage equals that of the system, and then to close the switch that connects the positive and negative wires of the dynamos to the circuit. The rheostat of the dynamo just started should next be manipulated until the dynamo takes its share of the total load. When the switch for the newly-started dynamo is closed there should be no change in the voltage of the system, but as its rheostat is adjusted to give the fresh dynamo a part of the load, the voltage of the system will rise slightly unless the rheostats of the other operating dynamos are shifted so as to lower their generated pressure. To disconnect a dynamo from the system just considered its rheostat should be changed so that the dynamo neither delivers nor takes current, and its main switch can then be opened without effect on the voltage of the system. While the load on one dynamo is being reduced, the rheostats of the other dynamos should be adjusted to keep up their voltage.

A much-used plan for throwing in a compound dynamo includes the use of a triple-pole switch adapted to connect in the positive, negative and equalizer leads of the machine simultaneously. Before a compound dynamo is connected in this way its rheostat should be adjusted to bring the dynamo voltage to equality with that of the system. At the instant the triple-pole switch is closed, the series coil of the added dynamo is put in parallel with those of the dynamos already in operation, and the new coil takes a share of the total current, that is determined by its resistance. The increase of ampere turns on the magnet frame of the added dynamo, by the current thus supplied to its series coil, raises the pressure generated by the dynamo, and it at once assumes a part of the load. If all of the dynamos in operation, including the one last added, are compounded for constant pressure, by the division of the total current between their series coils, the voltage of the system is not changed by the dynamo last started.

Should the current in the several series coils operate to over-compound all of the dynamos equally, two undesirable results are produced at the moment a fresh dynamo is connected. These are an increase in the voltage of the system and a transfer of a disproportionate part of the total load to the dynamo last added, provided, of course, that its capacity is not so exceeded that its overcompounding property is lost. For example, suppose that an over-compounded dynamo which has a terminal e.m.f. of 220 volts at no load, and 240 volts at full load, will also show a rise to 255 terminal volts at full load if started with the rheostat adjusted for a terminal e. m. f. of 240 volts at no load. Let this dynamo be in operation, delivering full load at 240 volts, and let a similar dynamo be brought to the terminal pressure of 240 volts, with no current in its series coil, and then connected to the bus-bars by a triple-pole switch, one blade of which puts the series coils of the two dynamos in parallel. The dynamo just added will increase the voltage of the system and the terminal pressure to about 248 volts, because its series coil will get one-half the total current, and the armature will take the entire load. The dynamo first in operation will have generated in its armature an e. m. f. lower than 248 volts and will take current as a motor from the bus-bar. The rise in voltage of the added dynamo, its assumption of the entire load, and the motor action of the dynamo first in operation can, of course, be checked by the prompt adjustment of the shunt rheostats, but these conditions are not desirable.

The use of overcompounded dynamos, especially in railway power plants, has brought into favor the plan of closing the equalizer connection of a dynamo which is to be cut in on a working circuit before the armature circuit is closed. As soon as the series coil of the starting dynamo is connected in parallel with the others the rheostat should be adjusted to bring the terminal pressure of the fresh dynamo to that of the system, when the switch completing the armature connection may be closed. The closing of this last switch should not change either the voltage or the load distribution of the system, and the dynamo last added may now be given its share of the load by further rheostat adjustment. An objection to this method arises from the fact that when the additional series coil is put in parallel with those at work, it takes a part of their current and thus lowers the voltage of the system, necessitating the immediate adjustment of the shunt rheostats. In the case of a dynamo operating at 240 volts and full load, above cited, if the series coil of a duplicate dynamo is put in parallel with the coil of the first before the armature of the second dynamo is connected, the voltage of the system will drop to the terminal e.m.f. of the first dynamo; that is, from 240 to 230 volts. A quick adjustment of the rheostat for the first dynamo is the best that can be done to check this drop of voltage.

Failure to keep in mind the distinction between dynamos compounded for constant terminal e.m.f. and those that are overcompounded has apparently led to the incorrect statement that an over-compounded dynamo, when adjusted until its terminal e.m.f. equals the voltage of a system with no current in the series coil, and then connected to the system in multiple with a similar dynamo already operating, does not raise the voltage of the system. A dynamo compounded for constant terminal e.m.f. increases its internal generated e.m.f. with its load, though the terminal volts remain the same for all loads. But an over-compounded dynamo not only increases its internal generated e.m.f., but also its terminal e.m.f., as its load or the current in its series coil increases. Consequently, an over-compounded dynamo, when adjusted to the voltage of a system with no current in its series coil must raise the voltage of the system when connected so that the series coil receives current.

The permanent connection of all series coils in parallel makes it possible to put dynamos in and out of service with the minimum of disturbance to the voltage of the system or to the distribution of loads, but such permanent connection is open to the objection that the series windings on each dynamo constantly have current in them. A three-pole switch for each dynamo, to connect the positive, negative and equalizer cables to the operating system simultaneously, is fairly satisfactory with series coils that compound for constant pressures. One disadvantage in this case is that when a dynamo is disconnected from a system in operation the series coils of the remaining dynamos receive an increase of current and consequently raise the voltage of the system. The use of a three-pole switch seems best suited to evenly-compounded dynamos, especially for incandescent lighting, where any drop in voltage is very objectionable. For over-compounded dynamos that arrangement of switches which allows the series coil of a newly-started dynamo to be put in parallel with the coils of operating dynamos before the armature circuit is closed generally is more desirable than the triple-pole switch. With large units on railway work, where a small drop in voltage is less objectionable than extreme fluctuations of load distribution, the independent switch arrangement is decidedly preferable.

THE SPRAGUE MULTIPLE-UNIT RAILWAY SYSTEM.

BY EDW. CHILTON.

The multiple-unit system takes its name from the fact that it has to do with trains made up of many units, any one of which is an independent converter of electrical energy into mechanical energy, so that a single car or a train of 25 cars or more can be started and controlled as smoothly and with much more flexibility than can a train pulled or pushed by a single motor-unit. Such a system is admirably adapted to handle trains under elevated or other steam-road conditions, for, as will be seen later, it has many strong features that combine to save labor, time and material in operation, and the cost of maintenance of roadways and structures.

In a multiple-unit train every coach has its own motor, controllers, resistances, car-wiring cables, air brake, hand brakes, heat and light fixtures, and trolley, plow or contact shoe for transmitting current from the line to the motive and auxiliary apparatus on the car. The main distinctive feature introduced on multiple-unit trains is that the whole train or any part of it can be operated from any controller on any coach. Take any number of single ordinary surface trolley cars, for example, equipped with any style of motors and K2 controllers, and extend their car wires as indicated in Fig. 1, providing the ends with suitable couplers so that any number of cars can be electrically connected. In Fig. 1 A A are the taps that go to the controllers on one car, and B B are the taps that go to those on the other; C, C and C are the couplers. The result of so connecting two cars or more is to place all of the motors on the same set of car wires so that all of them or any of them can be operated from any controller.

Such a train of cars would constitute a multiple-unit train system, but such a system is open to several very serious objections. In the first place, such an arrangement necessitates the transmission and handling of large currents. For example, if the controller on one of the end cars is being used, the current from all of the cars has to pass through that controller. Suppose that the train has six coaches and that each coach, when the train is under full headway, takes a current of 300 amperes. Now the wiring on the last car in the train has to carry only its own current of 300 amperes, but the wiring on the car next to it has to carry the current of two cars, or 600 amperes, and the wiring on every car must carry its own current and that of all cars behind it, so that the wiring and the controller on the first car must handle 1800 amperes—the current of six cars.

As any car is liable to be the front end or operating car, if the full benefit of the multiple-unit feature is to be enjoyed, the wiring of every car must be able to stand with safety a normal current of 1800 amperes and an abnormal current of perhaps twice this during the period of acceleration. The cost of the car wiring alone for such a system would evidently be prohibitive. Also, it would be impracticable to construct a controller of reasonable size that could satisfactorily handle currents of 3000 or 4000 amperes, as it would be required to do at times.

A third and more serious objection is the impracticability of making a coupling device to satisfactorily transmit large currents from one car to the other; such a coupling must necessarily be flexible, so that it may respond to the various contortions and vibrations of the train; and it must be light, so that it can be easily handled when taking on or cutting off an additional coach. The fulfillment of either of these requirements is practically impossible under the conditions. The fourth objection to such a system is that the current for the whole train must be collected by one car, for the current cannot get through the controller on any car except the one whose controller is in use.

Any system, then, that requires the transmission of the main working current from one car to another must be set aside as undesirable. The main working condition to be fulfilled in the design of any multiple-unit system of control is that the working current be delivered directly to the car that utilizes it. Every car must have its own trolley pole and wheel or contact shoe, as the case may be. Suppose a train of six ordinary trolley cars, equipped as usual, and mechanically coupled, but electrically independent of each other; further suppose that by a system of signals the six motormen on the cars could be made to operate their respective controllers in synchronism; that is, all the controller drums to advance or retard at the same rate and rest on the same notch at the same time. Such a train of cars, with a motorman on each car, all acting under the same impulse, would be a multiple-unit train; but such an arrangement, besides being almost impracticable, would defeat one of the strongest arguments in favor of the multiple-unit system of control, namely, that of economy in operation.

There have been several devices designed to take the place of the motorman on each car, and all of them are practical and ingenious. On all of the systems, of which there are three, the car has the ordinary equipment of motors and resistances. In one system there is no individual motor controller of the usual type; the resistance is cut in and out and the series-parallel combinations of the motors are effected by means of electromagnetic switches, operated by means of a small switch situated on the platforms of the car, and known as the master controller. In another system the main controller drum and all of its accessories are operated by means of compressed air, stored in a reservoir and admitted to cylinders whose pistons operate the controller mechanisms; the air supply is controlled by means of valves actuated by electromagnets, energized by dry or storage cells. The battery circuit includes a small controller, situated on the car platform, and called the operating box.

In the system that forms the specific subject of this article—the Sprague system—the main controller is rotated by means of a small motor connected to the drum shaft. The motor is controlled by means of a small platform controller called the master controller. On all three of these systems there are two independent sets of circuits on each car, one being the main motor circuit, and the other the control circuits; there is no electrical connection whatever between them. In fact, on the Westinghouse system this condition is emphasized by the fact that the main motor circuit is, of course, operated by current from the trolley, while the control circuit is operated by battery current. In all cases the main motor circuit bears about the same relation to the control circuit that the telegraph-pole line has to the local sounder circuit inside of the office.

In the case of a multiple-unit car the control circuit is closed first; this operates a mechanism—an air valve, or electromagnetic switch or a motor—which closes the main motor circuit to start the car. Fig. 2 is a car-wiring diagram of the Sprague system of control as applied to a car equipped with two motors. Here, the heavy lines all belong to the main motor circuits; they represent wires and connections that carry the main current that propels the car. The light lines represent the connections of the control circuits; M is the main controller drum and *m* is the control-circuit part of the main drum; it is mounted on the same shaft, but has no electrical connection in common with any of the main motor connections, save the

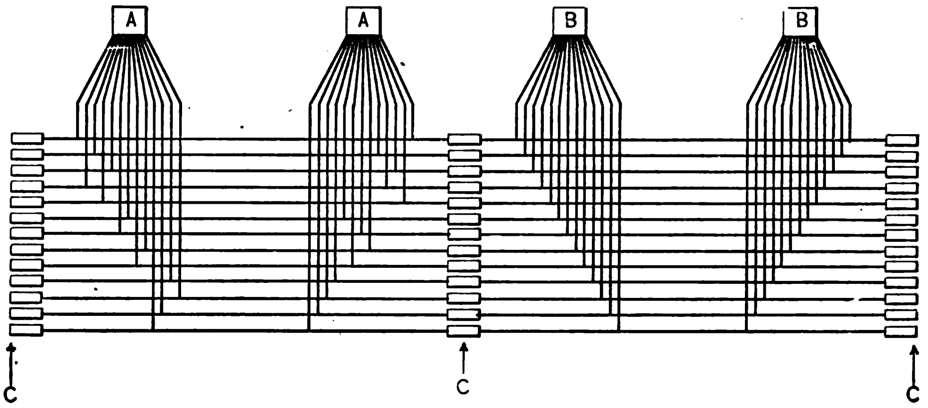

FIG. 1.—DIAGRAM OF CONNECTIONS BETWEEN TWO CARS.

ground connection, which is necessarily in common to all devices working on a ground-return circuit; P is the armature of the pilot motor that drives the main controller; F 10 and F 14 are the two field coils of the pilot motor (these two coils are so connected that when one of them is used the pilot motor runs in one direction, putting the main controller "on," and when the other field coil is used the direction of the motor is reversed, running the controller "off"); B¹ is a solenoid coil in series with the pilot motor, which releases a spring-impelled clamp brake that stops the motor immediately the current ceases to flow through it. The brake and motor are so related that when the motor is "on" the brake is "off," and when the motor is "off" the brake is "on."

A is a seven-section resistance coil, which is unique in that the conductor is an air-insulated iron casting. Fig. 3 shows how each leaf of the resistance coil is constructed. These leaves are mounted on a substantial slate base and allow the currents of air to have a clean sweep through them. The reverser is a drum operated by two electromagnets, as indicated in Fig. 4. As the current entering the junction of the two solenoids, which are in multiple, takes the path, *a*, *b*, through one coil or the path, *a*, *c*, through the other, the reverser drum is pulled one way or the other against the restraining tension of a strong centralizing spring. The reverser coils are a part of the control circuit, and the reverser cannot be operated, and hence the car can not be started, unless the control circuit is in order. Furthermore, if this circuit should get out of order while the car is under headway the reverser coils become dead and unable to hold the drum against the pull of the spring, which brings it back to the "off" position.

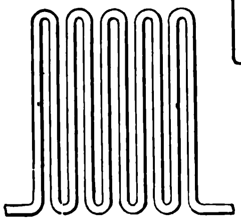

FIG. 3.

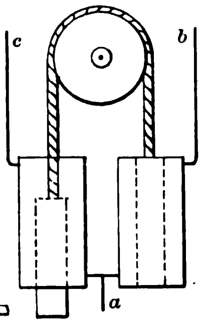

FIG. 4.

Both the reverse and main drums are provided with powerful magnetic blow-out coils to prevent arcing. The reverser drum, like the main drum, carries contacts for both the main motor circuit and the control circuit, but there is no electrical connection between them; L and L are two line switches that admit current to the pilot motor and to the reverser; both must be closed in order to operate the car, and both must be open to entirely "kill" it; T is what is called the throttle; this device makes it impossible to accelerate above a predetermined rate and saves the apparatus much abuse. It will be seen that the main current flows through it. If this main current rises above a certain value the plunger lifts the copper disc off the pegs 10 and 18, interrupts the pilot-motor circuit and stops the advance of the main drum; as soon as the current falls to the limiting value the disc drops, the motor starts and the controller resumes its progress.

The three solenoids, A, B, C, to the right of the throttle are called relays and are a part of the control apparatus. The left-hand relay, A, is called the coast relay, because it is used to run the main controller down to the "off" position, when it is desired to have the train coast along without power; the relay, B, operates to start the pilot motor and run it up to the last series notch, but no further; and the relay, C, runs the pilot motor up to the last multiple notch. The master controller, K, controls the pilot motor and the reverser coils. This controller has a neutral

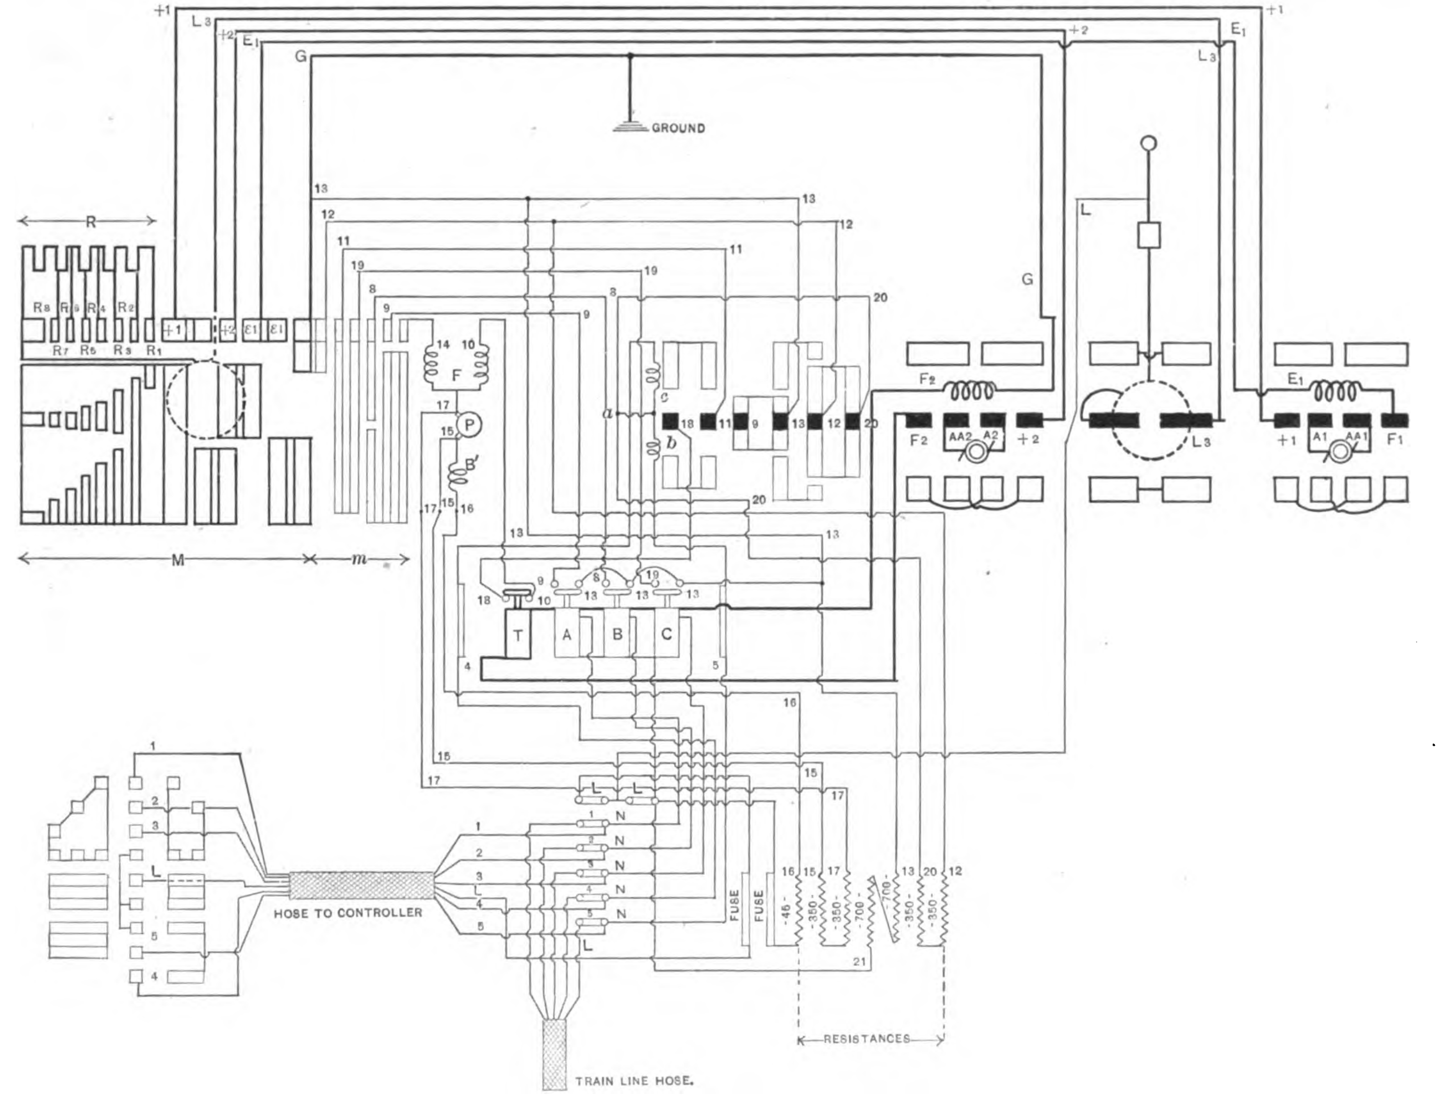

FIG. 2.—CAR WIRING DIAGRAM OF THE SPRAGUE MULTIPLE-UNIT SYSTEM.

position, just as the old Sprague street-car controller had, and the car is started ahead or back according as the controller handle is thrown to one side or the other of the neutral point. There are three forward positions on the controller drum, but only one position marked on the top. There are two reversing positions on the drum, but only one notch marked on the top.

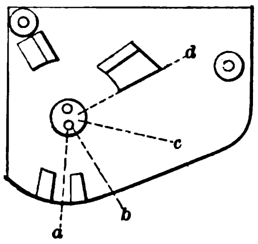

FIG. 5.—CONTROLLER TOP.

Fig. 5 shows the controller top. When the handle is in dotted position, *a*, the controller is at the "off" position; when at position, *b*, the pilot motor does not start, but the reverser drum is thrown to the "ahead" position and the relay, A, is picked up. In the position, *c*, the relay, B, picks up, starts the pilot motor, and this runs the car motor controller up to full-series point, when the pilot motor stops. If the handle be advanced to the position, *d*, the multiple relay, C, operates and the motor controller is run up to full multiple position. This is as far as the handle will go counter-clock-wise. If the motorman releases the handle in this position its spring will carry it back to the position, *b*, but no further, because an interference tongue on the handle goes against the right-hand side of the "off" position lug and stops there. Then the reverser drum remains in position, ready for the next start, but in the meanwhile the relay, A, has operated to run the pilot motor in the reverse direction, so that the main controller drum is run to the "off" position.

In order to get the master-controller handle past the lug to the "off" position it is necessary to press a button which raises the interference tongue on the handle and allows it to pass the lug on the dial. As soon as it passes this lug, the reverser drum is thrown back to the "off" position, in which position the main motor circuit is open in about fourteen places. Should the motorman allow the controller handle to go from any "on" position to the "off" position quickly, it does not give the pilot motor time to run the main drum to the "off" position, so that the main circuit is opened solely by the reverser; but as the reverser opens the circuit in ten places, and as it is provided with a powerful magnetic blow-out coil, indicated by the dotted lines, no arcing can take place.

In order to reverse the motion of the car the master-controller handle must be released from the "off" position, between the lugs, and moved over to the left-hand side. This operates to make the current pass through the other reverser field coil, with the result that the reverser drum is thrown to the "backward" position, reversing the armatures of the two main motors, and with them the direction of motion of the car. As a rule, the motormen run between the positions *b* and *d*, rarely having occasion on the road to drop the reverser back to its "off" position. The series of switches, N, are all operated by a single handle and serve to cut out the train line. The train line is composed of seven very small flexible wires running the full length of the train; these are the wires of the control circuits and carry but little current. They are connected between coaches by means of couplers little larger and no heavier than an ordinary air-brake hose coupler. By means of the train line cut-out switches, one or more cars can be cut out of a train without interfering with the operation of any of the other cars on the train, and the train can even be operated from one of the cars that is cut out.

STEAM INJECTORS FOR BOILER FEEDING.

There are many situations where the injector is pre-eminently adapted for boiler feeding. As it returns the steam it uses to the boiler, it is the most economical method of feeding a boiling, unless there be a waste heat from other sources which may be utilized to heat the feed-water almost up to the boiling point. Considered purely as a pump, it may not seem an economical apparatus, as it uses considerably more steam than an ordinary direct-acting steam pump. The steam, which it uses, however, heats the feed-water very greatly above its original temperature, so that an injector cannot logically be considered merely as a pump, but must be credited with the heat imparted to the feed-water; all of the heat in the steam goes back in the water except the small amount lost by radiation.

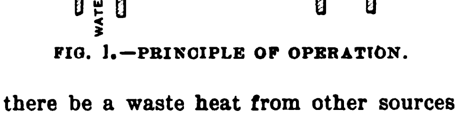

FIG. 1.—PRINCIPLE OF OPERATION.

Injectors are divided into two general classes, single-tube and double-tube. The ability of a single-tube injector to deliver water against a pressure decreases as the height to which the injector lifts the feed-water increases. For example, a prominent type of single-tube injector will deliver against 150 lbs. boiler pressure, if it is not required to lift the water more than 2 ft. If the injector has to lift the water 18 or 20 ft., however, it will only deliver it against 85 lbs. of boiler pressure.

Double-tube injectors are provided with two sets of tubes, one set for lifting the water and the other to do the work of delivering it against the boiler pressure. It would seem from this fact that the height to which the injector is required to lift the water would not affect its ability to deliver it against pressure. That this is not true, however, will appear upon consideration of what happens in the injector. The lifting tubes do all of the work of lifting the water, but when it is brought to the injector chamber, these tubes deliver it to the forcing tubes under a certain amount of pressure, which is added to the force imparted by the jet of steam in the forcing tube. Now, if the lift is so high that the lifting tubes will do no more than bring the water up to the injector, then the forcing tubes have to do all of the work of delivering it; whereas if the lift is short, the lifting tubes will not only lift the water to the injector but turn it over to the forcing tubes under a considerable pressure, thus enabling them to deliver it against a higher opposing pressure than they could alone overcome.

All injectors depend for their operation on the same fundamental principle, to wit:—the condensation of steam in a chamber where it meets the cold feed-water, thus producing a partial vacuum into which more water rushes, and consequently accelerating the flow of the combined steam and water to a velocity so great as to project the water into the boiler against the static steam pressure.

Injectors differ in minor details of design so as to accomplish these ends most efficiently and at the same time render repairs and renewals more readily made, but there is no difference in injector designs so far as fundamental requirements are concerned. Every injector must contain a steam nozzle, which delivers a jet across the water inlet; a combining tube, where the water and steam combine, resulting in the condensation of the latter, and a delivery tube in which the velocity of the stream is reduced. The principle of the condensation being involved, it is evident that the colder the feed-water, the better the injector will operate. It is also evident that there is a limiting temperature beyond which the injector will not work at all.

Fig. 1 shows an outline of an injector illustrating the principle of operation, but without any constructional details. Steam issuing from nozzle, C, at a high velocity, by entrailment exhausts the air from the pipe, B, causing the water to rise; the water mingling with the steam in the chamber of nozzle, D, condenses it, producing a partial vacuum and thereby accelerating the flow of steam and water through the nozzle, D, where it obtains its maximum velocity. If at this high velocity the water were delivered against the quiescent boiler pressure, there would be a great waste of energy, and to avoid this another nozzle with diverging sides is always added so as to effect the desired change of velocity as economically as pos-

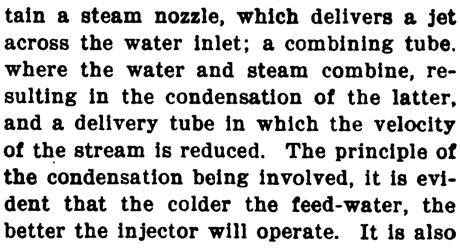

FIG. 2.—METROPOLITAN AUTOMATIC.

sible. The tube, H, shown in the engraving, is introduced for this purpose; the water passes from this tube to the boiler at a reduced velocity. A check-valve, I, is necessary in order to prevent back flow from the boiler in case the injector fails to work, and an overflow outlet, G, is also required for the purpose of rendering the injector free from opposing pressure in starting up.

Figs. 2 to 11, inclusive, represent typical single-tube injectors of American make. The Metropolitan, shown by Fig. 2 and made by the Hayden & Derby Manufacturing Company, New York, is started by rotating the handle just as one does the hand wheel of a valve-stem. As soon as the entrance to the steam nozzle, S, is uncovered, steam rushes through, drawing water up the water-supply pipe into the suction nozzle, V. The condensation takes place in the nozzle, C, and the water is delivered through the tube, D. The check-valve, P, opens into the overflow. The steam nozzle is removable by taking out the plug, O; the delivery nozzle cannot be removed without taking down the boiler connection, A, B.

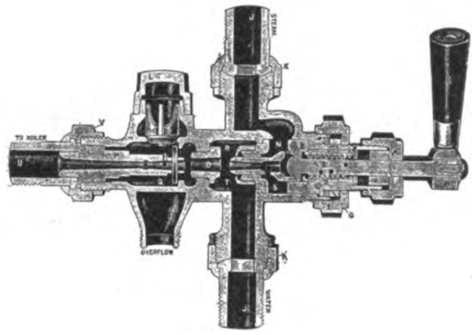

FIG. 3 — BUFFALO INJECTOR

The Buffalo automatic injector, made by the Sherwood Manufacturing Company, Buffalo, N. Y. (see Fig. 3), is generally similar to the Metropolitan. The manipulation is precisely the same, but the removal of the gland nut, E, renders all of the interior accessible and all of the nozzles removable except the delivery tube P. This must come out at the delivery end, as is the case with almost all injectors. The exterior appearance of the machine is quite simple and substantial, as Fig. 4 shows.

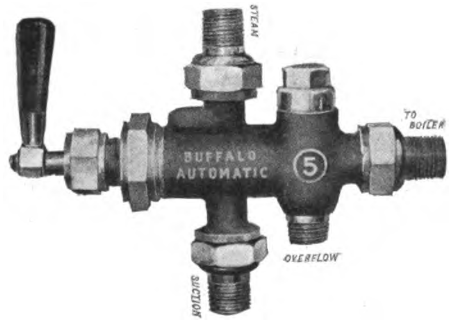

FIG. 4 —BUFFALO INJECTOR.

The Little Giant injector, Fig. 5, has the peculiar feature of a sliding combining tube, K, which is moved toward or away from the steam nozzle by means of the lever, W. The steam valve is also somewhat peculiar; the main admission is through an annular opening around the outside of the valve, 7, and steam is also admitted through holes in the wall of this valve to a "needle" jet which it carries and which delivers near the end of the steam nozzle. The adjustment of the combining tube, K, regulates the water supply. The steam valve is removable by taking off the gland, but the steam connection must be removed to get out the steam nozzle. The combining tube can be taken out by unscrewing its gland nuts and taking off the lever, W. This injector is made by the Rue Manufacturing Company, of Philadelphia, Pa.

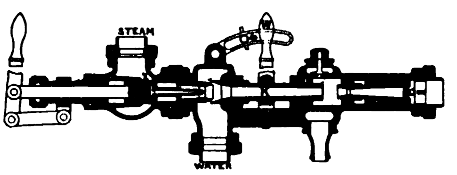

FIG. 5 —LITTLE GIANT INJECTOR.

The Penberthy special injector, manufactured by the Penberthy Injector Company, Detroit, Mich., is a very simple type. There are no adjustments to be made in the machine itself. All that is necessary in order to start it is to open a valve in the steam-supply pipe, which is connected to the upper right-hand union shown in Fig. 6. The steam nozzle is indicated by the letter, X, the combining tube by the letter, G, and the delivery tube by the letter, H. All of these tubes may be removed without breaking any connections, by taking off the screw caps, 4 and 8; the check-valves in the overflow may be removed by taking off the cap, N. Figs. 7 and 8 illustrate the Penberthy automatic injector, which, as will be seen, is of somewhat simpler construction than the special injector shown by Fig. 6. The construction of the injector is evident from Fig. 8. In order to start it, it is only necessary to open a valve in the steam-supply pipe and throttle the flow of water in the boiler-feed pipe until the discharge at the overflow ceases.

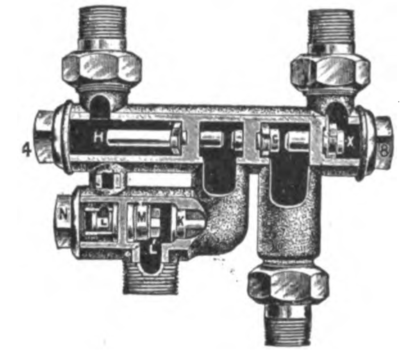

FIG. 6.—PENBERTHY SPECIAL.

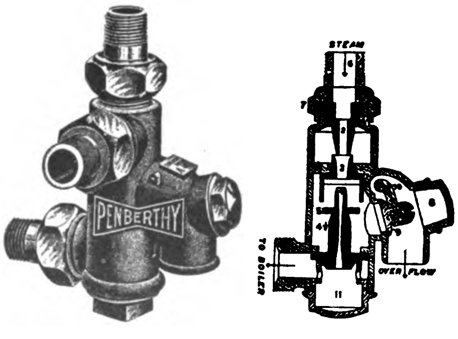
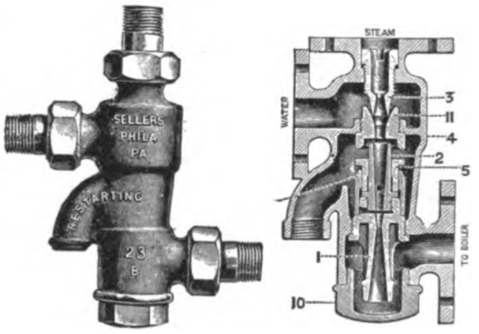


FIGS. 7 AND 8.—PENBERTHY AUTOMATIC.

The Sellers restarting injector, shown by Figs. 9 and 10, made by Wm. Sellers & Company, Philadelphia, Pa., is equally simple, there being no valves to manipulate in the injector itself. As its name implies, it is restarting, and it is also a lifting injector. The arrangement for preventing the entrance of air to the overflow is somewhat unusual. The steam enters at the top through the steam nozzle, 3, lifting the water to the injector, and the partial vacuum caused by the condensation of steam in the draft tube, 11, raises the bushing, 5, up against the mouth of the draft tube, preventing the entrailment of air through the overflow outlet. In order to remove the steam nozzle, 3, the steam connection must be broken, but all of the other tubes may be removed from the bottom by taking off the cap, 10. A somewhat unusual feature of this injector is the discharge of water from the delivery tube up against the blank wall of the cap, 10, instead of directly against the check-valve in the boiler feed pipe, which is usually the case. Fig. 9 gives an exterior view of the injector, with screw unions, and the cross-sectional view. Fig. 10 shows it fitted for flange connection.



FIGS. 9 AND 10.—SELLERS RESTARTING INJECTOR.

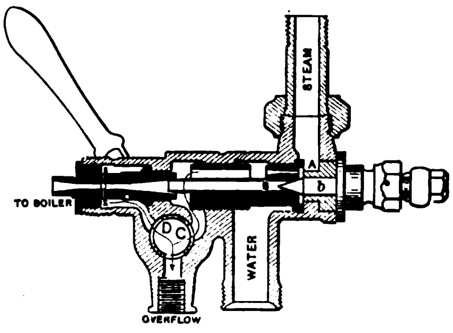


FIG. 11.—EXCELSIOR INJECTOR.

Fig. 11 represents the Excelsior injector, made by N. A. Watson, Erie, Pa. This injector differs from most of the other single-tube machines in that the starting lever closes the overflow outlet after opening the steam valve. The steam valve is a conical plug, indicated by the letter, *b*, in the illustration. The back end of the valve stem is connected to the starting handle by a link, so that throwing the lever over to the right backs the valve out of the steam inlet, B. A further movement of the handle over to the right rotates the plug valve, D C, so as to close the overflow outlet.

Double-tube or compound injectors, as intimated in the opening paragraphs of this article, operate on precisely the same principle as the single-tube type, the difference being merely that the injector is provided with two sets of tubes, one set to lift the water and the other set to force it into the boiler. The Leader injector, Fig. 12, made by the Randle Machinery Company, Cincinnati, Ohio, belongs in this class of machines. It only differs in construction from the Excelsior, just described, in having the auxiliary lifting tubes just above the water inlet. The valve motion is precisely the same as that of the Excelsior injector.

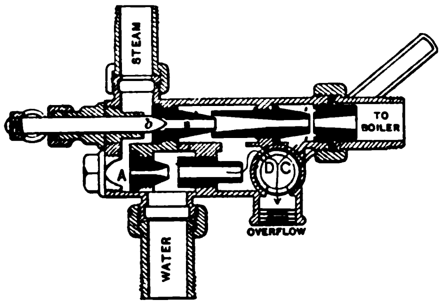

FIG. 12.—LEADER INJECTOR.

Fig. 13 represents the Sherwood double-tube injector, made by the Sherwood Manufacturing Company, Buffalo, N. Y. The operation of the injector will be apparent from the sketch; simply pulling the starting handle outward opens first the valve covering the mouth of the steam tube, 22, and then opens the valve, 2, to admit steam to the forcing tube, 24. The lower set of tubes raises the water to the chamber of the injector, and the upper set forces it into the boiler. The overflow valve, 18, is closed by the lateral movement of the valve cam, 19, which is connected outside the injector by means of a link to the starting handle, the connection being made at the point where the cotter pin is shown. A movement of the cam, 19, to the right allows the overflow valve, 18, to drop against its seat. All of the interior parts, except the delivery tube, 25, are removable without breaking any connections.

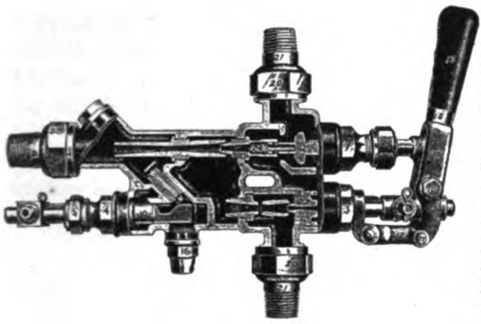

FIG. 13.—SHERWOOD DOUBLE-TUBE.

One of the oldest of the double-tube injectors is the Korting, manufactured by L. Schutte & Co., of Philadelphia, and illustrated by Fig. 14. It is controlled by the movement of a single handle, as is the case with almost all injectors. The lifting nozzle is indicated by the letter A, and the forcing nozzle by the letter B. The lever is connected outside the injector by a link to the overflow valve, which is opened when the injector is shut off and closed after it is started, just as in the case of the Sherwood. Both sets of nozzles are removable without breaking any connections, being in line with the two plug caps shown above and below the center of the machine at the left-hand end.

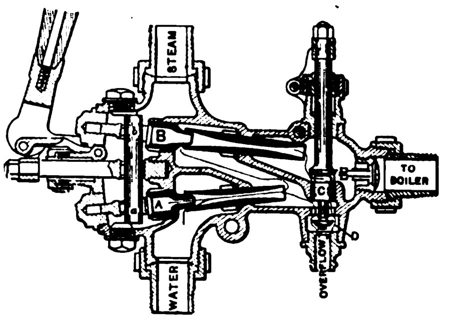

FIG. 14.—KORTING INJECTOR.

A construction somewhat simpler than the Korting is the Niagara, shown by Fig. 15, made by the Eynon-Evans Manufacturing Company, Philadelphia, Pa. The engraving shows the injector adapted to the Sellers standard pipe connection. A feature of the machine, however, is that it may be changed from this arrangement to suit the Monitor pipe connection, which is the standard for railroad work. This is accomplished by interchanging the overflow nozzle, C, with the plug, P, and replacing the water connection, E, with a longer leg or nipple. It is not necessary to manipulate the hand wheel, S, in starting; this is merely for regulating the capacity of the injector. The handle, H, opens both the lifting and the forcing steam nozzles. All of the interior parts except the delivery nozzle may be removed without breaking connections.

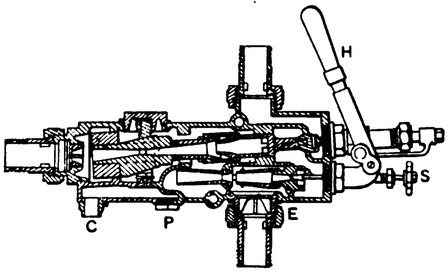

FIG. 15.—NIAGARA INJECTOR.

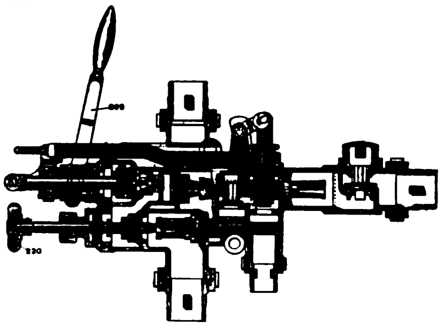

FIG. 16.—METROPOLITAN "1898."

The Metropolitan "1898" injector, Fig. 16, is similar in construction to the Niagara in that it has a separate regulating valve, 220, for adjusting the capacity of the machine, in addition to the starting handle, 269, which admits steam to both the lifting and the forcing tubes and closes the overflow valve. The Metropolitan double-tube injector, "Model G," is shown by Fig. 17. Its operation will be evident from an inspection of the sectional cut. All the tubes of this injector are removable without breaking any of the steam or water conections; a separate valve is required to adjust the delivery of water. The Metropolitan injectors are built by the Hayden & Derby Manufacturing Company, New York.

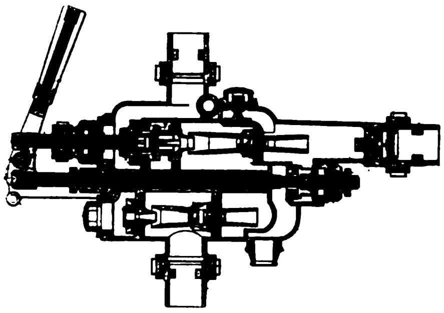

FIG. 17.—METROPOLITAN DOUBLE-TUBE.

The Hancock "inspirator," Fig. 18, is one of the best-known injectors in use in this country. Its manipulation is, however, not so simple as that of the other injectors described. There are three valves to handle on the injector itself and an additional valve in the steam pipe. In starting up, the overflow valves, 1 and 3, must be opened, the forcing valve, 2, closed, and the valve in the steam pipe opened to admit steam to the lifting nozzles on the left. As soon as the water appears in the overflow, the valve, 1, is closed, the forcing valve, 2, opened, which allows the forcing nozzle to carry water to the boiler, and the overflow valve, 3, is closed. This injector is manufactured by the Hancock Inspirator Company, New York City and Boston, Mass.

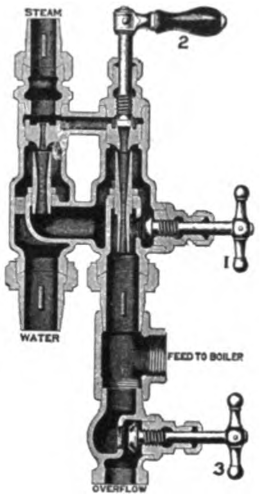

FIG. 18.—HANCOCK INSPIRATOR.

Lessons in Practical Electricity

TRANSFORMER CONNECTIONS.

Two or more transformers built to operate at the same potential and frequency may be connected together in a variety of ways; in fact, the primary and secondary terminals may each be considered exactly as the terminals of direct-current dynamos, with certain restrictions. The two principal precautions which must be observed in combining transformer terminals are that the terminals must have the same polarity at a given instant, and the transformers should have practically identical characteristics. The latter condition is not absolutely essential, but it is emphatically preferable. For example, if a transformer which has 2 per cent regulation be connected in parallel with one which has 3 per cent regulation, as indicated in Fig. 38, at no-load the transformers will give exactly the same e.m.f. at the secondary terminals, but at full-load one will have a secondary e.m.f. of, say, 98 volts, while the other has an e.m.f. of 97 volts. The result is that the transformer giving only 97 volts will be subject to a back e.m.f. of one volt from its mate. This will not cause excessive current to flow backward through the secondary winding of the low-voltage transformer, but it will disturb the phase relations and lower the power factor and efficiency of the combination; in such a case it is much better to work the secondary circuits of the two transformers separately.

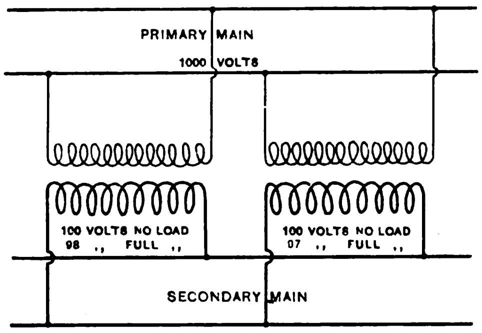

FIG. 38.—UNLIKE TRANSFORMERS IN PARALLEL.

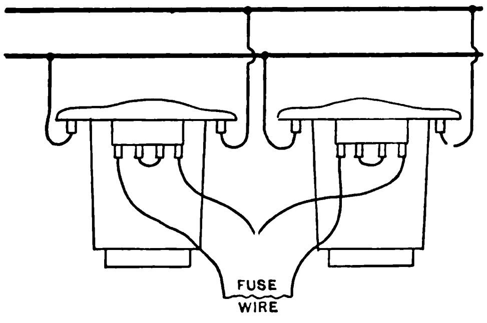

FIG. 39.—COMPARING INSTANTANEOUS POLARITY.

In case the transformers have practically the same characteristics it is necessary, as stated above, to make sure that the secondary terminals connected together have the same polarity at a given instant; it is not necessary to find out definitely what the polarity is, merely that it is the same for both terminals. This can be easily done by connecting two of the terminals as shown in Fig. 39, by a small strip of fuse wire, and then touching the other two terminals together. If the fuse blows, then the connections must be reversed; if it does not, then they may be made permanent. It is seldom advantageous, however, to operate transformer secondaries in parallel; occasionally it may be necessary as a temporary expedient, but where the load is such as to require a greater capacity than that of a transformer already installed, it is much better to replace it by a large transformer than to supplement it by an additional transformer of its own size.

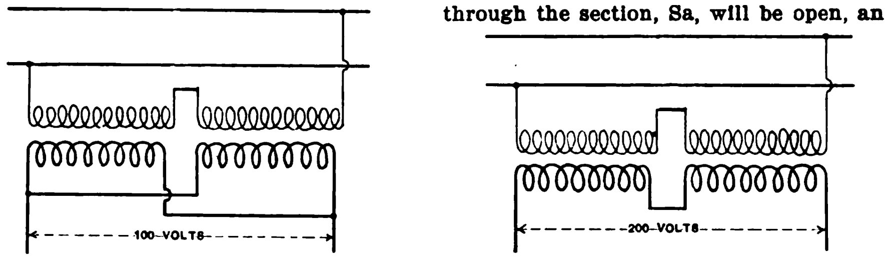

FIG 40.—SECONDARY CONNECTIONS FOR DIFFERENT VOLTAGES

All modern transformers have the secondary windings divided into at least two sections which may be connected up either in parallel or in series. If the secondary e.m.f of a transformer having two sections is 100 volts with the terminals in parallel, then connecting them in series will give 200 volts at the free secondary terminals, as indicated in Fig. 40. If the transformer be of the core type, and the two sections of secondary winding be wound on different limbs of the core, as in Fig. 41, it will be advisable, if the secondaries are to be operated in parallel, to make the connections ample and permanent, so that there will not be any liability to a difference between the current flowing in one secondary winding and that flowing through the other.

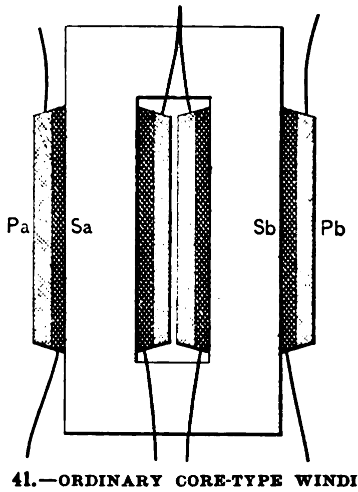

FIG. 41.—ORDINARY CORE-TYPE WINDING.

Still referring to a transformer which has the two secondary sections on different legs of the core, if the secondary terminals are connected up to a three-wire distribution, as shown diagrammatically in Fig. 42, it is advisable to make the fuse, Fc, in the middle wire, considerably smaller than necessary to pass the normal load in either side of the circuit. The reason for this is as follows: Should the fuse, Fa, be blown, the secondary circuit through the section, Sa, will be open, and the corresponding half of the primary winding, Pa, will have a much higher impedance than the half of the primary winding, Pb, the inductance of which is so greatly neutralized by the load on the secondary winding, Sb, as explained in previous lessons. The result will be that the counter e.m.f. of the primary section, Pa, will be very much greater than that of the section, Pb, and as the sections are in series the current must be the same through both halves of the winding; the drop or difference of potential, therefore, between the terminals of Pa will be much higher than that between the terminals of Pb, consequently, the secondary voltage of Sb will be greatly lowered and the service impaired. As the primary winding, Pa, is designed to take only one-half of the total impressed e.m.f., the unbalancing referred to will subject it to a considerably higher e.m.f. than the normal value; consequently, the magnetic density in that leg of the transformer core will be much higher than normal, and the transformer will heat disastrously.

If the fuse, Fc, in the middle wire be made, say, one-half the capacity of each of the other fuses, this condition will be relieved by the blowing of this fuse, and as the lamps in the live circuit would not be anywhere near candle-power if the circuit remained intact, the blowing of the middle fuse will not be any disadvantage to the user of the lamps. Some makers avoid the contingency just described by dividing each secondary coil into two sections and connecting a section on one leg in series with a section on the other leg of the core, so that current applied to

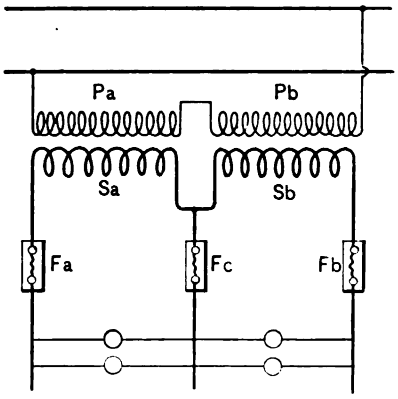

FIG. 42.—THREE-WIRE SECONDARY SERVICE.

either pair of the secondary terminals will circulate about both legs of the core.

In the case of two-phase distribution each circuit may be treated as entirely independent of the other so far as the transformers are concerned. Two transformers are used, one transformer being connected to one primary phase and supplying one secondary phase, and the other transformer being connected to the other primary phase and supplying the other secondary phase, as indicated in Fig. 43, exactly as though each primary and secondary phase were an ordinary single-phase system, independent of the other phase. In such cases it is possible for the two phases to remain electrically independent throughout the system, although it is not customary to thus arrange the wiring.

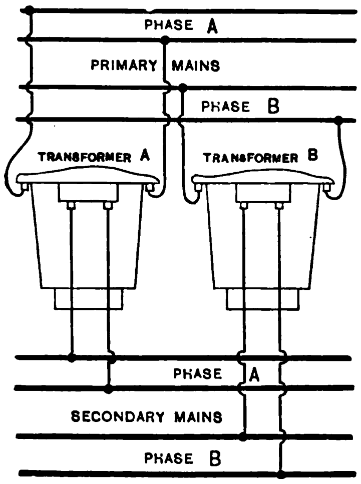

FIG. 43.—TWO-PHASE CONNECTIONS

A method of connection commonly used to obtain economy in wiring is that shown by Fig. 44, where the primaries of the transformers are connected independently to the two phases, and the secondaries are joined to a three-wire distribution, the middle wire being about one-half larger than each of the two outer wires. In the former case, Fig. 43, it makes no difference which secondary terminal of a transformer is connected to a given secondary wire, so long as no transformers are used in multiple. For example, referring to the diagram, the left-hand secondary terminal of transformer, A, could just as well be connected to the lower wire of the secondary phase, A, and its right-hand terminal connected to the upper wire, the only requirement being that the two pairs of mains shall not be "mixed;" that is to say, transformer A must not be connected with one secondary terminal to phase A and the other to phase B. In the case shown by Fig. 44 there is not quite so much freedom in making connections. One secondary terminal of each transformer must be connected to one of the outer wires and the other two terminals must be both connected to the larger middle wire of the secondary system. It makes no difference, however, which two secondary terminals are joined and connected to the middle wire so long as the other terminal of each transformer is connected to an outer wire of the secondary system.

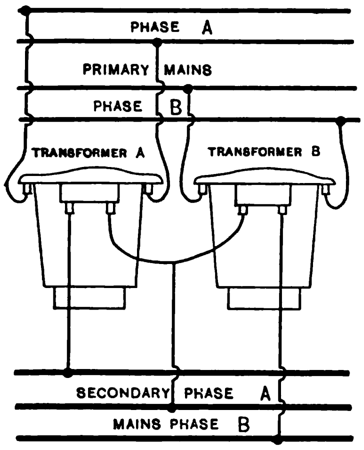

FIG. 44—TWO-PHASE CONNECTIONS; THREE-WIRE SECONDARY.

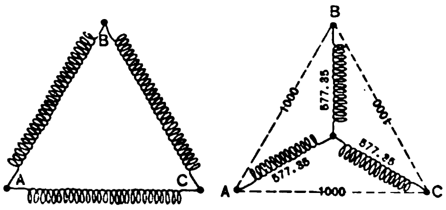
The methods of making three-phase connections are more rigid, as the three phases are inseparably interlinked. There are two ways of connecting up the primaries and secondaries, one known as the "delta" connection, and illustrated diagrammatically by Fig. 45, and the other known as the "star" connection, and illustrated by Fig. 46. In both diagrams the line wires are lettered, A, B and C. Fig. 47 shows the primaries and secondaries connected up delta fashion, corresponding to Fig. 45, and Fig. 48 shows them connected up star fashion, corresponding to Fig. 46. In both of the latter sketches the secondary wires are lettered to correspond with the respective primary wires. When the primaries are connected up delta fashion, the voltage between the terminals of each primary winding is the same as the voltage between the corresponding two wires of the primary circuit, and the same is true of the secondary transformer terminals and circuit wires.



FIGS. 45 AND 46—DELTA AND STAR DIAGRAMS.

The current, however, flowing through the transformer winding is less than the current in the line-wire, for the reason that the current from any one line-wire divides between the windings of two transformers. For example, in Figs. 45 and 47, part of the current from the line-wire, A, will flow from A to B through the left-hand transformer, and part from A to C through the right-hand transformer; if the current in the line-wire, A, is 100 amperes, the current in each transformer winding will be 57.735 amperes. When transformers are connected up star fashion, as in Figs. 46 and 48, the current in each transformer winding is the same as that in the line-wire to which it is connected, but the e.m.f. between the terminals of each transformer winding is 57.735 per cent of the e.m.f. from wire to wire on the circuit. For example, if the primary e.m.f. from A to B is 1000 volts, the e.m.f. at the terminals of the left-hand transformer (from A to J) will be only 577.35 volts, and the same is true of each of the other transformers if the system is balanced.

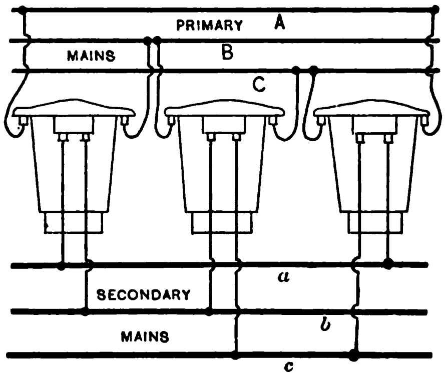


FIG. 47.—THREE-PHASE DELTA CONNECTIONS.

These statements apply, of course, to both primary and secondary windings, from which it will become evident that if the three transformers of a three-phase circuit be connected up star fashion at the primaries, and delta fashion at the secondaries, the secondary voltage will be lower than if both sides are connected up star fashion. For example, if the transformers are wound for a ratio of 10 to 1, and are connected up with both primaries and secondaries alike, no matter whether it be delta fashion or star fashion, the secondary e.m.f. will be one-tenth of the primary e.m.f.; but if the primaries be connected up star fashion on a 1000-volt circuit, and the secondaries be connected up delta fashion, the secondary voltage will be only 57.735 volts, instead of 100 volts. The explanation of the difference between the voltage per coil in a delta system and that in a star system is that in the former each winding is connected directly across from wire to wire; whereas in the star system, two windings are in series between each pair of line-wires. The voltage of each winding is not reduced to one-half, however, because the e.m.fs. are out of phase with each other, being 120°, or one-third of a cycle, apart; consequently, instead of having 500 volts at the terminals of each coil in Fig. 46, the voltage is 577.35. The same explanation applies to the current values in a delta system. The current phase between A and B, in Fig. 45, is 120° removed from that in the winding between A and C; consequently, the sum of the two currents, in the wire, A, is 1.732 times the current

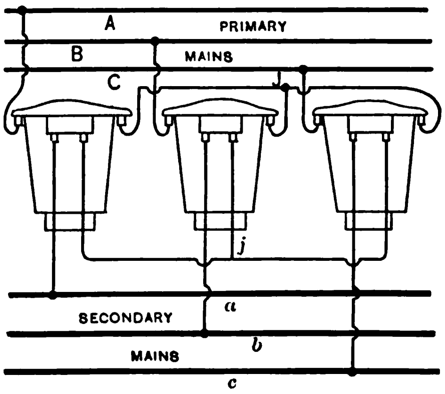

FIG. 48.—THREE-PHASE STAR CONNECTIONS.

in each wire; or, to state it the opposite way, the current in each winding is .57735 of the current in the wire, A. It will be well for the reader to remember that in all cases e.m.fs. differing in phase when connected in series, combine according to the well-known law of the parallelogram of forces; currents differing in phase, and connected in parallel, combine according to the same law.

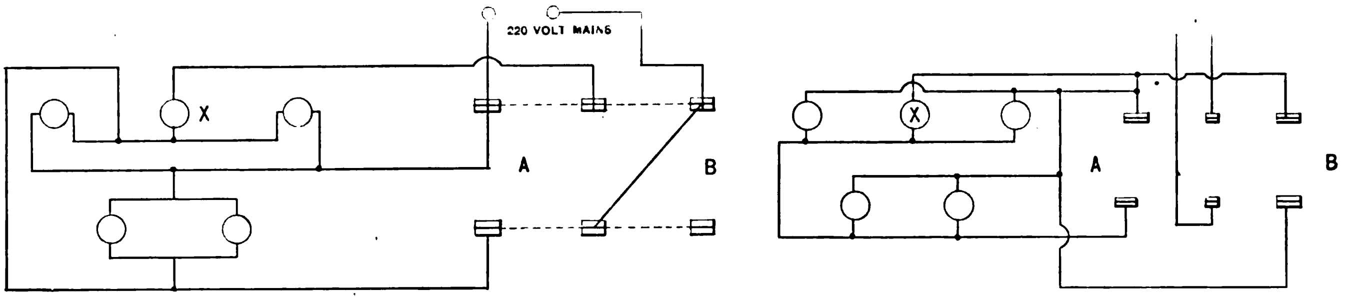
Letters on Practical Subjects

Electric Bells on Lighting Circuits.

To the Editor, American Electrician;

Sir:—Referring to Mr. Root's method of connecting electric bells on lighting circuits which was published in your December number, I beg to suggest that a still simpler method would be to connect a small resistance coil in series with a lamp across the electric light mains, and connect the bell and its push button in shunt with the resistance coil. By this means the proper voltage can be obtained at the terminals of the bell, and the lamp may be used in the ordinary manner for lighting purposes. A. R. Van Volkenburgh.

Chicago, Ill.



FIGS. 1 AND 2.—WIRING PUZZLE SOLUTIONS.

◆

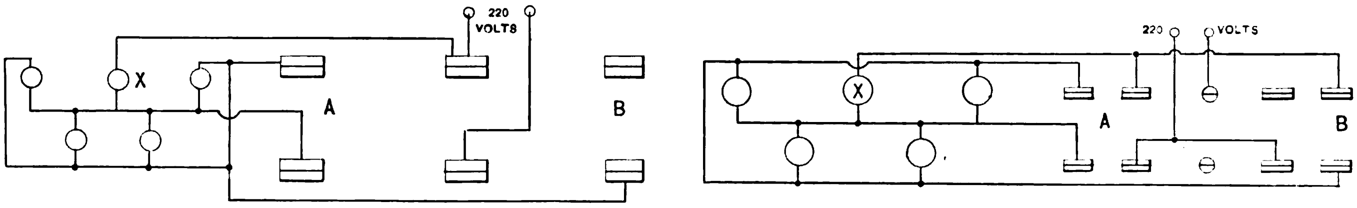
A Wiring Puzzle.

To the Editor, American Electrician;

Sir:—I send herewith a diagram (Fig. 3) which solves the puzzle submitted by Mr. Havens in the December number of the American Electrician. One side of the lamp, X, is connected permanently to one side of the supply circuit, the pressure of which is 220 volts. With the switch thrown over to A all of the lamps are in parallel, and when it is thrown over to B the lamp, X, is in series with the other four, which remain in parallel.

Geo. W. Malcolm.

Brooklyn, N. Y.



FIGS. 3 AND 4.—WIRING PUZZLE SOLUTIONS.

To the Editor, American Electrician;

Sir:—I send herewith a diagram (Fig. 2) of wiring in answer to the letter from A. L. Havens in the December number. The voltage of the circuit is the same as that of the lamps, 220 volts; I do not see how it could be anything else. With the switch in position A, all of the lamps burn; in position B, only the lamp, X, burns. It may be well to add that the reason for this is that the lamp, X, is in series with the other four lamps, which are in parallel when the switch is thrown over to B. Consequently, the four lamps in parallel do not show any light, and as they are turned out one by one the resistance of the group is increased, cutting down the current through the lamp, X, until all of the four lamps in parallel are cut out, when the circuit through X is opened.

Lockport, Ill. Ralph G. Focht.

To the Editor, American Electrician;

Sir:—I believe the accompanying diagram (Fig. 1) to be a solution of the wiring puzzle published on page 584 of the December number. When the switch is thrown over to the side, A, all of the lamps are in parallel on the 220-volt circuit; when the switch is thrown over to B, the lamp, X, is in series with the other four, which are in parallel. Fred Dustin.

Minneapolis, Minn.

To the Editor, American Electrician;

Sir:—Referring to Mr. Havens' wiring puzzle in the December number, it is not stated whether the switch to be used must be single-break or double-break. Assuming from this that one is at liberty to use whichever he pleases, I submit the accompanying diagram (Fig. 4) as a solution of the problem. It will be noticed that one side of the supply circuit is connected to the switch pivot instead of the jaws, while the other side is connected to the two inner jaws, as usual. This is necessary in order to change the connection between one side of the lamp, X, and one side of the group of four lamps. A single-break switch could be used, but in this case the upper side of the lamp, X, would have to be connected directly to the side of the circuit which is shown connected to the switch pivot. The explanation of the different phenomena described by Mr. Havens is that when the switch is over to the side, A, all of the lamps are in parallel, and burn at full candle-power; when it is thrown over to B, the lamp, X, is in series with the other four, which are in parallel, and consequently the lamp, X, burns not at full candle-power, while the other lamps do not show the current that is passing through them because of the very small amount passing through each lamp. As the four lamps are switched off one by one, the resistance of the group increases, cutting down the current and consequently the brilliancy of the lamp, X; when the final lamp of the four is switched off the circuit is opened and the lamp, X, is extinguished.

W. C. Townsend.

New Orleans, La.

[All of the above diagrams fulfill the requirements specified by Mr. Havens with the exception of Fig. 2. This diagram fails because the lamp, X, is permanently connected in parallel with the two lamps on each side of it by means of the cross-connection near the upper left-hand switch jaw. It seems evident that Mr. Focht intended this connection to be broken when the switch is thrown over to the side, B, as his explanation of the effect of switching out the various lamps is entirely correct; the diagram, however, does not show this.

Fig. 3 also represents a solution sent in by Mr. A. R. Van Volkenburgh.—Editor.]

◆

Unusual Action of an Arc-Light Dynamo.

To the Editor, American Electrician;

Sir:—The electric light company here operates a Ball double-armature arc dynamo with the two armatures connected in series in the circuit. One night recently upon starting up the machine everything ran all right for a few moments and then the lamps died out. I shifted the brushes around the commutator to the no-voltage point and then threw them back again; the circuit lighted up, but in a few minutes died out again. This operation was repeated several times and it was noticed that one of the journal boxes of the armature shaft ran excessively hot as long as the brushes were in the normal position and cooled off when they were shifted up to the no-voltage position. After a while it was noticed that the brushes of one commutator were turned under, and upon close examination it was discovered that that armature and commutator were running backward at a high rate of speed.

The armature had become loose on the shaft and the main-line current was driving it backward as a motor. When the brushes were in the normal position the counter e.m.f. of this armature ran up and cut down the e.m.f. of the belt-driven armature so that the circuit died out; when the brushes were thrown up to the no-voltage position the counter e.m.f. of the loose armature was zero and the circuit picked up again when the brushes went back to the commutating position, only to be again killed by the speeding up of the loose armature. The heating of the journal was due to the fact that the armature spider was revolving around the shaft in the opposite direction of the rotation of the shaft itself and therefore heated the shaft. When the brushes were thrown to the no-voltage position the armature slackened its speed and the heating decreased. This occurrence is such an unusual one that I submit it thinking that it will prove of interest to others who have dynamos of this type.

Electric Car Troubles.

To the Editor, American Electrician;

Sir:—Any railway superintendent bothered with leaks and burn-outs of fuse boxes in winter, owing to leakage, will find the following a remedy for this annoyance. Fit four porcelain insulators very tightly into the fuse-box base, and fasten with wood screws, as shown by Fig. 1. As the engraving shows, there is a space between the fuse-box and the car-sill. This will do away with sheet rubber and insulating paint, which afford only temporary relief. Better still is an insulator provided with a brass female screw thread imbedded in the sill, except ¼ in., which should extend beyond the sill for the fuse-box to bear against, as shown by Fig. 2.

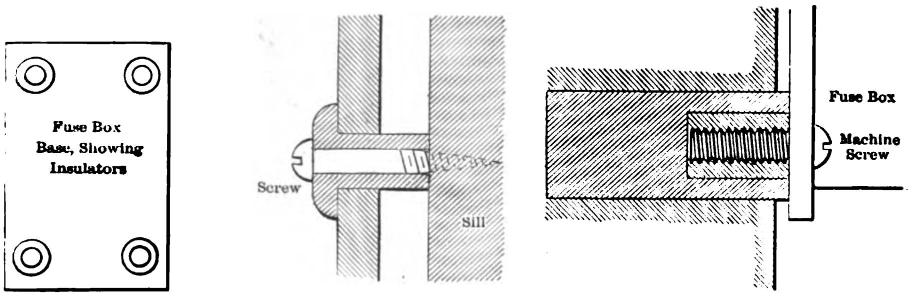

FIG. 1.—ELECTRIC CAR TROUBLES —FIG. 2.

The cause of a tie-up for an hour or more, one rainy, disagreeable day, was the band wires coming off an armature. The car was on a six-mile line, running to a pleasure park—the only line controlled entirely at the power-house switchboard. We opened that circuit, and found the ground was on that line. It had occurred in this way: After fusing several times, a heavier fuse had been put in, and when the power came on again, the controller was on the first notch, where it had been left by the motorman so that he might know when the current came on. As it happened, several strands of the wire had wrapped themselves about a brush holder and made contact with the frame also. The fuse was just large enough to knock out the circuit-breakers.

Of course, if the motorman had had his controller off, the circuit-breakers would have opened only when he tried to start. Some men are sharp enough to suspect their car as being the one causing trouble in these cases; so they wait until the power has been on the line for some time. If the power goes off as soon as they attempt to start, a close search often locates the fault, which can then sometimes be remedied without calling on the inspector. It should nevertheless be reported as soon as possible.

A glance at the station ammeters when closing the line circuit-breakers often reveals the fact that many men resort to the practice of leaving the controller on first notch, instead of using the lamp circuit to indicate when the power is again on the line.

The Control of Lights From More Than One Point.

To the Editor, American Electrician;

Sir:—The method of wiring incandescent lamps for control from different points which was described by Mr. Van Vleet in your December number is one which is commonly used and the only one that I have ever seen described in wiring books. The accompanying diagrams, Figs. 1, 2 and 3, show a method which I have used and which is more economical in wiring than the other one. The only difference is in reversing the relation of the three-point switches to the circuit. The result of this is that only one stretch of wire is necessary between the two three-point switches. Fig. 1 shows the arrangement for two stations or switches, Fig. 2 shows the arrangement for three stations, and Fig. 4 that for four. Any number of stations may be connected up by simply adding four-point switches. In the old method the two end switches are three-point, while all the intermediates are four-point switches. In the method here shown the three-point switches are placed at each end of the stretch of wire which includes the lamp or lamps to be controlled. It is evident that the greatest advantage of this arrangement is where there are only two stations, as in Fig. 1, because here the amount of extra wire required between switches is only one-half that required by the method more generally used and described by Mr. Van Vleet.

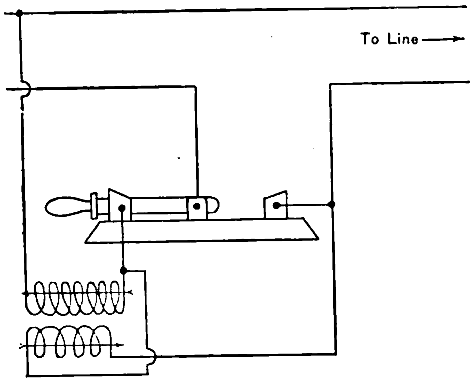
An Improvised Booster.

To the Editor, American Electrician;

Sir:—Some time ago I had to face the problem of running a 1000-volt primary circuit across a river too wide to hang copper wire across, and also too wide to use steel wire without getting a drop so great as to bring the voltage at the far end down entirely too low for the service. It was evidently a case of boosting the voltage, but I did not have any booster and could not wait to order one; so I took an ordinary transformer and connected the secondary in series with the line and the primary across the line just back of the secondary. The transformer was wound for 10-to-1 voltage, so that the secondary boosted the e.m.f. of the line a little over 100 volts (the primary voltage at the booster being about 1050). In order to cut out the booster during very light loads and get rid of the losses in the core, I connected it up to a double-throw single-pole switch, as shown in the diagram. Throwing the switch over to the right opens both the primary and secondary windings of the transformer and closes the break in the main line which is ordinarily filled by the secondary winding.



Denver, Colo. Ed S. Morgan.

Electrical Catechism

555. *How much current is required to melt a wire?*

When the wires are open to the air and when long enough so that the cooling effect of the terminals does not extend to near the middle of the wires (the fuse wires being from 2 to 12 ins. in length, according to their diameters) the currents required for melting are approximately as indicated in the following table for copper, lead and solder wires:

FUSING CURRENT IN AMPERES.

B. & S. Gauge No.	Diameter in inches.	Copper.	Lead.	½ Lead & ½ Tin.
36	.005	4	..	..
34	.006	5	..	..
32	.008	8	1	1
30	.010	11	..	..
28	.013	14	2	2
26	.016	20	3	..
24	.020	30	4	3
22	.025	42	7	5
20	.032	60	10	7
19	.036	70	11	9
18	.040	83	13	11
17	.045	100	15	13
16	.051	120	17	15
15	.057	140	20	18
14	.064	166	22	20
13	.072	200	27	24
12	.081	235	33	30
11	.091	280	38	35
10	.101	335	44	41
9	.114	390	51	48
8	.129	450	62	58
7	.144	520	77	73

The above figures are calculated from a law discovered by Preece, that the diameter (in inches) of a copper wire equals the cube root of the square of the quotient of the melting current in amperes divided by 10,244. For lead, the divisor is 1379. For the half-and-half solder, lead and tin, the divisor is 1318. The figures for lead and for solder agree closely with results of experiments by Bathurst. Part of the figures for copper fuses have been tested experimentally and found closely correct.

556. *What is a fuse block?*

A fuse block is a device for holding a fuse. It usually consists of brass clamps mounted on porcelain. Generally a porcelain or mica cover is provided, both for the purpose of preventing the fuse from flying when melting, or "blowing," and also to improve its looks, and to reduce the amount of "live" surface exposed to accidental contact. Fuse blocks are made in many different styles and for many different situations. For use on high potential circuits, such as the primary lines of 1000 volt or higher pressure circuits, and often for 100-volt circuits, the fuse is commonly placed in a separate cover piece, so that the fuse wire can be clamped in place in the cover before being connected with the live wires.

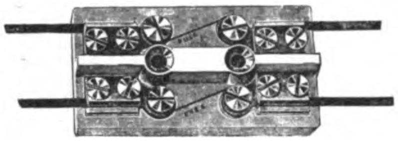


FIG. 1 — MAIN CUT-OUT.

557. *What are the principal kinds of fuse blocks?*

There is a great variety to suit various purposes. For use in electric light and power circuits, fuse blocks or "cutouts" may be classified into "mainline cutouts" and "branch blocks." A branch block is used for connecting branches to a larger circuit, the fuses being so arranged that if trouble occurs on the branch it is cut off without opening the main line. As its name indicates, a mainline cutout is placed in the main line. Figs. 1 and 2 show common forms of main and branch blocks for use on circuits for electric light or power inside buildings. Fuse blocks for use out of doors are made weatherproof, being encased in cast-iron boxes. For circuits using very small currents, such as telephones, special forms of fuse are employed.

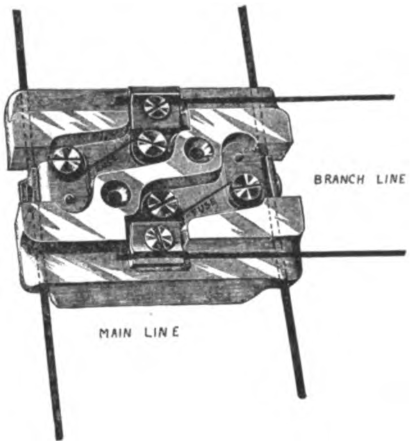

FIG. 2.

558. *What is an enclosed fuse?*

In an enclosed fuse the fusible wire is placed in a tube or in a cavity within porcelain or some other insulating substance. The space around the fuse wire is sometimes filled with some substance that will prevent the formation of an arc after the melting of the fuse. One style, shown in Fig. 3 has the fuse wire surrounded by a chemical substance, such as borax or sal ammoniac, that unites with the fuse wire and by forming a non-conducting substance destroys the conductivity of the fuse in case its temperature rises above a specified degree. Sometimes a fine fuse is spread outside the tube so as to melt after the main fuse inside and thus indicate whether it has melted. In others, such as the Edison fuse plug, the fuse wire is encased in a glass or porcelain cup from which air draughts are excluded by the cover. Enclosed fuses are more reliable than the older open fuses because the fuse wire is under practically the same conditions at all times and will therefore melt at a more definite temperature; they are coming into extended use.

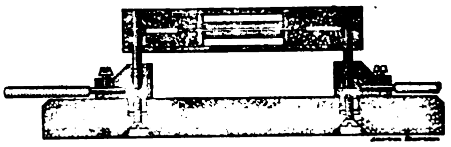

FIG. 3.—ENCLOSED FUSE.

559. *What is a protected fuse?*

Some manufacturers make fuse blocks in which the fuse is enclosed in a porcelain tube or channel having a small aperture through which the vapors following the melting fuse can escape, the arc being blown out. The tube protects the fuse from air draughts and from contact with other substances and also fixes it at a definite length. In the protected fuses the fuse wire is generally in a piece separate from the rest of the block, so that the fuse may be renewed while the cover or plug piece is entirely detached from the circuit, thus making them safer to handle than the ordinary open fuse block.

560. *What is a detachable fuse?*

The fuse terminals of a detachable fuse block are attached to the cover piece, that is, to a piece which may be removed from the stationary block so that the fusible portion may be placed in the cover or "pocket" while entirely disconnected from the circuit, the connections being made when the cover is placed in position on the base. See Fig. 4.

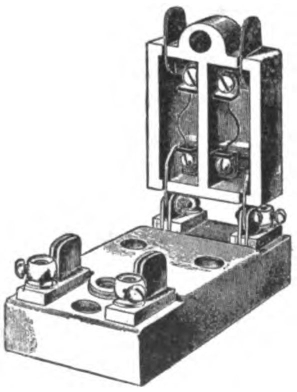

FIG. 4.

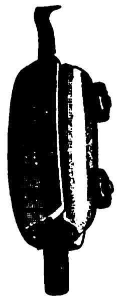

FIG 5.

561. *What is a "bug" cutout?*

Bug cutouts are small single-pole cutouts for placing in cramped and awkward places, such as in fixtures, where a regular fuse block is impracticable. (Fig. 5.)

Queries and Answers

IMPORTANT.—No attention will be given to inquiries which do not give the full name and address of the inquirer.

What is the latest calorific value accredited to carbon completely burned? T. S. M.

14,600 B. T. U. per pound.

Would the underwriters approve using No. 18 annunciator wire to connect sixteen 3-c.p. lamps in series on a 220-volt circuit? R. L. T.

Most assuredly not.

Is there any way of preventing the needle of a steam gauge from quivering in accord with the strokes of the engine supplied from the same boiler, except by nearly closing the small cock in the gauge syphon? W. J. C.

None that we know of.

I connected the secondary of a battery-excited induction coil to the primary of another, but got no current from the secondary of the second coil. Why was this? I. B.

Because the resistance of the first secondary winding is entirely too high to pass sufficient current to excite the primary of the second induction coil.

Is a double-pole single-break switch preferable to a single-pole double-break switch? If so, why? W. T. S.

Yes; because the double-pole switch leaves the apparatus entirely dead when the switch is open, while the single-pole switch leaves one terminal of the apparatus still connected to one side of the circuit.

What is the difference between a plug valve and a piston valve in steam-engine work? G. H. C.

A piston valve may or may not be a plug valve according to its construction. If it is hollow in the center it is not a plug valve. On the other hand, a plug valve may be either a piston valve, reciprocating parallel with its longitudinal axis, or it may be a rocking valve, reciprocating circularly about that axis.

What is the best way to supply a lamp in a telephone booth during the day when incandescent service is not obtainable? During the night the lamp is supplied from an ordinary 110-volt incandescent circuit. The door is provided with an automatic switch which cuts out the lamp when the booth is not in use. F. M. A.

Change the lamp which is now in the booth to a 95-volt 50-c.p. lamp, and connect it in series with seven small storage cells during the night. During the day, disconnect the storage cells from the circuit and use them to light a 12 or 14-volt 8-c.p. lamp.

Why is the iron loss in a transformer reduced by putting more turns in the winding; is not the flux greater? Adding more turns gives a greater exciting force and produces more flux. W. F. G.

In a transformer used on a constant-potential circuit adding more turns does not increase the exciting force; the magnetizing force is reduced by a greater number of turns. The amount of flux necessary to produce the requisite counter e.m.f. is less; therefore, the core loss is less. If the transformer were on a constant-current circuit then the flux and the core loss would be greater with a greater number of turns in the winding.

About what pressure is carried in the boiler of a steam automobile? (2). About how long does it take to get up a full head of steam, starting with cold water? C. H. H.

Two hundred pounds. (2) From 10 to 20 minutes, according to the type of boiler.

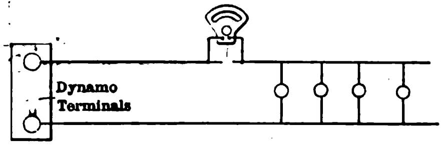
What is the difference between a hydrocarbon engine and a kerosene-oil engine? J. W. E.

None; the term hydrocarbon merely means that the fuel used is composed of hydrogen and carbon. Both kerosene and gasoline come under the head of hydrocarbons.

What is meant by "cycle" in alternating-current work? E. H.

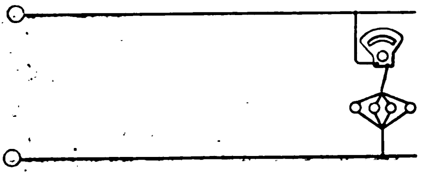
A cycle is two alternations of the current or e.m.f. as the case may be—that is to say, starting from zero the e.m.f. and current rise to a maximum in one direction, then fall to zero again, then rise to a maximum in the opposite direction and come back to zero; this is one cycle.

If a voltmeter be connected in series with an incandescent lamp circuit like an ammeter, as shown by the accompanying sketch,



will not the whole current pass through it and burn out the coils? 2. Will the lamps light? W. T. K.

Not if the voltmeter is built for a voltage equal to or above that of the dynamo which supplies the circuit. Such a connection simply means connecting the voltmeter across the terminals of the dynamo in series with the group of lamps, as shown in the second diagram. The current through the voltmeter coils will be less than if it were connected directly across from wire to wire of the circuit. If the voltmeter be designed for an e.m.f. much lower than the circuit e.m.f., however, it will be burned out, just as it would if connected across the line in the ordinary manner. 2. No.



Is more power required to raise a body of water to a given height than the same body of water would develop in falling from that height? If so, what makes the difference? C. E. S.

Assuming that the rates of raising and falling are the same, more power is required to raise a body of water than that body develops in falling, on account of the friction which has to be overcome in raising it, and the friction loss which is suffered by the falling water. If the element of friction could be entirely ignored the power would be precisely the same in both cases.

How can a series-wound booster dynamo be connected up so that it lowers the voltage instead of raising it? A. J. W.

Reverse either the terminals of the field winding or the connections between the brushes and the circuit, continuing to drive the armature in the same direction as before. If the field terminals are reversed, the result will be a reversal of the polarity of the field magnet, which will cause the voltage to oppose the e.m.f. of the circuit. If the armature terminals are reversed, the polarity of the brushes will continue the same as before, but their effect upon the external circuit obviously will be reversed.

How can two-phase currents be transmitted over three wires? (2). Is a special winding required on the generator, or some transformer? (3). In which of the three wires must a wattmeter be connected? H. A. G.

Combine two of the wires from the two phases into one wire of 1½ times the cross-section of each of the other two. (2). The generator armature must have a separate winding for each phase, or else transformers must be interposed between the four leads from the generator and the three legs of the circuit. (3). The series winding of the wattmeter should be inserted in one of the outside wires of the three-wire feeder, and the potential coil connected across from the large middle wire to one of the outer wires. The wattmeter will indicate only the energy supplied to one side of the circuit, however; if the two sides are absolutely balanced, multiply the readings of the wattmeter by 2.

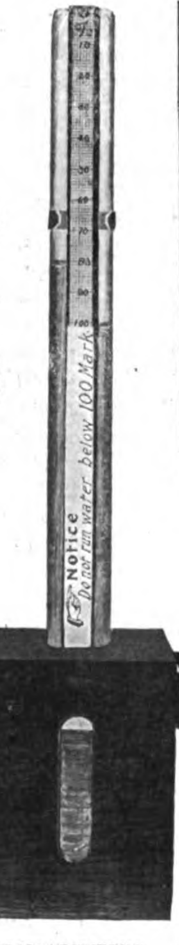
What is the difference between integrating and recording wattmeters? (2) When a differentially-wound booster helps a storage battery to discharge does it help the battery or does the booster cease to generate? If the latter, why is the booster not cut out of circuit during the discharge? J. C.

These terms are used interchangeably, but strictly there is a difference. A recording wattmeter integrates the energy passed through it with respect to the length of time of the service. An integrating wattmeter may be a recording wattmeter or simply an instrument to indicate variations in power.

(2.) When a differentially-wound booster is used in connection with a storage battery it merely interposes more or less counter e.m.f. in the storage-battery circuit, according to the conditions of the load. If the condition is such that the load is heavy then the counter e.m.f. of the booster is lowered so that the batteries can discharge and help out the generators; as the load becomes lighter the counter e.m.f. of the booster increases, reducing the discharge of the batteries, and when the load falls below the comfortable capacity of the generators the booster does not give any counter e.m.f. and allows the dynamos to charge the batteries. The booster cannot be cut out of circuit because the automatic regulation just mentioned would be annulled if it were thrown out; moreover, this would require personal attendance, whereas with the use of a properly designed booster no attendance is necessary.

BRYAN-MARSH COMPARIMETER.

One of the most ingenious uses to which the electrolytic action of current upon water has been put is found in a little instrument manufactured by the Bryan-Marsh Company, of New York City, for the purpose of testing the economy of incandescent lamps. The instrument consists of two glass tubes mounted side by side in the stopper of a vial containing slightly acidulated water. The open ends are carried down almost to the bottom of the vial, so as to be always below the level of the water; the upper ends are closed. Two lamp sockets are mounted on the sides of the box containing the vial, as shown in the cut, and these sockets are connected in parallel by wires which lead through glass tubes, the wire for the left-hand socket passing through the left-hand tube and the one for the right-hand socket passing through the right-hand tube. The lamps to be compared must of course be of the same candle-power and voltage as the two sockets are connected in parallel across the circuit from which the testing current is taken. Before turning on the current the instrument is turned upside down so that the water fills both of the tubes, then it is righted and the current turned on. The passage of current through the water in the tubes liberates gas which rises in the tubes and forces down the liquid against the external atmospheric pressure, which had previously held it up. The amount of gas liberated is proportional to the amount of current passing; consequently, the water in the tube corresponding to the lamp which takes the most current will be forced downward more rapidly than that in the other tube. A scale, graduated from zero to 100, is provided, as shown in the engraving, and this forms the means for a direct comparison of the efficiencies of the two lamps. The current is kept on until the level of the water which is falling most rapidly almost reaches 100, when the lamps are switched off and the additional gas liberated will bring the level down to 100. Then the level of the water in the other tube is noted. If the level is 98, for example, it shows that the lamp on that side takes 98 per cent of the current taken by the other lamp. One of the evident advantages of the instrument is that fluctuations of the e.m.f. of the circuit supplying the testing current do not vitiate the results of the test.



COMPARIMETER.

THE C & C SERIES-PARALLEL SYSTEM OF CONTROL FOR PRINTING-PRESS MOTORS.

The peculiar requirements of printing-press electric-motor service and the difficulties of providing accurate speed control through abnormally wide ranges of speed are too well known to need reparticularization here. In order to meet these requirements and provide the degree of control demanded, the C & C Electric Company has perfected what is termed a "series-parallel" method of control for printing-press motors. This consists broadly in providing the armature of the motor with two distinct windings and commutators which may be connected either in series or in parallel; providing compound field windings, the series coils of which are cut in and out of circuit; and effecting various combinations of these parts with the controlling apparatus, which is partly operated by hand and partly by automatic devices.

Fig. 1 is a view of the motor, which is a multipolar machine of usual construction except for the features mentioned above. Fig. 2 represents the controller lever, which is provided with a quadrant and spring latch to lock the controller handle in the various running positions. The lower end of the controller handle is connected with the controller itself by means of a rod or link; and the controller, shown by Fig. 3, is a combined field and armature rheostat, provided also with additional contacts which close circuits through two sets of solenoids actuating what are known as the "on-and-off" switch and the "series-parallel" switch. The function of the on-and-off switch, as its name indicates, is simply to open and

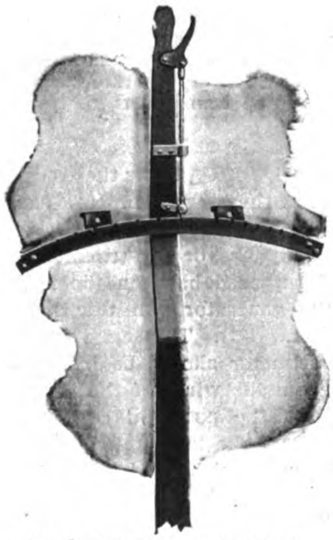


FIG. 2.—CONTROLLER LEVER

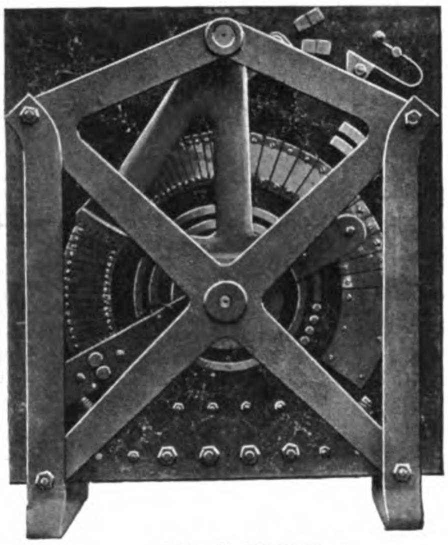

FIG. 3.—RHEOSTAT.

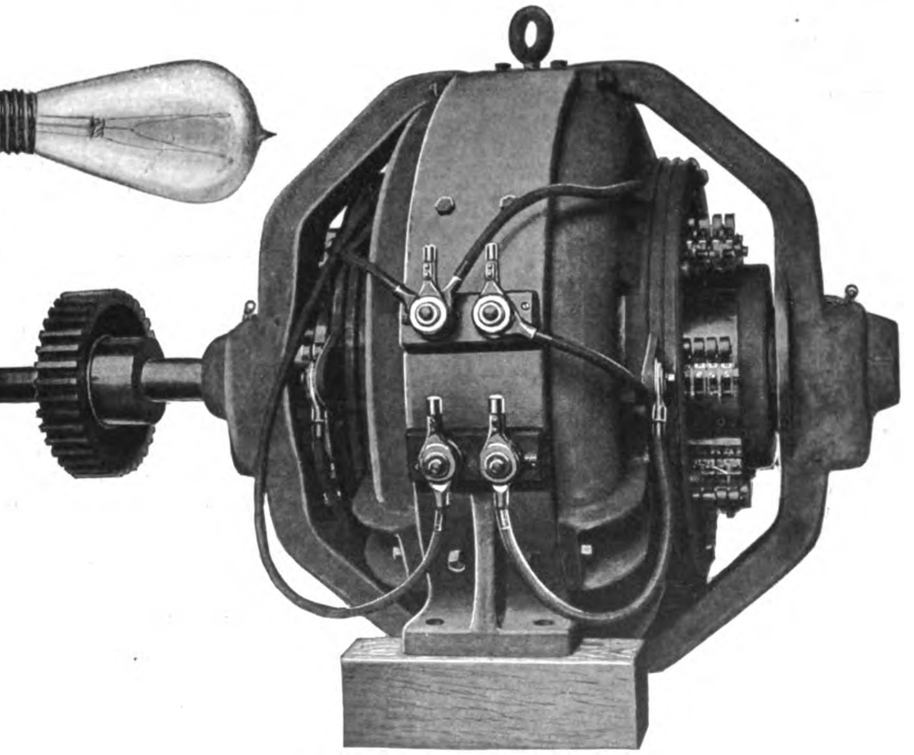

FIG. 1.—DOUBLE-COMMUTATOR MOTOR FOR PRINTING-PRESS SERVICE.

close the main circuit of the motor, and thus prevent the arcing and burning which would take place at the traveling contact finger of the rheostat. The series-parallel switch throws the two armature windings in series or in parallel according to the position of the controller, one solenoid throwing the switch in one direction and the other throwing it in the opposite direction. The controller connections are such that at the instant when the series-parallel switch operates to throw the armature windings from series into parallel, a small amount of resistance is interposed in the armature circuit to prevent too sudden an increase in speed. The on-and-off switch can also be thrown to break the motor circuit and stop the motor by pressing any one of several emergency buttons which are provided at different points. The apparatus is so arranged that when the machinery is stopped by pressing an emergency push the motor cannot be started again until the controller lever has been thrown back to the starting position. Four emergency pushes of the floor type are ordinarily supplied, and one on a wall panel near the press.

The principal regulation is obtained by cutting in and out the series field coils and changing the two armature windings from series to parallel and vice versa. As intimated above, there is also a resistance in the shunt field circuit of the motor which gives from 5 to 10 per cent increase above the normal working speed of the press. This resistance, however, is what might be termed an "emergency device" for obtaining higher speeds at each control point in the case of a rush.

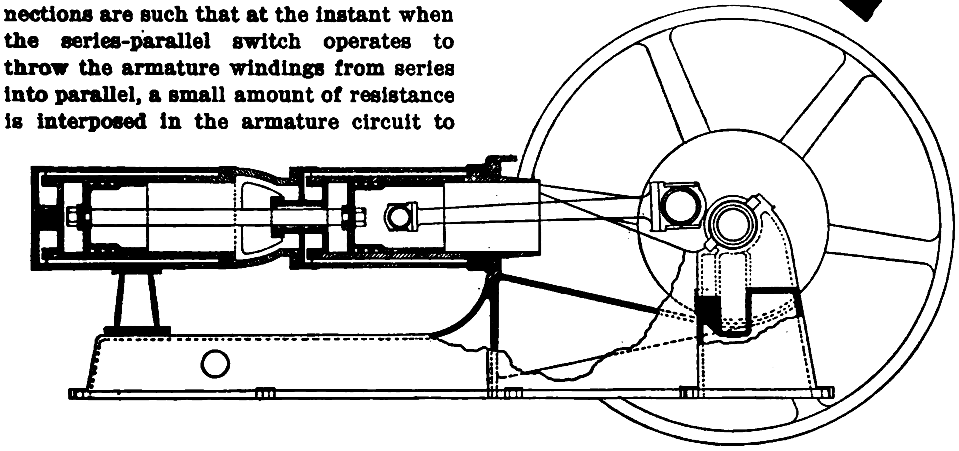

FIG. 1.—SECTIONAL VIEW OF ENGINE

◆

THE "MODERN" GAS ENGINE.

The Modern Gas Engine Company, of Buffalo, N. Y., is manufacturing a line of very compact double-cylinder engines, one of which (a 30-h.p. engine) is shown in perspective by Fig. 2, and in section by Fig. 1. In ordinary single-cylinder engines of the four-cycle type, only one explosion for each two complete revolutions can be obtained. In the engine here shown, an impulse on the crank is obtained at every revolution, the cylinders acting alternately. The arrangement of the cylinders in tandem obviously simplifies the construction and reduces the weight of the engine as compared with double-crank construction.

The bearings are self-oiling; the connecting rod is made of forged steel and provided with removable babbitt linings, which construction, it is stated, has been found to be more satisfactory than the strap arrangement. One of the most important features of construction is the arrangement of the piston rod connecting the two plungers. The rod passes through a stuffing box, of course, and this stuffing box is thoroughly water-jacket[illegible] the piston rod is made of forged s[illegible]nd in order to prevent the rod from cutting the packing in the stuffing box, a cast-metal sleeve is provided, extending from piston to piston, and completely enclosing the piston rod.

Regulation is effected by throttling the charge, which, as is well known, gives more uniform rotation than the hit-and-miss method. The ignition is electrical; the igniters are built up on small cast-iron plugs, which are inserted in the wall of the respective inlet-valve chambers, and held in place by two studs.

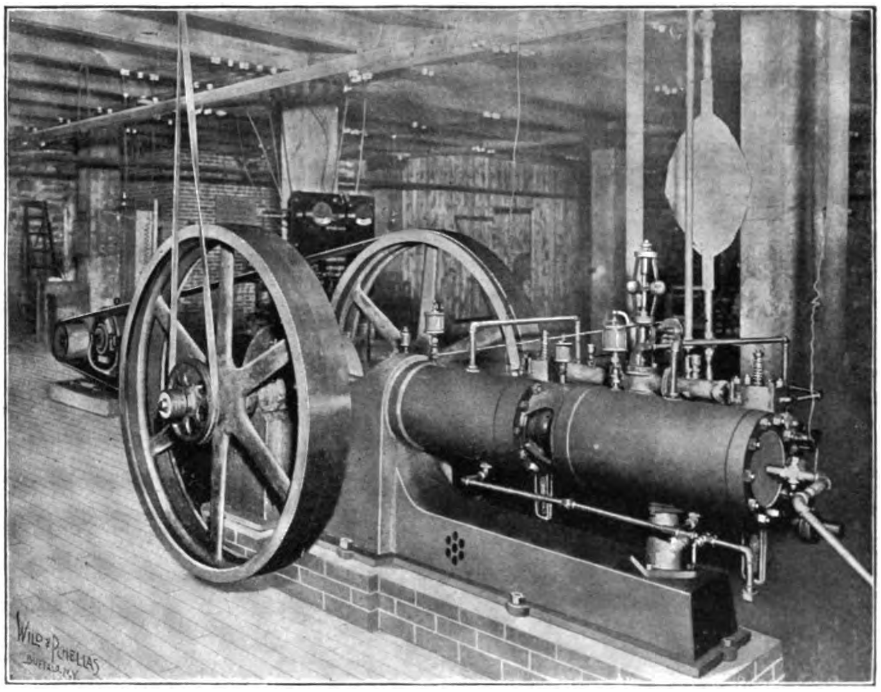

FIG. 2.—A 30-H P. "MODERN" GAS ENGINE.

The builders call particular attention to the fact that the platinum points of the igniters are kept cool by being located in the inlet chambers instead of in the cylinders, as they are directly in the path of the fresh charges of cold air and gas. The company is giving special attention to the design of these engines for electric-light work, and supplies the engines adapted either for direct connection or belt driving. Complete electric-lighting outfits are built for 40, 50, 60, 80 and 100 lights capacity.

◆

AUTOMATIC PLATING MACHINE [illegible]R ARC-CARBONS.

A new machine for automatically and continuously plating arc-light carbons which was installed last fall by the United States Carbon Company is a most ingenious piece of special mechanism. The principle of the machine is simplicity itself. The carbons to be plated are deposited in large quantities in a hopper from which they are taken by a revolving drum and automatically fed to 3000 individual holders carried on a continuous chain belt. The holders, in circuit with the plating current, carry the carbons for a distance of 175 ft. through 14 plating tanks, passing from one tank to the next over large idler wheels. After passing through the plating tanks the carbons pass through three tanks containing hot water, for boiling out the copper salts and fixing the color of the copper coating.

The endless belt carrying the carbons then returns overhead through the drying chambers, and after being registered on a mechanical counter the carbons are automatically discharged from the holders onto a conveyor which carries them a distance of 50 ft. to the packing room. This machine has a capacity of 120,000 carbons a day. Among the electrically-operated labor-saving devices used in connection with this machine is a small double-trolley motor car, for lifting and moving any one of the large plating tanks when it becomes necessary to clean it out.

New Apparatus and Appliances

G. I. ENCLOSED ARC LAMPS FOR SERIES ALTERNATING CURRENT CIRCUITS.

Figs. 1 and 2 illustrate the principal features of a series of alternating-current arc lighting system developed by the General Incandescent Arc Light Company, of New York. The lamps are intended to operate in series groups on constant-potential circuits and are of the enclosed-arc type; the difference of potential required at the terminals of a series of lamps is 80 volts per lamp. The feed-regulating solenoids are in shunt with the arc and control the feed through a Ω-shaped laminated armature and clutch applied directly to the carbon. As there are no windings in series with the arc, the voltage at the lamp hanger is practically identical with that across the arc, namely, 72 volts. These lamps are connected in series with a regulator, which operates to maintain constant current through the group; the allowance of 80 volts per lamp is to include the drop in the regulator.

The latter consists of a pair of coils into which the legs of a laminated U-shaped core are drawn by the current circulating in the coils. Two retractile springs oppose the attraction of the solenoids. It is evident that the farther the cores are drawn into the coils, the greater will be the reactance of the latter; when the current exceeds the amount for which the springs are adjusted, the coils pull the cores in until their reactance is increased sufficiently to cut down the current flow to the proper value. The standard size of regulator is designed for use in series with 25 lamps; for circuits of over 25 lamps, two or more regulators (according to the number of lamps) are used in series. This practice is preferred over the use of larger regulators, because of the better ventilation and lesser strain on the insulation of several small windings, as compared with a single large one.

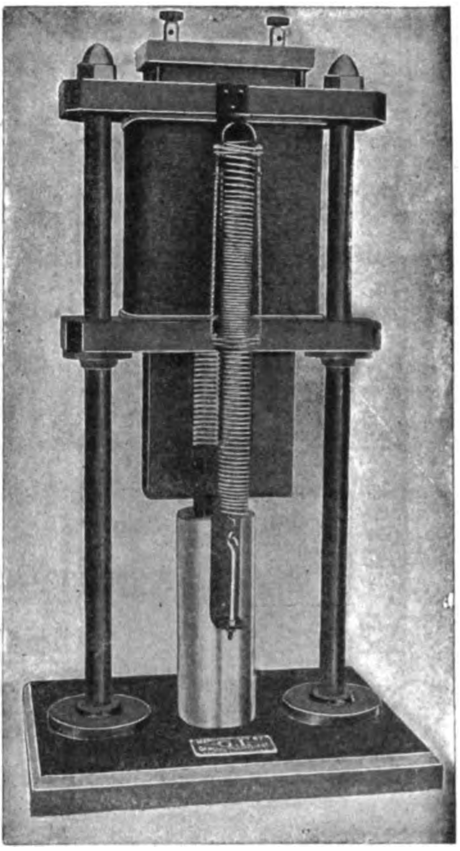

FIG. 2—REGULATOR FOR SERIES GROUPS.

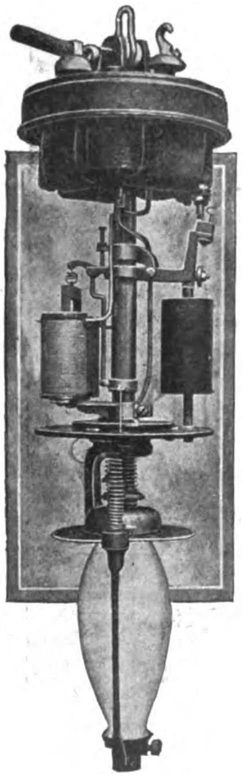

FIG. 1.—G. I LAMP.

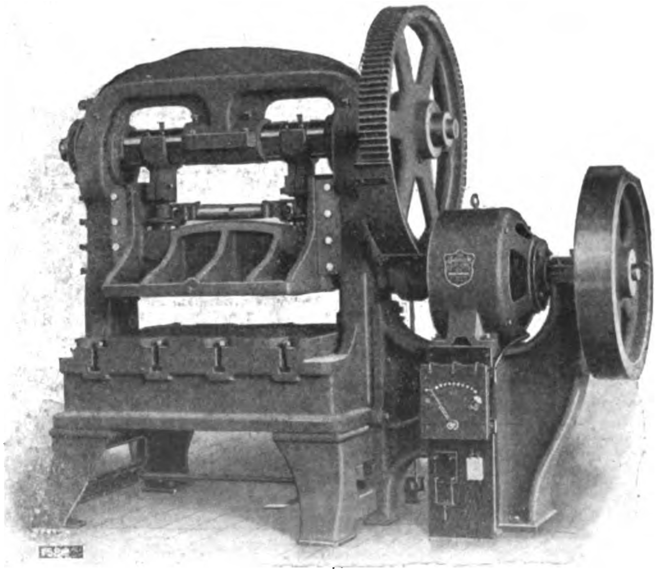

FIG. 3.—BULLOCK MOTOR DRIVING A BLANKING PRESS.

BULLOCK MACHINE TOOL MOTOR.

The Bullock Electric Manufacturing Company, Cincinnati, Ohio, is manufacturing a special type of motor, known as "Type N," and designed particularly for driving machine tools. The motor is a multipolar machine with a circular cast-steel yoke and laminated sheet steel magnet cores bolted to the yoke. The magnet core punchings have half pole-shoes, and in assembling the cores the punchings are alternated, so that while the complete core shows a pole-shoe on each side, the thickness of the pole-shoe parallel with the armature shaft is only one-half the thickness of the magnet core. The result is that the pole-face is magnetically saturated, conducing to sparkless operation. The magnet coils are machine wound and insulated before being placed on the magnet poles. The armature core discs are annealed and japanned before assembling. The armature winding consists of formed coils of the usual type, insulated before being placed on the core, and held in the slots by wedges of hard wood. The machine is furnished either semi-enclosed or completely enclosed, according to the conditions under which it is to work. Fig. 3 shows one of these motors geared to a stamping press. For this class of service, where the load comes in the shape of a sudden shock at intervals, the motor is provided with a heavy fly-wheel, which takes the brunt of the shock. These machines are built in sizes ranging from ⅛ to 35 horse-power at 300 r.p.m.; 1 horse-power to 70 horse-power at 600 r.p.m.; 1½ horse-power to 100 horse-power at 900 r.p.m., 2 horse-power to 25 horse-power at 1200 r.p.m. These ratings are for motors with ventilating openings in the end plates, as shown in the illustration; when the motor is completely enclosed its rating is lower, of course.

PRINGLE PORCELAIN PLUG AND FLUSH RECEPTACLE.

W. T. Pringle, of Philadelphia, has brought out a new form of plug and receptacle for incandescent-lighting service, which are illustrated by Fig. 4, below. The illustrations are practically self-explanatory. The plug is of high-grade nonabsorbent porcelain, carrying flat contact strips on the two edges furthest removed from each other, and is provided with the usual facilities for fusing. The handle, or part of the plug which is exposed when it is in the receptacle, is handsomely finished in dead black to resemble hard rubber. The receptacle has a cover which entirely encloses the socket when the plug is withdrawn, leaving a smooth continuous metal surface exposed. The connections are made from the front, thus obviating the objection of having to push a lot of slack wire

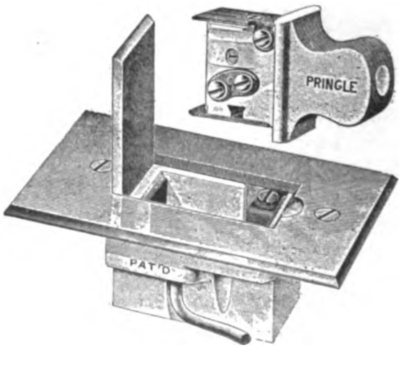

FIG. 4.—PRINGLE PLUG AND RECEPTACLE.

back into the wall. The depth of the porcelain is less than 1½ ins., so that the receptacle may be used in comparatively thin partition walls. The face plate need not be put on until the wiring is finished.

L-H ENCLOSED-ARC LAMPS.

Figs. 5 to 7, inclusive, represent the direct-current enclosed-arc lamp made by the Lea-Hooven Manufacturing Company, of Anderson, Ind. The mechanism of the lamp is very clearly shown by Fig. 6; the clutch, which is a modification of the Brush type, is actuated by a double solenoid, the movement of the armature being suitably damped by a dash-pot. The dash-pot cylinder is provided with two steel ball valves and the plunger is of fiber graphite. This construction is said to obviate the flickering which is so often seen when an arc is first struck, and to render the mechanism free from irregular action due to expansion of a dash-pot plunger. Connection between the upper carbon and the stationary part of the mechanism is not effected by means of a sliding contact, but by a flexible cord from the upper end of the carbon to one solenoid terminal. The resistance wire is wound on a core consisting of a piece of flattened bicycle tubing having a grooved strip of vitrified porcelain on each edge, as shown by Fig. 5. The wire, therefore, cannot sag under the influence of its own heat and cause short-circuits between convolutions. Fig. 7 illustrates the readiness with which access is had to the inner globe and carbons. The lamp measures 22 ins. in length, over all, when fitted with a globe, and 21 ins. when fitted with a shade.

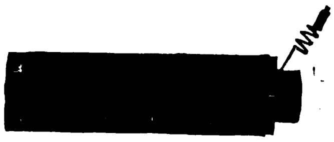

FIG. 5.—RESISTANCE COIL.

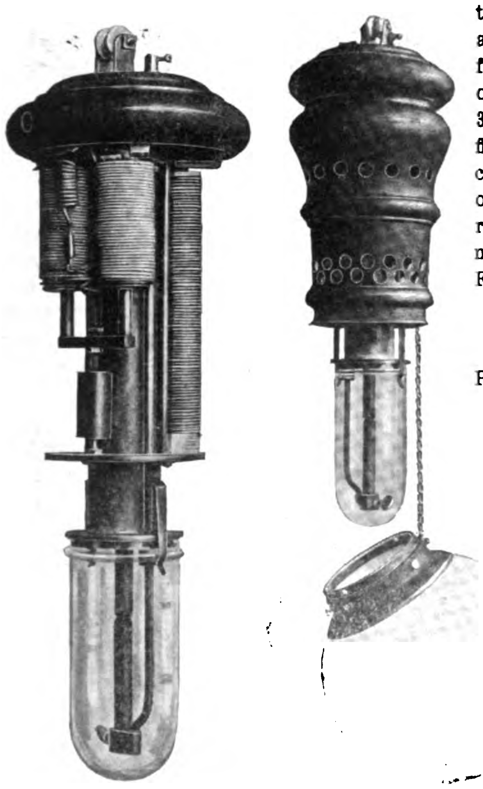

FIG. 6.—LEA-HOOVEN ENCLOSED ARC LAMP —FIG. 7.

THE FRANKLIN DYNAMO.

Parsell & Weed, of New York City, are supplying the parts for an interesting little machine, designed for amateur construction. Fig. 8 shows the machine complete. The field magnet is made up of laminations and is of the horseshoe type. The design of the machine is very similar to the small bipolar Perret motor. The yoke of the field magnet is made up of alternate long and short strips, in order that the laminations may completely fill the space bounded by the outline of the yoke cross-section. The armature core is of the slotted type having eight slots for armature coils. When used as a motor, this little machine will drive a sewing-machine, a dental engine or a watch-maker's lathe. The winding is designed for battery current with 10 volts e.m.f. at the terminals of the machine. When run as a dynamo the machine will maintain four 2-c.p. lamps. The complete machine occupies a space of 3½ ins. x 6½ ins., is 3½ ins. high and weighs 5¼ lbs. The firm supplies the parts in various stages of completion; they are supplied in the rough or partly finished, or completely finished ready for assembling and winding; the machine is also supplied completely built. Full instructions go with each set of parts.

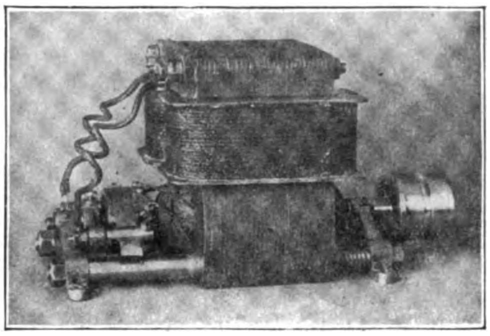

FIG. 8.—FRANKLIN DYNAMO.

P. P. P. ROD PACKING.

The Quaker City Rubber Company, Philadelphia, Pa., calls attention to a peculiarly elastic form of rod packing which is illustrated by Figs. 9 and 10. The packing consists of two strips each of triangular cross section surmounted by an approximately semi-circular cross section of eleven strands, as shown in Fig. 9. The object of the triangular sections is to obtain a positive mechanical spreading when pressure is applied to the packing; an inspection of Fig. 10, which shows the packing in a stuffing box, will render this clear. The semi-circular portion of the packing is compressed so as to fill the entire available space, and the triangular sections slide upon each other with the same result. The stranded portion of the packing is an absorbent cushion which holds the oil and keeps the rod lubricated. The triangular sections are made with a view to withstanding wear. The packing is said to be impervious to the action of acids, alkalies and sulphurous waters, and to remain soft and elastic throughout its life.

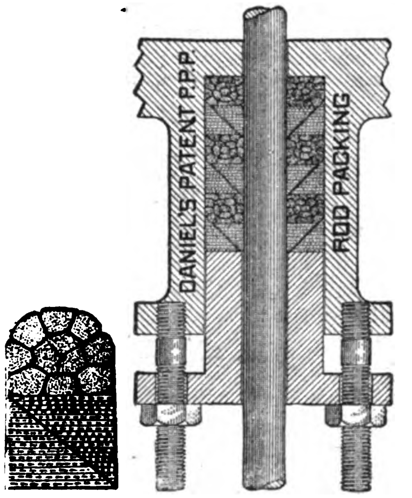

FIG. 9.—P. P. P. PACKING.—FIG. 10.

NEW ZIMDARS & HUNT FLUSH PLUG RECEPTACLE.

Figs. 11 and 12 illustrate the latest form of flush receptacle and plug brought out by Zimdars & Hunt, of New York City. One of the principal features of the apparatus is that when the plug is in position within the receptacle there is no protruding knob to be injured by accidental blows and to mar the ornamental appearance of the face-plate of the receptacle. As the engravings plainly show, the receptacle is provided with a split cover, each half being hinged to the plate; the two halves form virtually two doors, which completely enclose the plug when it is in the receptacle. The new form of recep-

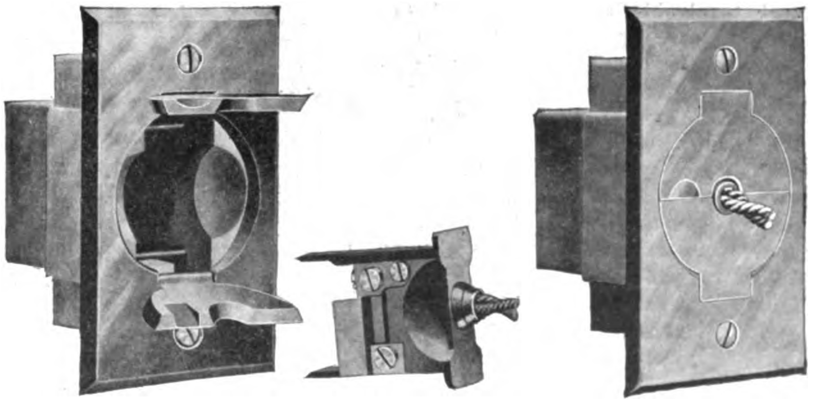

FIG. 11.—ZIMDARS & HUNT PLUG AND RECEPTACLE.—FIG. 12.

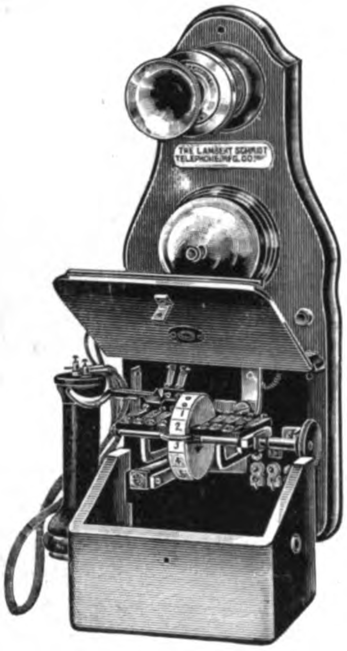
tacle is provided with binding posts at the top so that removing the face-plate enables the workman to make the wire connections easily when the receptacle is in place on the wall. The plug is provided with knife-blade contacts which fit into substantial clips in the pocket of the receptacle, and it also has fuse connections. The face-plate is supplied in polished bronze or in brass finish, as may be desired.

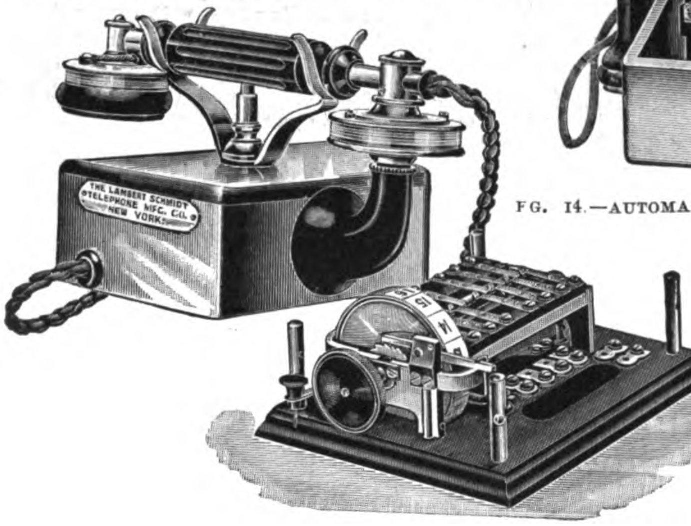
AUTOMATIC-RESET INTERCOMMUNICATING TELEPHONE.

The Lambert Schmidt Telephone Manufacturing Company, New York, has recently introduced an automatic-reset intercommunicating telephone outfit which is illustrated by Figs. 13 and 14. Fig. 13 illustrates the desk telephone outfit, which comprised a black-enameled base surmounted by a switching device encased in a nickel-plated cover. On the top of the cover is a metal support, forked at the ends, through the center of which passes a tube with a hard rubber piston extending upward from within the cover. The microtelephone, or combined transmitter and receiver, is connected to the stand by a flexible cord and lies horizontally in the forked supports. The selective switch consists of a series of metal pins projecting at different angles from a central revolvable steel shaft, and arranged to make wiping contact with stationary springs mounted on each side of the shaft and connected with the various stations of the system. The spindle of this switch is normally held at the home position by a spring witnin the box and carries a ratchet wheel having a number of teeth corresponding with the number of stations, and consequently, the number of positions to which the switch may be turned. A pawl is so arranged that when the microtelephone is removed from its support the piston beneath the center of the handle is allowed to rise and bring the pawl into engagement with the ratchet wheel, so as to hold the selective switch in the position to which it has been turned before the telephone was removed from its support when the conversation is finished and the telephone replaced it presses down the rubber piston and releases the ratchet wheel, allowing the spring to return the switch spindle to the home position. The spindle also carries an aluminum wheel bearing the numbers of the stations, as shown in Fig. 13. When the cover is in place these numbers come opposite a little window in the top of the box so that the position of the selective switch is indicated through this window. The procedure in calling up is as follows: The microtelephone is first removed from its support and the switch is revolved by means of the knob at the side of the box until the number of the station wanted appears at the window on top. Then that station is rung up by means of a push button, not shown in the engravings. Taking the telephone off its support allows the pawl to engage with the ratchet wheel, as mentioned above, so that the switch remains at the point to which it was turned, until the telephone is replaced on the hooks. The system requires one individual wire for each station and two common wires running through all of the stations. A common battery is used for ringing, but local batteries are required for the transmitters. This arrangement is also applied to wall telephones, as indicated by Fig. 14. The construction is precisely the same except that the ordinary form of transmitter and receiver are used, the latter being hung on a receiver hook of the usual form.



THE LAMBERT SCHMIDT TELEPHONE MFG. CO.

FG. 14.—AUTOMATIC-RESET WALL OUTFIT.



THE LAMBERT SCHMIDT TELEPHONE MFG. CO. NEW YORK

FIG. 13.—AUTOMATIC-RESET DESK OUTFIT.

RICHMONDT ELECTRO-GALVANIZED CONDUIT.

One of the principal difficulties encountered in installing wiring in conduits is the abrasion of the insulation by rough surfaces within the conduit in the course of drawing in the wire. With a view to eliminating this trouble, the Richmondt Electric Wire Conduit Company, Milwaukee, Wis., has brought out what it calls an electro-galvanized wire conduit tubing, the principal feature of which is the provision of a uniformly smooth surface on the interior wall of the conduit pipe. This is obtained by applying a coating of enamel to the wall throughout the length of the tube. The conduit tube is reamed in order to obtain an absolutely uniform size and it is then completely galvanized, including the threads, after which the enamel is applied to the interior wall. The couplings are also galvanized. Another feature which contributes to the ease of drawing in the wire is a slight flaring of the end of each section of conduit, as indicated in Fig. 15. This of course removes the sharp edge at the end of the pipe and prevents liability to abrasion of insulation at that point.

FIG 15.—ELECTRO-GALVANIZED CONDUIT

CLIMAX STEAM JOINT CLAMP.

Fig. 16 represents a Climax pipe joint clamp which is made by James McCrea & Co., of Chicago, for large pipes of say 10 ins. diameter and over. Referring to the engraving, the section marked A is a rigid clamp held tightly to the pipe by set screws. The middle section, B, is a loose collar, the function of which is to compress the packing, 1, which lines the interior of the collar, C. This latter collar is put around the pipe next to the joint and the clamp, A, is then set up tightly on

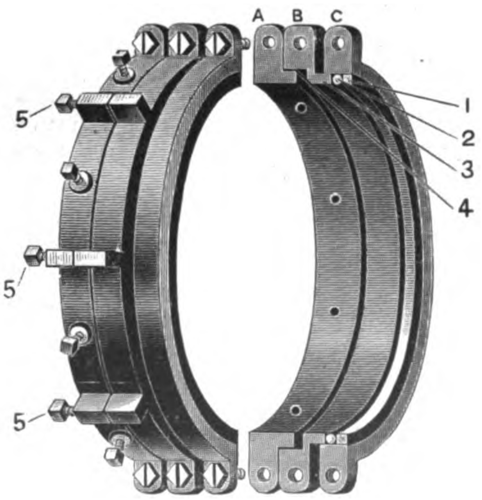


FIG. 16.—CLIMAX STEAM JOINT CLAMP.

the pipe. The set screws, 5, are then set up, forcing the loose ring, B, over toward the ring, C, and compressing the packing ring, 1, against the shoulder of the joint through the medium of the follower ring, 2.

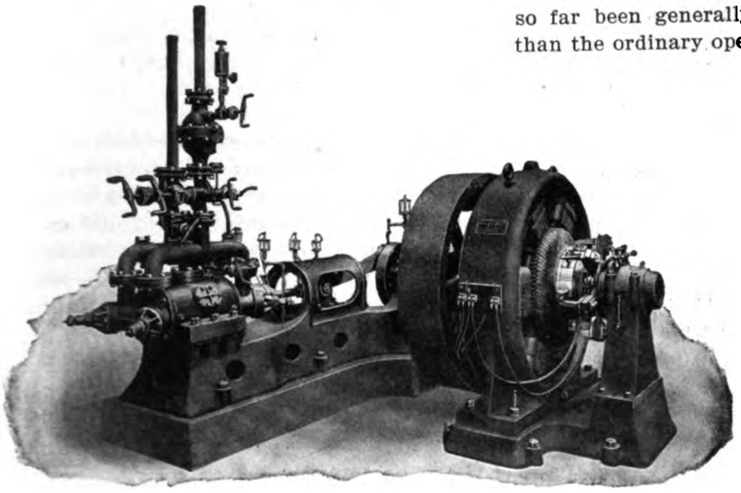

FIG. 17.—TRIUMPH REFRIGERATING OUTFIT.

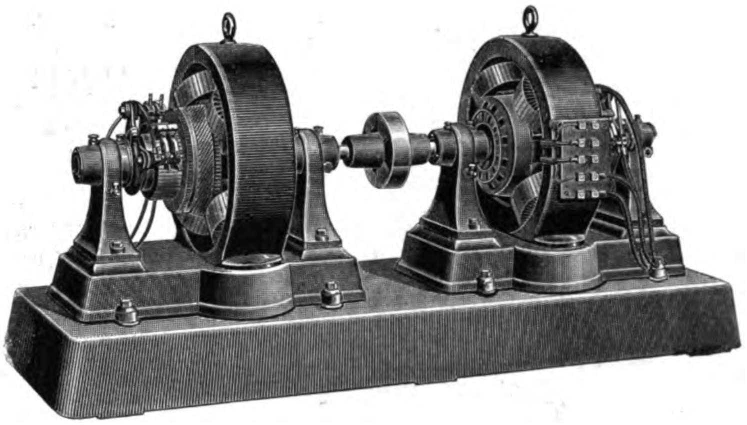

FIG. 18.—MOTOR DYNAMO FOR TELEPHONE EXCHANGES.

TRIUMPH MOTOR AND AIR COMPRESSOR.

Fig. 17 represents a compact air-compressing outfit built by the Triumph Electric Company, Cincinnati, Ohio, for the new office building of the Union Trust Company of that city. The outfit forms part of the refrigerating plant of the building. The output of the motor is 25 horse-power, but as it runs at the extremely slow speed of 75 r.p.m., the frame of a 60-kw. generator had to be used for its construction. The motor is a six-pole machine with compound field windings, the series winding being used in order to obtain high torque without excessive current when the compressor is passing the maximum points at each end of the cylinder, the ice machine being double acting. A speed of 85 r.p.m. is obtained, when desirable, by the use of a rheostat in series with the shunt-field winding of the motor. The plant is to furnish 350 gallons of ice water an hour, filtered at 38° Fahrenheit. and water is furnished to the refrigerating plant at a temperature of 85 to 90°. The plant also includes two triplex pumps belt-driven by slow-speed Triumph motors running at 600 r.p.m.; one of these pumps is used for circulating the brine and the other for delivering ice water to the distributing system, which extends throughout the seventeen stories of the building.

SEMI-ENCLOSED COMMERCIAL GENERATORS.

Enclosed and semi-enclosed dynamos and motors of small sizes have been familiar to engineers for some years past, but machines of considerable size have not so far been generally built in any other than the ordinary open form. Fig. 19 herewith illustrates the field magnet of a new type of semi-enclosed generator developed by the Commercial Electric Company, of Indianapolis, Ind., and built in sizes from 25 to 120 kw. capacity. The machine is multipolar, of course, and the feature which differentiates it from the other multipolar generators built by this company is the use of the perforated end plates, which partially inclose the field magnet cores and windings. The armature is of the usual type, having a slotted core carrying form-wound and heavily insulated coils. A complete armature and its commutator are illustrated by Fig. 20.

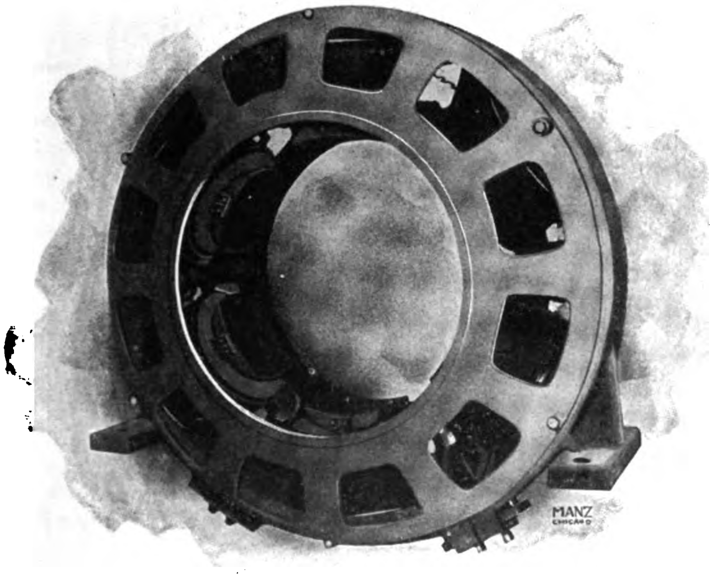

FIG. 19 —SEMI-ENCLOSED GENERATOR MAGNET

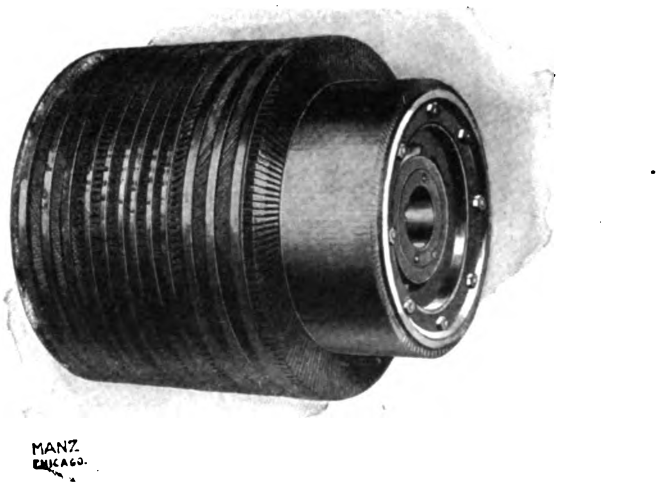

FIG. 20 THE ARMATURE.

HOLTZER-CABOT TELEPHONE EXCHANGE MOTOR-DYNAMO.

The accompanying illustration, Fig. 18, represents the latest type of motor-dynamo brought out by the Holtzer-Cabot Electric Company, Brookline, Boston, for telephone exchange service. The motor is a standard direct-current multipolar machine and drives the telephone generator through a flexible insulated coupling. The dynamo is provided with an unusually large number of armature coils and commutator segments, which feature, combined with a peculiar shape of pole-shoe, enables the machine to deliver an almost absolutely non-pulsating current. The manufacturers claim that the e.m.f. is so nearly uniform that the users of the telephone cannot tell that the current is not supplied from a battery. The dynamo may be used either for direct service or for charging storage batteries in multiple with the service mains. The outfit is built in sizes ranging from 1-kw. to 10-kw. output.

SCOTT HIGH-PRESSURE VALVE.

Fig. 21 represents a Scott gate valve built by the Roe Stephens Manufacturing Company, Detroit, Mich., for extra heavy pressures. This line was designed to fill a demand for a thoroughly durable and reliable valve to work under the heaviest steam pressures used in practice. The valves are tested to 1000 lbs. pressure per square inch. The body of the valve, as shown by the illustration, is reinforced by ribs parallel with the barrel. A peculiar internal construction is employed by means of which, it is said, all wear is removed from the face and seat, and springing of the discs is entirely prevented. The discs are raised by their lugs coming in contact with shoulders on a cylindrical wedge, and the lugs are so arranged that the bearings of one disc slightly rotate on the other; consequently, the least movement of the stem releases one disc in advance of the other, making it easy to open the valve under heavy pressure.

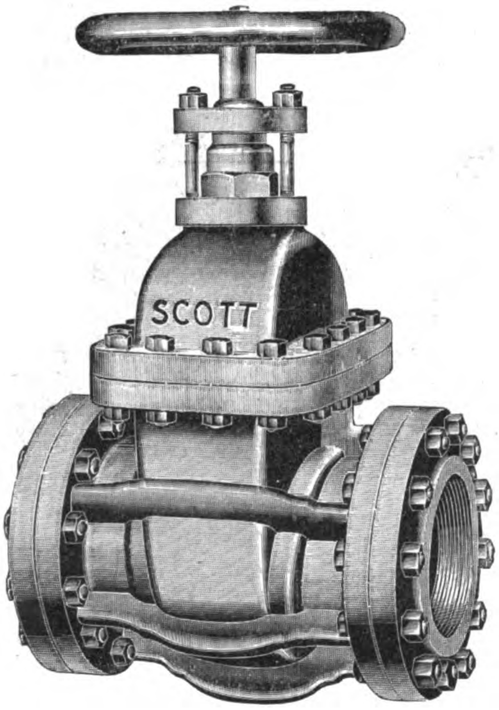

FIG 21.—SCOTT HIGH PRESSURE VALVE.

A NEW QUEEN PHOTOMETER SCREEN.

Queen & Co., Inc., of Philadelphia, Pa., have brought out a modification of their well-known Lummer-Brodhun photometer screen and sight box, which is illustrated in Fig. 22 herewith. The manufacturers state that the improvements embodied in this box enable the operator to obtain a balance, without the reversal of either the box or screen, which will be correct within 1/10 of 1 per cent on an average of 15 to 25 readings taken with the box set in all the various positions. This box is also said to be accurate on reversals within 2 millimeters on a 2500-millimeter bar; that is to say, within 8/100 of 1 per cent. When it is considered that photometer boxes are not ordinarily guaranteed within 10 millimeters on reversals, the extreme accuracy of this instrument will be appreciated. In order to keep the interior of the box clean and free from dust, the sides are fastened on with screws having milled heads, so that no tool is required to take off the sides for dusting out the box. The engraving shows the sight box mounted on a truck for use in connection with an ordinary photometer track; this truck is so arranged that it will take the regular Bunsen sight box, so that it may be used in connection with either type of box. There is also a convenient device for clamping the carriage at any desired position on the photometer bar.

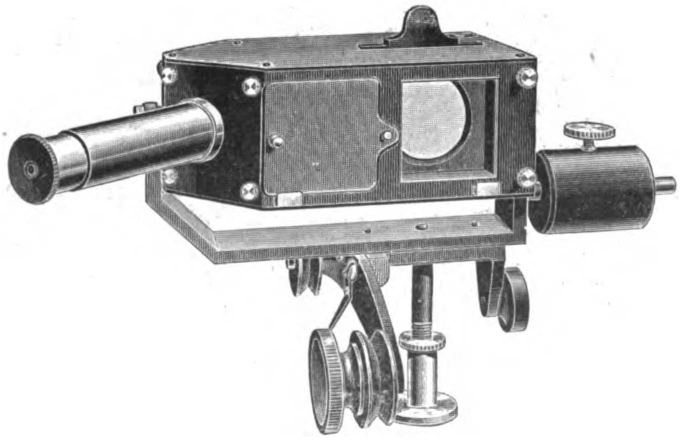

FIG. 22—PHOTOMETER SCREEN AND SIGHT BOX.

ELGIN ADJUSTABLE PIPE WRENCH.

The Elgin adjustable wrench, marketed by the Western Electric Company, is an extremely handy tool. Although the jaws are of the well-known "alligator" type, it is easily and accurately adjusted, and has a wide range of usefulness. It will hold pipe, nipples, collars, rods, and square, hexagonal or round nuts, making it useful to steam engineers, electricians, machinists and almost all other metal workers. It is nicely proportioned, well finished and fully nickel-plated; it is of steel, with hardened jaws, 7 ins. long, and weighs ten ounces. Fig. 23 illustrates the wrench and indicates clearly the method of adjustment.

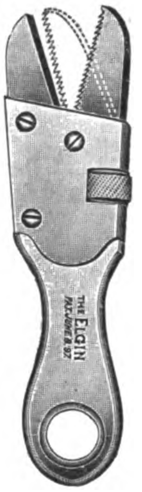

FIG. 23.

REPLOGLE RELAY-RETURNING WATER-WHEEL GOVERNOR.

Fig. 24 illustrates the latest form of Replogle water-wheel governor built by the Replogle Governor Works, Akron, Ohio. This governor is a development of the electrical relay apparatus which was formerly built by this company, but it is purely mechanical in operation. The general principle of the governor is exactly the same as that of the electrical governor, which is familiar to most readers of this paper, the chief difference being that the pawls are thrown into and out of engagement with the respective ratchet wheels by the direct action of the fly-ball governor shown at the top of the machine. This new form of governor is said to give even closer regulation than the electro-mechanical type which was its progenitor. It is built in several sizes to suit various requirements, and adapted for use in connection with all classes of water-wheels, from the ordinary turbine to the heaviest impact wheel under high heads.

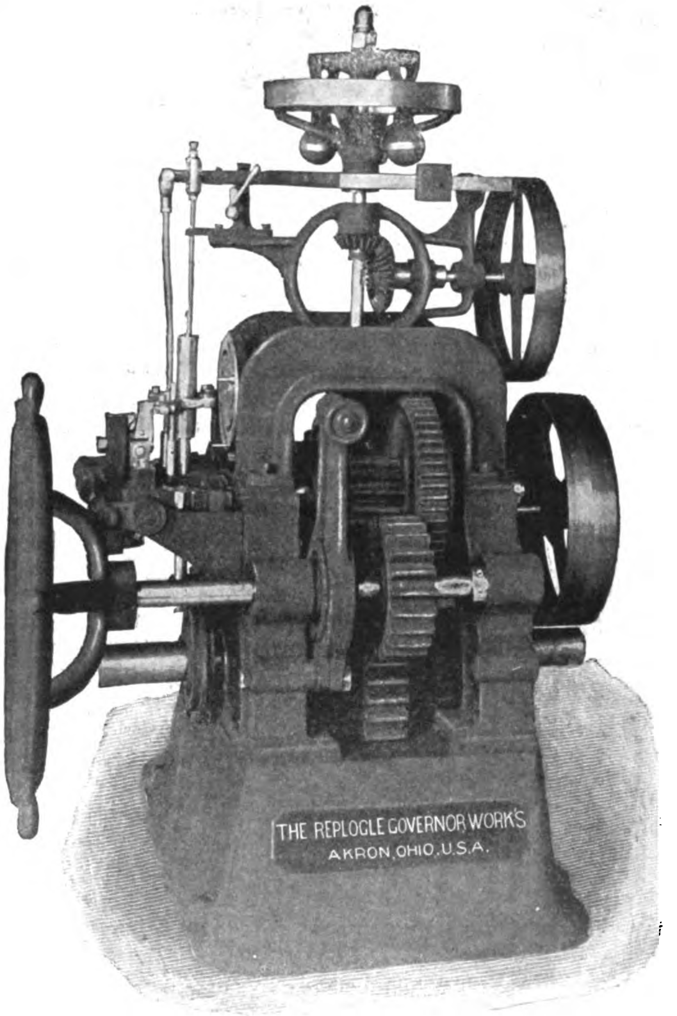

FIG. 24.—RELAY-RETURNING WATER-WHEEL GOVERNOR.

THE BUSINESS SITUATION AT THE CLOSE OF 1900.

THE BURT MANUFACTURING COMPANY, Akron, Ohio; Oil Filters.—We have had an exceedingly prosperous year and look for a good trade during 1901.

STANDARD TELEPHONE AND ELECTRIC COMPANY, Madison, Wis.; Telephones.—We have had a very successful year's business and the outlook for 1901 is good.

CENTRAL ELECTRIC COMPANY, Chicago; Electrical Supplies.—Business for the year 1900 has been satisfactory, and we regard the prospects for 1901 as encouraging.

WALSH'S SONS & CO., Newark, N. J.; Second-hand Apparatus.—Conditions during the year have been gratifying, inasmuch as during the entire period business has been quite brisk.

THE HAINES & NOYES COMPANY, Chicago; Telephones.—Our goods have sold well and our future prospects are excellent. We have many large contracts on hand and we have many others in view.

NEW YORK & OHIO COMPANY, Warren, Ohio; Incandescent Lamps and Transformers.—Our business for the past year has been very satisfactory and we believe it will remain in this condition the coming year.

MARINETTE IRON WORKS, Marinette, Wis.; Gas Engines.—Business during the past year has fully met our expectations, and we are looking forward with confidence to a good market for the coming year.

THE ECONOMY ELECTRIC COMPANY, Warren, Ohio; Renewing Incandescent Lamps.—At present our factory capacity is being taxed to the utmost to keep up with orders, which are daily increasing.

SCHUREMAN & HAYDEN, Chicago; Second-hand Apparatus.—Our business for the year 1900 has been just double that of the previous year, and from present indications the new year should be fully as prosperous.

JAMES LEFFEL & CO., Springfield, Ohio.; Turbines and Engines.—In our Samson turbine work we have done a fine business during 1900, and our future inquiries and prospects are good for the coming year.

PRISMATIC ELECTRIC SIGN COMPANY, Syracuse, N. Y.; Electric Signs.—Business conditions during the past year in our line have been extremely favorable and the future for this class of business looks very bright.

MICA MACHINE COMPANY, Pittsburg, Pa.; Mica Machines.—Business in general is the best we have ever known it to be, and prospects are still better. We expect to have all we can attend to during the coming two years.

CREST MANUFACTURING COMPANY, Cambridgeport, Mass.; Automobile Motors.—Our business has increased very rapidly up to the present time, and we consider that the outlook for business next year is exceedingly good.

THE REPLOGLE GOVERNOR WORKS, Akron, Ohio; Water Wheel Governors.—The past year's business has been the most satisfactory that we have ever experienced; so far as we can judge, the outlook for 1901 is most promising.

HUGO REISINGER, New York; "Electra" Carbons.—Business during 1900 has been exceedingly good, and in view of the enormous growth of enclosed arc lighting, a largely increased demand during the season of 1901 is expected.

I. P. FRINK, New York; Reflectors.—We have found business during the past year all we could expect and more, as the demand for our line of goods has been particularly strong, and the prospects for the coming year look very bright indeed.

THE WARREN ELECTRIC AND SPECIALTY COMPANY, Warren, Ohio; Transformers and Incandescent Lamps.—The business in transformers is greatly exceeding our most sanguine expectations, and the outlook for future business is bright.

SKINNER ENGINE COMPANY, Erie, Pa.; Steam Engines.—The business done by this company during the year 1900 has been the largest and most satisfactory in its history, and the prospects seem to indicate even better conditions for the coming year.

LEA - HOOVEN MANUFACTURING COMPANY, Anderson, Ind.; Arc Lamps.—Our business has been good, and we expect to have a much larger business in the coming year, as we are getting a great number of inquiries, especially in the far South and West.

THE HART & HEGEMAN MANUFACTURING COMPANY, Hartford, Conn.; Switches.—The volume of business and collections for the past year have been most satisfactory. We see no reason why the same conditions should not prevail during the coming year.

THE NEW PROCESS RAW HIDE COMPANY, Syracuse, N. Y.; Gears and Pinions.—Our business for the year of 1900 has been larger than that of any previous year and satisfactory in every way. We confidently anticipate the continuance of good trade for the coming year.

THE WIRT ELECTRIC COMPANY, Philadelphia, Pa.; Rheostats.—We expect to considerably increase our plant and space, after which time we shall be in a position to take care of more work, but at the present time we are obliged to work at night to keep up with orders.

NEWTON MACHINE TOOL WORKS, Philadelphia, Pa.; Machine Tools.—We have had the largest output of any year since we have been in business. We have recently received very satisfactory orders and the prospects are of the best. We have recently trebled our shop capacity.

GEORGE W. LORD, Philadelphia; Boiler Compounds.—We are particularly busy; in fact, the year 1900 has been the most prosperous we have had, but we will be very much disappointed if our business during the year 1901 does not show an increase of at least 25 per cent.

AMERICAN MINIATURE AND DECORATIVE LAMP COMPANY, New York; Incandescent Lamps.—We have done the largest business during 1900 since our existence. We anticipate a still larger business for 1901 and are about getting ready in again doubling our capacity for any emergencies.

WILMARTH & MORMAN COMPANY, Grand Rapids, Mich.; Drill Grinders.—Our sales were very much larger in 1900 than in 1899. There was a material increase in 1899. There was a material increase in the amount of export business. We do not see why there should not be a good business in 1901.

AMERICAN ENGINE COMPANY, Bound Brook, N. J.; Engines and Generators.—We have had more business than we could possibly handle, running our establishment night and day. We have just completed a large addition to our works, and we think the outlook for the coming year very encouraging.

TEXAS ARM AND PIN COMPANY, Beaumont, Texas; Cross Arms, Pins and Brackets.—The past year has proven phenomenally successful, we think we can reasonably expect to increase our sales 100 per cent. in 1901, which, in our opinion, will be the greatest construction year in the telegraph and telephone world.

THE CROUSE-HINDS ELECTRIC COMPANY, Syracuse, N. Y.; Switches.—We have had more business than we could handle during the past year, and the outlook for the coming year is most bright for a continued increase. We are so well satisfied with the prospects for 1901 that we are doubling our capacity.

DIAMOND METER COMPANY, Peoria, Ill.; Meters and Transformers.—Our business for the past year has been much better than the year before; in fact, we have had all that we can possibly do and take care of our trade, and from present indications we look for a continuance for at least some time to come.

THE SPRAGUE ELECTRIC COMPANY, New York; Dynamos, Motors and Interior Conduits.—Owing to a constantly increasing demand for its product, the Sprague Electric Company has been obliged to greatly increase the floor space in the New York office, which is now located on three floors of the factory.

GARL ELECTRIC COMPANY, Akron, Ohio; Telephones.—Business for the past year has been quite satisfactory and the prospects for 1901 are first-class. The company is just being reorganized and after this matter has been settled we are looking forward to a very busy time, being just as busy as we can be at present.

PERU ELECTRIC MANUFACTURING COMPANY, Peru, Ind.; Porcelain Goods.—Business during the past year has been very satisfactory. In order to meet the large demand for our goods we have been compelled to enlarge our factory from time to time, and are now making many changes which will increase the capacity very largely.

JOSEPH DIXON CRUCIBLE COMPANY, Jersey City, N. J.; Lubricants.—We can only say that we have during the entire year of 1900 been pushed to our utmost capacity to fill our orders. We have made large additions to our works, and the prospects for 1901, so far as we can see, are apparently as good as they were in 1900.

ROYAL ELECTRIC COMPANY, Peoria, Ill.; Alternators and Transformers.—Our business this year has been highly satisfactory. We have sold a greater number of generators than in any year before, and at prices that have netted us a nice profit. Our collections have been prompt and satisfactory. With our increased facilities we expect to treble the volume of our business in 1901.

ZIMDARS & HUNT, New York; Switches and Switchboards.—The past year has been satisfactory. While the period immediately preceding the election is usually one of diminished activity, there was this year little if any diminution in the volume of business handled at this time. The outlook for the coming year is decidedly encouraging.

THE HOMER COMMUTATOR COMPANY, Cleveland, Ohio; Commutator Work.—Business of the past year has proven very satisfactory to us, so much so, in fact, that we were enabled to build a new factory in which we are now located. We think there is a very bright outlook for next year's business and hope to get our share of it.

MONTAUK MULTIPHASE CABLE COMPANY, New York; Fire Detective Wire.—In our opinion, the year 1900 has been quite prosperous. Our orders have been much larger than for the previous year, being for thousands of feet instead of hundreds; one of our latest house installations required 7,500 ft. The outlook for 1901 is very promising.

THE EMERSON ELECTRIC MANUFACTURING COMPANY, St. Louis, Mo.; Motors.—Business for 1899 was good; 1900 was better, and for 1901 we look for the best showing of all. There is a generally hopeful and satisfactory feeling apparently prevading the entire business community, as reflected in that trade in which we are directly interested.

BLISS-CHESTER COMPANY, Providence, R. I.; Metal Goods and Stampings.—Our house was organized July 1, 1900, and we have had the pleasure of a very encouraging business from the start. Our contracts are now beginning to come in for the year of 1901, with every indication of a good business, taken at good prices, throughout the year.

H. M. N. MUHLE, Dayton, O.; Storage Batteries and Grids.—Business with me in the past months has been exceedingly fine. I have orders from some of the largest concerns in the country. Central station managers are realizing more every day the advantage of storage batteries, and I think there is a bright future for the storage battery business.

MACHADO & ROLLER, New York; Electrical Instruments.—In spite of continuous night-work, we are over four weeks behind on orders for our new "column" indicating and recording instruments, and although we are making prompt deliveries on our lines, it is hard work to keep up. We see no present indications of a falling off in business.

THE STROMBERG-CARLSON TELEPHONE MANUFACTURING COMPANY, Chicago; Telephones.—Our business, as well as the independent telephone business in general, has had a continued healthy growth and has far exceeded that of any previous year. The prospects for the first year in the new century are even brighter than at any time in the past.

THE BALL & WOOD COMPANY, New York; Steam Engines.—We have found the business conditions during the year just closing on the whole very satisfactory, and have been pleased to note that the demand for our engines has been well maintained and compares very favorably with 1899. We regard the prospects for the coming year as unusually favorable.

THE STEWART HEATER COMPANY, Buffalo, N. Y.; Heaters.—We have had about all the business we could handle during the past year, and are now as busy as bees trying to fill our orders. The prospects for the coming year are good, in fact better than they have been for several years. We have orders enough now on our books to keep us hard at work for the coming month.

STANDARD UNDERGROUND CABLE COMPANY, Pittsburg, Pa.; Wires and Cables.—We believe the business of the current calendar year in the electrical and allied lines to have been the most prosperous in the history of those industries. While we consider the outlook for 1901 to be quite good, we do not believe that business will be so large in the electrical and allied lines next year as it has been this year.

THE D. M. STEWARD MANUFACTURING COMPANY, Chattanooga, Tenn.; Lava Insulators.—The last year's business has been eminently satisfactory to us. We have had a large increase in all the lines which we manufacture, and this is true to a greater extent of lava insulators than any other line. We have some contracts on hand for delivery next year, and every indication points to a successful and profitable year.

COMSTOCK MANUFACTURING COMPANY, Comstock, Mich.; Engines.—The year 1900 was the best year we have had. For eighteen months we have been behind our orders and are still behind; and in our particular line, the manufacturing of small automatic engines, the indications are that in 1901 our business will be even still better than 1900. We are buying new machinery and adding new additions to our shops.

JOHN S. NOWOTNY, Cincinnati, O.; Dynamos and Motors.—We have enjoyed in the past year an excellent business. In fact, we have done far more business than we had anticipated. We have every reason to believe that we are now just passing into an era of prosperity in this country that will extend from ocean to ocean, and we are backing up our judgment by preparing to reap the harvest for the next three years to come.

THE STODDARD TELEPHONE CONSTRUCTION COMPANY, Monroe, Mich.; Telephones.—We have found business to be exceptionally brisk during the past year and look for a large increase in the sales of our long distance telephones during the coming seaon. The demand for bridging telephones has been unprecedented, showing that the independents are looking well after their toll lines and increasing their earnings thereby.

WARD LEONARD ELECTRIC COMPANY, Bronxville, N. Y.; Rheostats and Circuit Breakers.—The year 1900 has been a very satisfactory one to us in every way. We did a much larger busines that year than ever before, and the fact that we secured the only gold medal in our line at the Paris Exposition has given a great impetus to our foreign business. Our business is growing rapidly, and we are sure that 1901 will be even better than 1900.

E. C. POWELL, Syracuse, N. Y.; Dynamos and Motors.—We have found business in this line exceedingly good during the past year. We are working a largely increased force. We have several large contracts at present, and the outlook for the new year is exceedingly bright. We seem to have more inquiries than at the same time last year, and with the amount of business in sight, hope to do a larger business in 1901 than we did this year.

ELECTRIC STORAGE BATTERY COMPANY, Philadelphia; Storage Batteries.—The development of the business of this company during the past year has been very gratifying, and especially so to those members of the company who took part in the "missionary" work that was done during the earlier years of the company's existence. The field for the profitable use of accumulators is constantly broadening, and the prospects for the coming year are most encouraging.

THE AKRON ELECTRICAL MANUFACTURING COMPANY, Akron, Ohio; Dynamcs and Motors.—Business for the past year has been the best in the history of the country. Our business has increased nearly four times over and above that of 1899, and from all indications it looks as though it will increase again at least that much, if not more, in 1901. We do not believe that the future in the electrical business has ever held out brighter prospects than at present.

THE ELECTRIC MOTOR AND EQUIPMENT COMPANY, Newark, N. J.; Photometers.—Our business for the past year has been a little more than double what it was for the year previous, and the indications are that the year 1901 will be one of the biggest years in the electrical business that has ever been known. With continuation of the present conditions of national commercial prosperity it is our impression that the electrical outlook for next year is most brilliant.

FARR TELEPHONE AND CONSTRUCTION SUPPLY COMPANY, Chicago; Telephones.—Judging from our heavy correspondence in the past month, there certainly must be a very bright prospect for the electrical trade in the beginning of the new year. Many lines and exchanges are to be rebuilt throughout, and many new exchanges are to go in. The electrical trade is certainly on the boom and we look forward to the best business the coming year that we have ever had.

THE TRIUMPH ELECTRIC COMPANY, Cincinnati, Ohio; Dynamos and Motors.—The volume of our business in 1899 exceeded by about 125 per cent the business of the previous year, and in 1900 careful estimates show that the business exceeded that of 1899 by 60 per cent. Judging from the large number of inquiries we are now receiving and the business that is resulting therefrom, we confidently expect considerably more business in 1901 than in the past year.

McINTOSH, SEYMOUR & CO., Auburn, N. Y.; Steam Engines.—The year 1900 has been better with respect to both the amount and the quality of the business than any previous year since the company was organized. The amount of business has been limited only by our capacity. Judging from the amount of work closed during the past four months, and from prospective business as indicated by inquiries, the year 1901 will fully equal, and probably surpass, the year 1900.

MICHIGAN ELECTRIC COMPANY, Detroit, Mich.; Electrical Supplies.—During the year 1900 this company has been kept busy in all of its various lines, having done, in fact, all the business we had facilities for following and handling, and we are satisfied we could have done more had our facilities been greater. As it is, however, our business shows a large gain over the business of all previous years. For 1901 we feel confident of doing even a larger business than we have done this year.

THE STILWELL-BIERCE & SMITH-VAILE COMPANY, Dayton, Ohio; Turbines, Pumps and Feed-Water Heaters.—Take it all around, this year has been the best year in the history of our company, although 1898 was also a most excellent year. Now that the political status has been so happily and satisfactorily fixed for another term of four years, we look forward to a period of great prosperity. Our inquiry is of the most hopeful character and all the indications point to an extremely busy year ahead of us.

GARTON-DANIELS COMPANY, Keokuk, Ia.; Lightning Arresters.—We have enjoyed an increase of 33 1-3 per cent over the business for 1899, which was our record-breaking year, being over double any previous year. Twenty per cent of our sales have gone abroad during 1900—this being another evidence of the superiority of American-made electrical apparatus. We look for a still greater business in 1901, and are making arrangements to begin the season with a larger stock of lightning arresters on hand than ever before.

ERICSSON TELEPHONE COMPANY, New York; Telephones.—The year 1900 went way beyond any previous year. At the close of 1899 most houses in the electrical line looked for an increase in 1900. Their expectations were fully realized in most cases, and in many were exceeded. The outlook for the opening year of the new century we believe to be most encouraging. The business conditions of the whole country are most favorable and seem to promise the assurance of a good trade, in all lines, but especially in telephones.

THE LAMBERT SCHMIDT TELEPHONE MANUFACTURING COMPANY, New York; Telephones.—We are highly satisfied with the outlook of the telephone business and certainly anticipate large results in the future. During the past year the business has developed largely, both in public exchange, interior and railroad usage of telephone apparatus. Judging from all standpoints, the outlook for the independent business could not be brighter either from the manufacturers' or from the exchanges' standpoint, and we expect to reap our share of the benefits with the rest.

HOLTZER-CABOT ELECTRIC COMPANY, Brookline, Boston, Mass.; Telephones and Specialties.—The year just closed has been a most satisfactory one. The prophesied reaction has not appeared so far, and the slight decrease in trade just before the presidential election has been followed by a steady improvement in business in all our lines of manufacture. A noticeable feature of business at the present time is the increasing demand for high-grade goods for domestic use and an increase of foreign orders. The outlook for 1901 is most encouraging, and we look forward to a steady and satisfactory business.

HENRY H. HUMPHREY, St. Louis, Mo.; Consulting Electrical Engineer.—The past year has been a very satisfactory year in my business, as I have had charge of a great deal of important engineering work. The usual amount of special investigations, tests, and reports have also been completed. The principal work on hand at present is a lighting and power plant for the DeBeers Explosive Works at Cape Town, South Africa, consisting of power plant and about 1,000 horsepower of motors, including air compressors, water-works pumping plant and refrigerating plant.

HARRISBURG FOUNDRY AND MACHINE WORKS, Harrisburg, Pa.; Steam Engines.—Last year was the most prosperous since the company's organization in 1857. Although equipped with an entirely new plant, buildings, etc., which has increased its capacity more than 100 per cent, it has received orders for engines of various styles and sizes to its full capacity and has been obliged to refuse nearly 50 per cent additional orders which have been offered. The company faces the new year with the brightest prospects and a firm belief in industrial and financial prosperity of the country.

BRYAN-MARSH COMPANY, Marlborough, Mass.; Incandescent Lamps.—The year 1900 has been the most prosperous year in our career. Our total output of incandescent lamps from Dec. 1, 1899, to Dec. 1, 1900, was 48 per cent in excess of any previous year. One reason for the heavy increase in sales is the opening up of new territory, and the large increase in foreign business through our new London office. The outlook for the future is believed to be unprecedented, and we are accordingly arranging to increase our factory output early in 1901 to from 20,000 to 22,000 lamps per day.

WARREN ELECTRIC MANUFACTURING COMPANY, Sandusky, Ohio; Inductor Alternators.—Our business has been extremely active during the entire year. Indeed, it has taxed our facilities to the utmost and at the present time we have unexecuted contracts in hand to keep our works employed to the extreme limit up to the first of next March. With regard to the prospects for 1901, it is our belief that the electrical business is to be the largest ever known. We shall be greatly surprised if every well-established electrical industry is not crowded with business during the entire year.

THE VILTER MANUFACTURING COMPANY, Milwaukee, Wis.; Steam Engines.—The past year has been one of the best since this company's existence, and the month of November was the banner month during that time. Our company has contracted for very much new business, so that the prospects for 1901, considering the number of inquiries still continuing to come in, are exceedingly favorable. We have operated our works, which are new and extensive, day and night for the past four years, and the outlook is such that we shall have to continue to do so for some time.

THE STANDARD AUTOMATIC GAS ENGINE COMPANY, Oil City, Pa.; Gas Engines.—The outlook for business seems excellent, especially in electrical lines. We have sold within the last thirty days two 250-h.p. engines; two 150-h.p engines, two 500-h.p. engines direct-connected to Westinghouse 300-kw. railway generators, and are on the point of closing a sale for four more 500-h.p. engines to drive belted alternators in parallel for street railway work; the last four all in one station. We are forced to triple our facilities to keep up with orders after having doubled our last year's output, all in large engines.

AMERICAN DISTRICT STEAM COMPANY, Lockport, N. Y.; Exhaust Steam Heating.—So far as this company is concerned, the year 1900 has been eminently satisfactory. The number of new installations and extensions constructed by us in 1900 numbers twenty-five. For lack of facilities the company was obliged to refuse some work that was offered. The outlook for the coming year is very promising indeed, and with increased facilities the company expects to accomplish more than in any previous season of its history. With the assurance of stability in the financial affairs of the country for years to come we look for a period of active business and great prosperity.

THE B. F. STURTEVANT COMPANY, Boston, Mass.; Blowers, Ventilating Fans, Engines and Dynamos.—The business of the past year was the largest in the company's history. The installation of fans for the production of mechanical draft for steam boilers has shown a great increase. The volume of domestic and foreign orders for forges has been noticeable, while the output of the rapidly growing electrical department has been far in excess of the previous year. This electrical output has been principally in the specialties of this company, namely, electric fans of all types and small generating sets. All departments have been taxed to the utmost and the outlook is favorable for the continuation of this condition.

ABENDROTH & ROOT MANUFACTURING COMPANY, New York City; Boilers.—We are closing 1900 with a very satisfactory volume of trade and of a quality particularly satisfactory. The unsteady iron and steel market which has characterized 1900 has undoubtedly retarded the buying movement somewhat, and it is generally conceded that a presidential campaign tends to have the same effect; but against both of these adverse conditions we are pleased to say that both the volume and the quality of business have been satisfactory. Indications certainly point to a strong increase in domestic buying, and we anticipate a substantial increase in the volume of business to be secured by our export department.

QUEEN & COMPANY, INC., Philadelphia; Scientific Instruments.—The apparently high prices to which raw material was forced early last year interfered somewhat with business, but as the year went on business conditions materially improved and were decidedly good during the latter part of the year. We have had a marked increase in inquiries from abroad, particularly for electrical instruments, the growing tendency to look to the United States for quality and efficiency in electrical instruments being very apparent. As the year closes we feel that business is on a more secure foundation than ever before, and there is nothing so far as we can see in the way of the development of a large and prosperous business for the year 1901.

ROE STEPHENS MANUFACTURING COMPANY, Detroit, Mich.; Valves.—The volume of business in 1900, in dollars and cents, with us is somewhat less than that of 1899, but we think the decline in prices of our goods from those prevailing in 1899 would average about 20 per cent. On this basis our output for 1900 would be larger than that of 1899, and the greatest since we have been in business. So we think with prices of material about present quotations, or possibly a little lower, there will be a large development in electrical and other lines in 1901 which will require heavy pressure machinery and fittings, and this should give us more business; so we hope 1901 will be the banner year of our existence and are preparing to meet such conditions.

THE CHICAGO RAWHIDE MANUFACTURING COMPANY, Chicago; Gears and Pinions.—Business conditions have been for us during the past year extremely favorable, both in our own city of Chicago and with our agencies in the Eastern cities. Our trade in rawhide belting, lacing and pinions is entirely with the manufacturer, so naturally we credit our own prosperity to the growth and new establishment of industries throughout the country. With the steady adoption of electrical power in plants and factories, both large and small, has come a demand for rawhide belting and pinions that has over doubled our business. We feel optimistic for a still larger increase during the coming year. Our European trade has almost kept pace with our home increase.

AMERICAN ELECTRIC FUSE COMPANY, Chicago; Fuse Wire and Links.—We are certain that the business delayed by reason of the election in 1900 is in course of preparation for 1901. This year, however, has not been in any sense a bad year; in fact, we think it has been a remarkably good one, but it is overshadowed by the overwhelming evidences of prospective business for 1901. We predict in the electrical line, which we believe to be the most progressive line in American business, the largest output in the history of the United States. The extraordinary increase in the number of inquiries and prospective orders since election warrant us in the belief that it will be necessary for electrical houses everywhere to run overtime next year to fill their orders.

GREGORY ELECTRIC COMPANY, Chicago; Second-hand Apparatus.—We have had a very satisfactory year, the increase in our business being constant and very gratifying. Through the increase in business we were compelled to enlarge our quarters and added the building 52, 54 and 56 South Clinton Street to our works in order to secure much needed additional floor space for our armature department, machine department, arc-lamp department and transformer department. We note a large demand for up-to-date apparatus, the average customer now being well posted on what constitutes good apparatus. Collections have been very satisfactory this year and we are looking forward to the coming year as one of exceptional promise. We believe the electrical industry has never been in a more satisfactory condition.

THE SHELBY ELECTRIC COMPANY, Shelby, Ohio.; Incandescent Lamps.—We have made as careful and thorough an investigation as possible through our twenty traveling representatives, with a view to determining the volume of business we can reasonably expect during the coming year. The consensus of opinion of all of our representatives is that we are to experience several years of unequalled prosperity. The questions that have been decided by the recent election have been decided in a way that has encouraged manufacturing industries in all lines, and this company is and has been enjoying the greatest volume of business it has ever experienced. We have been constantly increasing our capacity and believe that if everyone is meeting with the same success that we are there will be no cause for complaint from any source.

THE C & C ELECTRIC COMPANY, New York; Dynamos and Motors.—We are pleased to be able to advise you that the year 1900 has proved in every respect the most successful year this company has ever experienced. Our sales were far larger than they ever were before, and we start the new year with a very large balance of orders; in fact, enough to keep our factory running at its fullest capacity for several months. It is our belief, and we think there is every indication to prove its reasonableness, that 1901 will be a decidedly better business year than 1900 has been. The increase in capacity which will be made by large numbers of manufacturing establishments will mean an increase in demand for electrical machinery in 1901, and we expect to get quite our share of the new orders. Orders for export have been constantly increasing, and we look for a very much larger increase during the next year in this branch of our business.

BULLOCK ELECTRIC MANUFACTURING COMPANY, Cincinnati, Ohio; Electric Light and Power Equipments.—We have had a most satisfactory trade during 1900, the last six months of which shows a greater volume of business done than the entire year of 1899. We have found it necessary to twice enlarge upon our facilities during the year, which will make the capacity January 1st, 1901, fully double that which it was January 1st of 1900. One gratifying feature of our business this year has been the large increase in export trade. Orders have come to us from Great Britain, Continental Europe, Russia, South America and Mexico with every indication that there will be a gradual and very satisfactory increase in the future. Another feature of our business is that during 1899 our largest unit was an 800-kw., while at the present moment we are prepared to build generators of 2000 kilowatts and larger if necessary. We are to-day crowded with orders for large units.

AMERICAN STEEL AND WIRE COMPANY, Chicago, Ill.; Wires and Cables.—The company's business in wires and cables for electrical purposes during the year 1900 has been very satisfactory. The production and sales show a large increase over any previous year in the history of the Washburn & Moen plants, where these goods are manufactured. The increases have been quite general in all departments of electrical products, but the greatest gains have been noted in the sale of "Crown" bonds and feeder cables of large capacity for light and power circuits. In these lines the producing capacity of the company has been taxed to its utmost. The distribution of orders has been quite general over all sections of the country and the increase in export orders has been very gratifying. The company is decidedly optimistic regarding the outlook for 1901. Every indication points to a still further increase in the demand for electrical products, and plans are maturing for very largely increasing the capacity of the mills engaged in turning out electrical specialties.

GENERAL ELECTRIC COMPANY, Schenectady, N. Y.—The business done during the year 1900 shows a large increase over that done in 1899, notwithstanding the fact that the latter year's business was the best in the history of this company. The number of new projects requiring large quantities of electrical apparatus and supplies have been numerous during the year. The prices of the raw materials chiefly used in the electrical work remained at the high record made during the year 1899, until November last. Since then actual advances have been demanded on these prices which, if continued, must ultimately lead to increased prices for finished electrical products. During the year noted improvements have been made in the equipment of central station lighting apparatus, the older and more inefficient types of generators and devices having been discarded and replaced by larger units of higher efficiency and of a more substantial character. In electrical railway work there has been a decided tendency toward the use of four motors per car instead of two, thus giving greater power, higher speed and generally more satisfactory service. The increasing demand for railway equipments for suburban and interurban work shows clearly the tendency on the part of all railway companies to extend their lines. Great advances have been made during the year in the equipment of large manufacturing plants with electric motors; the practice of equipping each tool with an individual motor is notable in machine shops of recent construction. So rapid has been the strides in the successful transmission of power by electricity over considerable distances, that the limiting factor is no longer the length of the transmission line, but is now merely a question of the market price at which the power can be sold. Power at a loss of only 8 per cent on the line is to-day being transmitted 80 miles in California. By electrical equipment, many water-powers, heretofore considered so inaccessible as to be of no commercial value, are now among the most desired of all properties. The electrical transmission of power from coal mines (using slack for fuel) is beginning to attract the attention of capitalists, and there are several plants of this character in different sections of the country which have proved to be great commercial successes.

LEGAL NOTE.

DIEHL FAN PATENTS SUSTAINED.—A perpetual injunction has been issued by the United States Circuit Court for the Eastern District of Pennsylvania, restraining the Marietta Manufacturing Company and H. Burd Cassel, Receiver, from the manufacture and sale of electric ceiling fans infringing the Diehl patents Nos. 465,360 and 465,361, dated December 15, 1891; No. 537,679, dated April 15, 1895, and No. 585,250, dated June 29, 1897.

OBITUARY.

WASHINGTON H. LAWRENCE, president of the National Carbon Company, died on November 23, at his home in Dover Bay, near Cleveland, from the effects of a broken arm. The bone failed to knit, and it was decided to amputate the arm, which was done, but with fatal result. Mr. Lawrence had been identified with electrical industries since the organization of the old Brush Electric Company, for which he furnished much of the capital. Later on he severed his connection with the Brush Company and devoted his attention to other branches, from which he selected the manufacture of carbons as his particular line of work. He combined with Myron T. Herrick, James Parmalee and Webb C. Hayes in forming the National Carbon Company, and many of the developments and improvements in the methods of manufacture are directly due to his ingenuity and foresight.

PERSONALS.

MR. C. W. WOODWARD has been appointed purchasing agent for the Electric Storage Battery Company to succeed Mr. John B. Falkner, Jr., deceased.

MR. J. M. HOLLISTER, who represented the Western Electric Company at Paris, read an extremely interesting paper on the "Electrical Features of the Paris Exposition" before the Chicago Electrical Association on December 21.

MR. FRANK C. MASON, general superintendent of the Police and Fire Alarm Telegraph System of Brooklyn, read an interesting paper on "The Fire Departments of our Cities" at a convention in Charleston, S. C., on December 13.

MR. W. S. ANDREWS read an interesting paper before the Schenectady General Engineering Society recently, on "Roentgen Rays," which has been reprinted in the shape of a little brochure, the illustrations of which include portraits of Roentgen and Faraday.

MR. MORRIS W. MEAD, superintendent of the Electrical Department of the city of Pittsburg, had the misfortune to have one of his legs broken one day recently by a fall from a ladder, due to the breaking of one of the rungs. Mr. Mead will be confined to his home for several weeks.

MR. R. S. STEARNS, recently connected with the New Orleans office of the Westinghouse Electric & Manufacturing Company, and formerly with the General Electric and Fort Wayne companies, relinquished his position with the Westinghouse Company on January 1 to engage in general contracting business.

MR. V. H. YARNALL has been appointed manager for the eastern district by Mr. John T. McRoy, maker of the well-known McRoy conduit. Mr. Yarnall's territory will also include Canada. Mr. Yarnall is widely and most favorably known in engineering circles, having been an active worker since 1882.

MR. H. C. WYBRO, manager of the Wybro-Hendy Company, of San Francisco, was recently in New York on a business trip for his company. While in the East, Mr. Wybro secured the contract for the three-phase transmission plant of the McCloud River Electric Power Company for the Bullock Electric Company, which he represents in California.

MR. FREMONT WILSON, who is well known in New York electrical engineering circles, read a paper on "Electrical Wiring" before a recent meeting of the Brooklyn Chapter of the American Institute of Architects. The paper was an able one and interest in it was enhanced by the lantern slides which illustrated the various points brought out by Mr. Wilson.

MR. ADOLPHE A. CHAILLET, hitherto technical manager for the Shelby Electric Company, has resigned that position to engage in consulting electrical and mechanical engineering. Mr. Chaillet has established his headquarters in the Ellicott Square Building, Buffalo; he will continue to be the technical adviser of the Shelby Company and will represent its lamp in his section of New York State.

MR. EDWIN R. WEEKS, ex-president of the National Electric Light Association, and one of the most active workers in that association, has established an office in the new Nelson Building, Kansas City, and will engage in electrical engineering. Mr. Weeks has been for many years at the head of the electric-lighting interests of Kansas City and is widely known as a central-station engineer of high ability.

MR. JAMES PARMELEE has been elected president of the National Carbon Company, Cleveland, Ohio, to succeed the late Mr. W. H. Lawrence. Mr. Parmelee has been the vice-president of the company since its organization, and is also the treasurer of the Wheeling & Lake Erie Railroad Company. Mr. Parmelee's vacated position of vice-president has been filled by the appointment of Col. Myron T. Herrick.

MR. B. A. BEHREND has been engaged by the Bullock Electric Manufacturing Company as designing electrical engineer, for which position he is admirably qualified. Mr. Behrend was formerly chief designer of the Oerlikon Works, Switzerland, and has been for several years an important contributor to electrical literature. He was tendered the chair of electrical engineering in the Technical Institute of Stuttgart, Germany, last spring, which is one of the finest professorial positions in Germany, but declined the offer.

MR. LUDWIG GUTMANN, who has for several years been the designing engineer for the Royal Electrical Company, of Peoria, Ill., and whose high ability in this direction wrought notable improvements in the machinery and apparatus of that company, has resigned his position in order to engage in general engineering work and also to put some of his inventions in commercial shape. Fundamental patents covering important types of apparatus were granted to Mr. Gutmann a number of years ago, among which apparatus is the induction wattmeter recently put on the market in the West.

MR. ALLEN D. SKINNER, the popular traveling representative of the Skinner Engine Company, Erie, Pa., was married on Christmas eve to Miss Florence Robinson, at the Park Presbyterian Church, Erie. The bride and groom have received almost innumerable tokens of the esteem in which both of them are held by wide circles of friends. It is seldom that a man who is given the privilege of selecting his own Christmas present makes such a judicious choice as has Mr. Skinner, and still more seldom that such high ambition is so promptly gratified. The American Electrician tenders its best wishes and the compliments of the season.

◆

TRADE PUBLICATIONS.

CALENDAR. The Standard Tool Company, Cleveland, Ohio.—A hanging calendar of the usual monthly-leaf form, each leaf containing a pointed statement regarding Standard drills, taps, etc.

BELT-DRIVEN SINGLE-PHASE ALTERNATORS. Westinghouse Electric & Manufacturing Company.—Circular No. 1036, superseding No. 1008, and describing the well-known Westinghouse alternators.

ROUND-END RAILWAY CAR-SEAT PANELS. J. G. Brill Company, Philadelphia, Pa.—Catalogue No. 67, describing the round-corner seat end panels employed by the Brill Company in the construction of open railway cars.

FLEXIBLE METALLIC TUBING. The United Flexible Metallic Company, Ltd., Philadelphia, Pa.—A catalogue of flexible metallic tubing, which is manufactured for all purposes, including the conduction of steam, gas and water.

NEW ERA GAS AND GASOLINE ENGINES. The New Era Iron Works Company, Dayton, Ohio.—A well-executed catalogue of standard size containing illustrations and a description of the New Era engines in considerable detail.

RAILWAY MOTOR CONTROLLERS. General Electric Company.—This is Bulletin No. 4288, superseding Bulletin No. 4215, and containing descriptions and illustrations of the full line of G. E. series-parallel and rheostatic controllers.

THE STURTEVANT ENGINES. B. F. Sturtevant Company, Boston, Mass.—Catalogue No. 103, in which are illustrated and described the well-known Sturtevant vertical and horizontal steam engines for electric light and other service.

CALENDAR. New England Electrical Works, Lisbon, N. H.—A very practical calendar for 1901, consisting of a heavy cardboard back with the New England company's advertisement at the head and the usual monthly calendar leaves at the bottom.

HOLOPHANE GLASS. Holophane Glass Company, New York.—A well-executed brochure containing illustrations of the complete line of Holophane globes for electric-light service and also containing an inserted price-list applying to the catalogue.

CALENDAR. The Bliss-Chester Company, Providence, R. I.—A hanging calendar for 1901 of the usual form but containing a novel illustrative feature, which consists of a photograph of a vivid flash of lightning taken at Hallett's Point near Hell Gate during a severe thunder storm.

CALENDAR. The Emerson Electric Manufacturing Company, St. Louis, Mo.—A convenient desk calendar in pad form mounted in a sheet-metal frame and containing a leaf for each day of the new year. Each leaf bears at the top a pertinent motto relating to Emerson apparatus.

CHARTER GAS AND GASOLINE ENGINES. Charter Gas Engine Company, Sterling, Ill.—A catalogue of the well-known Charter gas and gasoline engines, which contains a thorough description of the engine illustrated by sectional and detail engravings, complete to a degree seldom found in gas-engine catalogues.

MOTOR-DRIVEN DUPLEX AIR COMPRESSORS. The Westinghouse Air Brake Company.—A handsomely-illustrated catalogue of self-contained air compressors and motors for use on electric-railway cars. The motor, as just intimated, is built on the same base with the compressor, so that each unit is complete in itself.

TYPE "H" TRANSFORMERS IN USE. General Electric Company.—Pamphlet No. 9085, containing fac-simile reproductions of letters from central-station men relating to their experiences with G. E. Type "H" oil transformers. The letters are all strong testimonials to the satisfactory results obtained from these transformers.

TELEPHONE APPARATUS. Central Telephone & Electric Company, St. Louis, Mo.—This is the seventh catalogue of the Central Company and contains illustrations and prices of the standard telephone desk and wall sets made by the company, together with an illustration and description of its full metallic-circuit central switchboard.

BRILL CONVERTIBLE CAR. J. G. Brill Company, Philadelphia, Pa.—A well-illustrated catalogue of the Brill convertible car, which is adapted to be changed from the open to the closed form and vice versa by means of sliding panels and windows. These are pushed up into recesses in the roof of the car in changing from closed to open construction.

MODERN STEAM GENERATORS. (Supplement.) Wickes Brothers, Saginaw, Mich.—A supplementary catalogue of standard size containing illustrations and a complete description of the Wickes vertical water-tube safety steam boiler. The book also contains a record of the results of an evaporative test made with a Wickes boiler at the Detroit Water Works.

SALARIED POSITIONS FOR LEARNERS. The International Correspondence Schools, Scranton, Pa.—A pamphlet containing photographs of a number of students who have been enabled to better their positions by reason of a course of studies with this school, and an outline of an advisory plan for persons wishing to avail themselves of the Correspondence Schools.

MASON TERRA-COTTA CONDUITS. The Potomac Terra Cotta Company, Washington, D. C.—A folder containing illustrations and a description of the Mason vitrified salt glazed terra-cotta underground conduit, together with a statement of the points of superiority claimed for this product and several strong testimonial letters from electric light and other companies which have used the conduit.

THE STEAM LOOP AND HOLLY GRAVITY RETURN SYSTEM. Westinghouse, Church, Kerr & Company, New York.—This is a superbly-executed book of standard catalogue size containing illustrations of representative plants in which the steam loop and Holly gravity return systems have been installed, together with an explanation of the principle of this system and a logical argument for its use.

WIRES AND CABLES. American Steel & Wire Company, Chicago.—This is a preliminary pocket-size catalogue of wires and cables for electric light, street railway, telephone and telegraph service, which will be followed later by a more complete and elaborate edition. The present production, however, will be found extremely convenient by those interested in the purchase of wire for any electrical service.

LEEDS PORTABLE TESTING SETS. Jas. G. Biddle, Philadelphia, Pa.—This is pamphlet No. 340, in which are described the various styles of testing sets marketed by Mr. Biddle, together with complete instructions for making Wheatstone bridge measurements, expositions of several methods of testing circuits and batteries, and checking voltmeters and ammeters. The information contained in the pamphlet is unusually practical and valuable.

CALENDAR. Kurz & Root, Appleton, Wis.—A calendar of the hanging type comprising a cardboard back with a calendar leaf for each month of the year. The upper part of

the cardboard base bears an unusually interesting illustration giving a view of the interior of the old Appleton central station which was the first one in America to supply incandescent light. This station was started up in October, 1882, under the management of Mr. Kurz, who is now the senior partner of the firm issuing the calendar.

THAT DEVIL DOUBT. The Emerson Electric Manufacturing Company, St. Louis, Mo.—A pamphlet handsomely printed on plate paper containing strong testimonials to the efficiency of Emerson alternating-current motors. While most of the letters are written by American users a considerable number come from distant parts of the world; notably, Hong Kong, China; Buenos Ayres, Argentine Republic, and Sydney, Australia. The raison d'etre of the title of the pamphlet is explained in the opening paragraph, which points out that the object of the catalogue is to remove from the minds of central-station managers who are not already converted any doubt as to the practicability of single-phase alternating-current fan motors.

BUSINESS NEWS.

WESTERN ELECTRIC COMPANY announces that it is prepared to supply arc-light carbons in any quantities for both direct-current and alternating-current lamps.

M. R. MUCKLE, JR. & CO., Philadelphia representatives of the Westinghouse interests, have removed their offices to the Stephen Girard Building, 21 South Twelfth Street, Philadelphia.

THE INDUSTRIAL WATER COMPANY, New York, announces that it has only the one office address, viz.: 15 Wall Street, New York, and that another company with a similar name has no connection with it.

D. M. STEWARD MANUFACTURING COMPANY, Chattanooga, Tenn., manufacturer of lava insulators, reports that it is filling orders from all parts of the world; especially large quantities are being sent to Germany.

THE SPRAGUE ELECTRIC COMPANY, New York, has just closed a contract for a large number of 20-h.p. slow-speed motors of the direct-connected type for operating the button machinery in the new plant of the Delaware Button Company at Wilmington.

M'KENNA BROS. BRASS COMPANY, Pittsburg, Pa., announces that since the establishment of its switchboard department it has received a great many orders for switchboards, and is receiving every day large numbers of requests for quotations on electrical work.

THE ELWELL-PARKER ELECTRIC COMPANY, Cleveland, Ohio, suffered the destruction of its plant by fire on December 17. The plant of the Brown Hoisting & Conveying Company was also destroyed by the same fire, the total loss being nearly a million dollars.

THE UNITED STATES CARBON COMPANY, Cleveland, Ohio, announces that contrary to all precedent, it will hereafter quote publicly the net prices of its carbons. This departure will naturally attract considerable attention, as it has been heretofore customary only to make quotations privately to prospective buyers.

ELMER P. MORRIS & CO., New York, have just closed a contract for 32,000 ft. of conduit duct for the Potomac Terra Cotta Company, Washington, D. C., to be used in connection with the Rapid Transit underground railway in New York City. This order will require eight freight cars for its transportation.

WAGNER ELECTRIC MANUFACTURING COMPANY, St. Louis, Mo., has removed its San Francisco office from 120 Sutter Street to 593 Mission Street, where much better facilities and more advantageous show rooms will be enjoyed. Mr. Clark, the company's representative in California, will continue in charge of the office.

THE AMERICAN BATTERY COMPOUND COMPANY, Chicago, Ill., has changed its name to the American Compound Company and removed its laboratories to 345-347 South Clinton Street. The sales department of the company has been placed entirely in the hands of the American Electric Fuse Company, who will therefore handle the "A B C" compound hereafter.

PARTRICK, CARTER & WILKINS, Philadelphia, have removed their offices to 1231-1239 Callowhill Street, and their factory to 407-409 North 13th Street. The buildings to which the firm has removed its offices and factory are new ones, and the superior accommodations obtained will enable them to more satisfactorily take care of their rapidly increasing business.

THE WARREN COMPANY, Chicago, Ill., manufacturer of the Warren pulley cover, has on file a large number of strong testimonial letters concerning this pulley covering. Fac-similes of several of these letters which the company is distributing amply confirm this claim, as the tone of the letters is universally commendatory and indicative of thorough satisfaction on the part of the users.

ANCHOR ELECTRIC COMPANY, of Boston, Mass., is urging the importance of installing only the best grade of fuse-blocks in connection with electric wiring. The company manufactures a line of fuse-blocks made from the finest grade of vitrified porcelain that can be obtained, and the goods are made in strict accordance with the requirements of the Code of Underwriters' National Association.

THE NEW ERA IRON WORKS COMPANY, Dayton, Ohio, manufacturer of gas and gasoline engines, reports that although the capacity of its plant has been doubled within the last few months, it is still very much behind its orders. The New Era line of engines ranges from 5 horse-power to 125 horse-power, and these engines have made a most creditable record, as the condition of the company's order books testifies.

JAMES McCREA & COMPANY, Chicago, manufacturers of steam specialties, have recently placed an agency for the Climax steam joint clamp with Geo. I. Roberts & Bros., 471 and 473 Fourth Avenue, New York, who will carry a complete stock and are in a position to fill all orders promptly. They have also placed an agency for the Pacific Coast with Pierce, Birs & Co., 31 Main Street, San Francisco, who will also carry a stock of the clamps.

JOSEPH DIXON CRUCIBLE COMPANY, Jersey City, N. J., manufacturer of graphite preparations, calls attention in a recent is-

sue of its little advertising periodical to the fact that Dixon's flake graphite, which has come into universal use for engine lubrication, can be used in an ordinary squirt can, just as oil is applied. It is of course essential that the can be absolutely dry; one which has previously contained oil will cause the graphite to clog.

THE BULLOCK ELECTRIC MANUFACTURING COMPANY, Cincinnati, Ohio, has almost completed a large addition to its machine shop and a new building for the accommodation of the brass foundry, boxing and brass-polishing departments. These additions were rendered necessary by the phenomenal growth of the Bullock company's business, and when they are completed it will be in position to more promptly take care of its rapidly multiplying orders.

THE AMERICAN SCHOOL OF CORRESPONDENCE, Boston, Mass., is sending out a special money card to be used by engineers and others desiring to examine the instruction papers and text books of the school. The card contains a pocket in which a silver 25-cent piece may be inserted and securely sealed, and a place for the sender's name and address and the name of the text book wanted. The card may be placed in an envelope and addressed to the school without the trouble of writing a letter or obtaining a postal order.

SPON & CHAMBERLAIN, New York, report that the new book on oil engines by Mr. A. H. Goldingham, although it has been out only a few weeks, has met with such favor that the first lot of books received from the printers has been entirely exhausted, over 500 copies being sold within the past four weeks. The book is said to be of special interest to draughtsmen and others interested in design, construction, installation and operation of oil engines. A review of it will be published in the proper department of this paper at an early date.

MR. HENRY B. CUTTER on December 15 retired from The Cutter Company, Philadelphia, his interest in the business established by him having been purchased by others who are represented by A. Edward Newton and Wm. M. Scott. Mr. Newton, who assumed the financial management of the company five years ago, has been elected president; Mr. Scott, who has been the chief engineer and patentee of the apparatus manufactured by the company, has been elected vice-president and general manager. It is understood that Mr. Cutter will retire from active business.

THE REPLOGLE GOVERNOR WORKS, Akron, Ohio, states that engineers and users of water-wheels are learning not to expect impossibilities. All that a water-wheel governor can do is to open and close the gates as the falling or rising speed may demand. This is precisely what a steam-engine governor does, but no one would think of asking the governor to control speeds for heavy changes of load on a steam engine that had no fly-wheel, and had a supply pipe only half the normal size for the full load. There are hundreds of water-power plants that offer substantially these conditions, and yet demand speed regulation for heavy changes of load.

NORTHERN ELECTRICAL MANUFACTURING COMPANY, Madison, Wis., has been awarded the contract for a complete new lighting plant by the city of Detroit, Mich. The machinery is to be of Northern and Stanley make. The city only considered two bids besides that of the Northern company, and a peculiar feature of these bids was their closeness, one of the other bids being only $9 higher than that of the Northern company. The fact that a contract of this magnitude and importance was entrusted to the Northern company, a comparatively young organization, is striking testimony to the reputation which it has made during its active existence.

THE BALL ENGINE COMPANY, Erie, Pa., recently received a most flattering letter from Mr. F. E. Drake, Director of Machinery and Electricity at the recent Paris Exposition, relating to the performance of the Ball Company's 300-h.p. engine at Vincennes. Mr. Drake states: "Our plant was the first of the entire Exposition installations to be put into active service, and since the starting of your engine we have never had a moment's shut-down or the least difficulty which could in any way be traceable to the engine. It has operated noiselessly and continuously and has made many friends among the foreigners who have visited the plant." These engines received a gold medal from the International Jury of Award at the Exposition.

THE CROUSE-HINDS ELECTRIC COMPANY, Syracuse, N. Y., received last month a most gratifying letter from the Manhattan Light, Heat & Power Company, of St. Paul, Minn., with reference to some switches which that company had previously purchased. The letter states that the prices which were quoted on the switches were somewhat higher than those quoted by other makers, and the purchasers had on that account naturally expected that the switches would be above the average in quality. When the switches came to hand, however, they greatly exceeded the anticipations of the purchasers, who were thereby moved to express their appreciation to the Crouse-Hinds Company and compliment them on the excellence of the apparatus furnished.

AMERICAN DISTRICT STEAM COMPANY, Lockport, N. Y., announces that the idea of central station heating seems to be taking a firm hold of the public mind in all wide-awake cities and villages. At the commencement of this season the company was employed installing over a mile of underground steam mains for the Seattle (Wash.) Electric Company, the largest pipe being 18 ins. in diameter. The work was completed in early autumn, and the Seattle company already has a large heating patronage, all the service being with exhaust steam. Something over two miles of mains have also been completed for the Atlanta (Ga.) Railway & Power Company. This is now in operation, and the company is serving exhaust steam for heating purposes to between thirty and forty customers, some of them being very large users.

THE STANDARD AUTOMATIC GAS ENGINE CO., Oil City, Pa., recently completed two engines of 600 horse-power each which are to be direct connected to Westinghouse 300-kw. generators, and has under way for the same customer two 150-h.p. engines for electric lighting. The company expects to close a contract for four 600-h.p. engines, all belted to alternators running in parallel on mixed load of arc and incandescent lights and rotary converters supplying current for a street railway. A novel and effective idea which will be used in installing this last plant will be that all the alternators will be placed in mechanical alignment and all or any two of them may be connected together by magnetic clutches, thereby being made to run absolutely in unison, distributing the load on all engines that may be running at the time, and entirely obviating any tendency toward hunting or racing.

THE STOREY GENERAL ELECTRIC COMPANY, successor to the Storey Motor & Tool Company, Harrison, N. J., manufacturer of dynamos and motors, has completed the removal of its offices and factory from Trenton, N. J., to a larger and newly equipped factory at Harrison, N. J. The new company, which is capitalized at $3,500,000, is the outgrowth of the steadily increasing demand for the well-known Storey motors, and with the larger facilities in shop room, machinery, etc., which are at its disposal will soon be in a position to handle a much greater volume of work in the same lines as those previously followed, and also to take up a number of additional lines which it was impossible to handle before on account of the lack of proper facilities. Mr. I. E. Storey, the proprietor of the old Storey Motor & Tool Company, is president of the new concern and has associated with him men who have both the ability and capital to push the new company forward to a prominent position in the electrical manufacturing field.

SOLID TRAINS TO NORTHERN MICHIGAN.

The Chicago, Milwaukee & St. Paul Railway is now running solid trains of palace sleeping cars, dining cars (serving meals a la carte) and first-class day coaches, through from Chicago to Calumet, Houghton, Hancock and other points in the Copper Country without change of cars, with direct connection for Marquette, Negaunee, Ishpeming, etc., and passengers from the East, South and Southwest will find this a most desirable route.

All coupon ticket agents sell tickets via the Chicago, Milwaukee & St. Paul Railway.

INDUCTION MOTORS IN A TOBACCO FACTORY.

THE POWER PLANT OF THE WETMORE TOBACCO FACTORY.

BY F. E BAUSCH.

The recent installation of an electric light and power plant in one of the largest independent tobacco factories in the United States presents an interesting application of the polyphase alternating-current system of power distribution, and the facility of handling a great variety of independent machines scattered on the various floors of an immense building, demonstrates strikingly the merits and success of this class of electrical operation. The plant of the M. C. Wetmore Tobacco Company, of St. Louis, Mo., with a capacity of 100,000 lbs. of tobacco daily and a pay-roll numbering about 1200 people, is the one under consideration.

South of the middle division of the factory is located the boiler-room, 80 ft. long, 50 ft. wide and 18 ft. high. There are six 150-h.p. horizontal boilers, built by the John O'Brien Boiler Works Company, of St. Louis, Mo., set in pairs. The boilers are supplied with Hawley Down Draft furnaces, consisting of one front and one rear manifold, with connecting grates. The smoke-stack stands alone and is anchored to a cast-iron base plate. It is 60 ins. in diameter and 100 feet high, inclined, the lower half being made of 3/16-in. steel and the upper half of No. 10 steel, with rings 5 ft. wide. The stack was also built by the John O'Brien Boiler Works Company. The steam auxiliaries are of the usual types.

The engine is a heavy-duty Corliss 18x36-in., built by the St. Louis Iron and Machine Works, St. Louis. It is located in the basement near the north wall of the middle division of the building. Its rating is 250 horse-power at 100 r.p.m., and 100 lbs. steam pressure. The engine has a 10-ton fly-wheel, 14 ft. in diameter. The valve gear is the standard hook releasing type, and the regulation of the engine is held within 2 per cent under all changes to load within full capacity.

The generator is a three-phase 230—133-volt General Electric alternator, with double voltage for lights and power. It is rated at 200 kilowatts, and is direct connected to the engine. The armature is Y-connected, and four-wire distribution is used throughout the building, the pressure between the "neutral" and any one of the outside wires being, of course, $\frac{1}{\sqrt{3}}$ of the pressure between the outside wires.

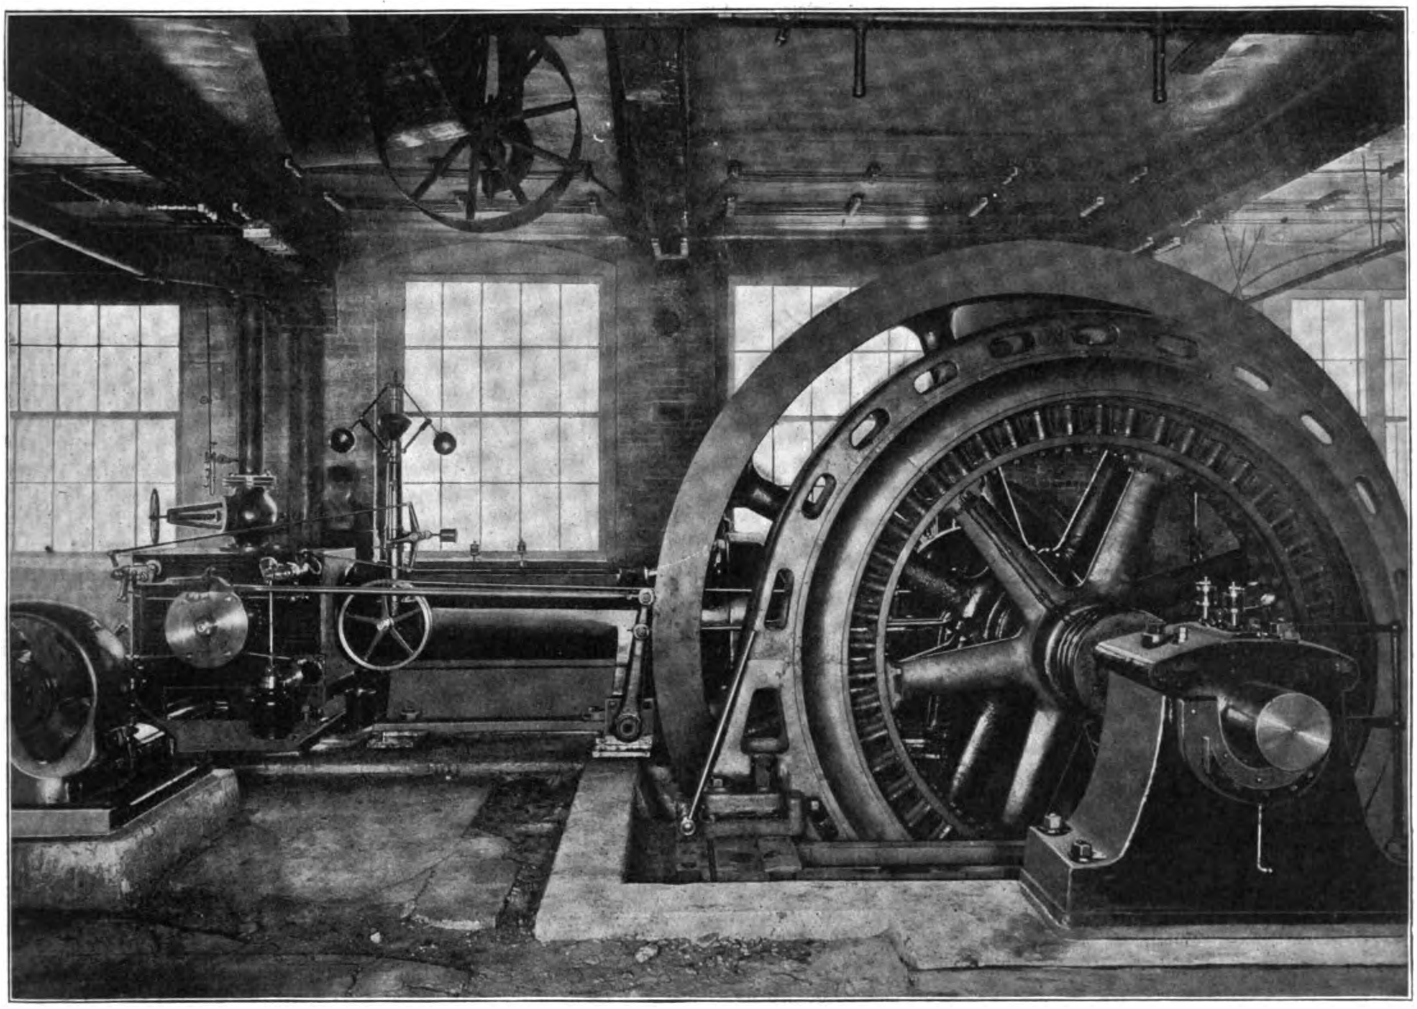

FIG. 1.—ENGINE AND THREE-PHASE ALTERNATOR IN THE POWER HOUSE.

The frequency is 40 cycles. A small direct-current unit is driven by a 25-h.p. Chase engine. This in day-time serves as the exciter for the alternator, and at night is used for incandescent lighting.

There are 23 General Electric induction motors, ranging from 1 to 30 horse-power and operated at 220 volts. The rotors of these motors are of the squirrel-cage type. The apparatus used to prevent excessive current rush at starting is a compensator connected in the motor primary or exciting current, as shown by Fig. 10. This arrangement cuts down the starting e.m.f. as well as the current, but this is not objectionable, as the maximum starting torque is not required. For full-load torque at starting the motors here used require approximately four times the full-load running current. If, therefore, the starting current must be kept at or below full-load current the motor cannot be expected to exert more than a quarter of full-load torque at starting.

For motors of 15 horse-power and under the compensator starters have three taps giving voltages of 40 per cent, 60 per cent and 80 per cent of the full circuit voltage. Compensators for motors above 15 horse-power have four taps, giving voltages of 40 per cent, 58 per cent, 70 per cent and 85 per cent of the circuit e.m.f. Motors with compensators are proportioned so that the primary and secondary have low self-induction. They contain a minimum amount of copper and a considerable amount of iron. These motors are especially adapted for factory work, the conditions involving light starting loads and practically constant full loads when up to speed.

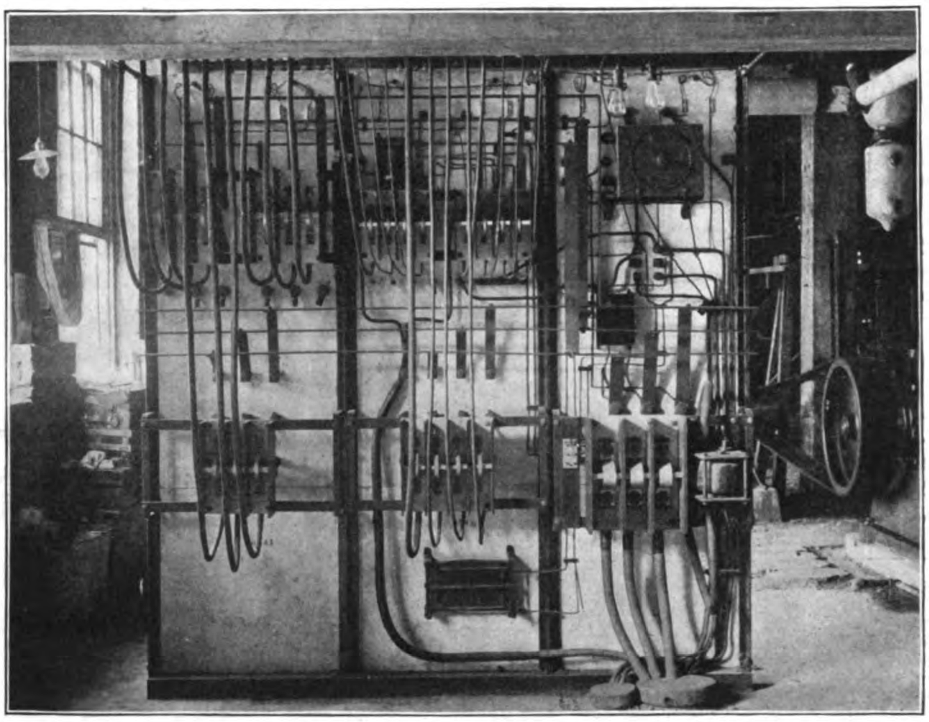

FIG. 3.—THE BACK OF THE SWITCHBOARD.

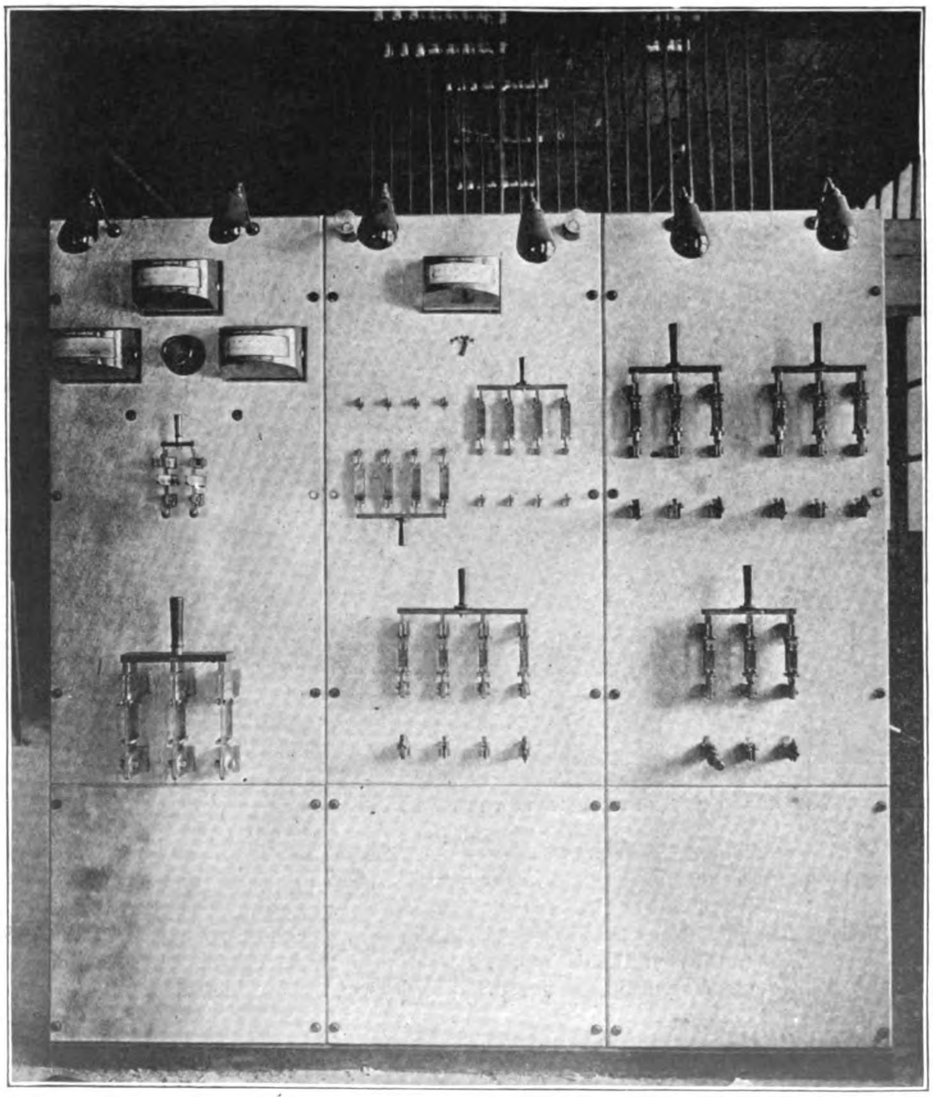

FIG. 2.—THE FRONT OF THE SWITCHBOARD.

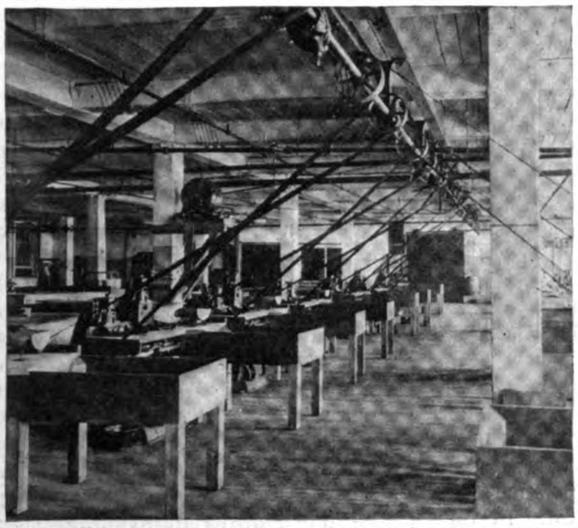
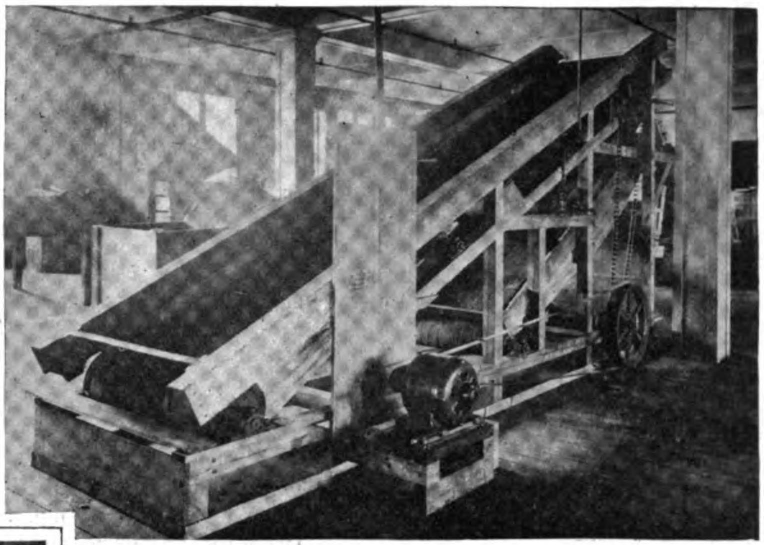
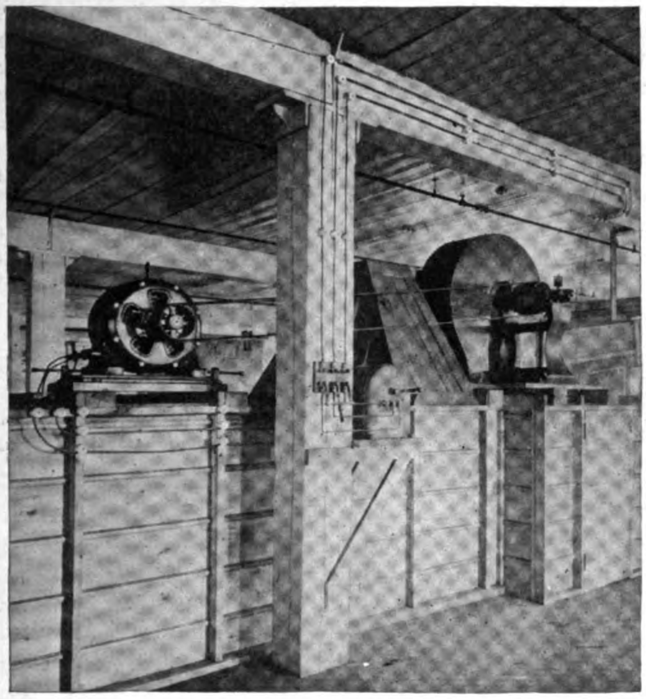
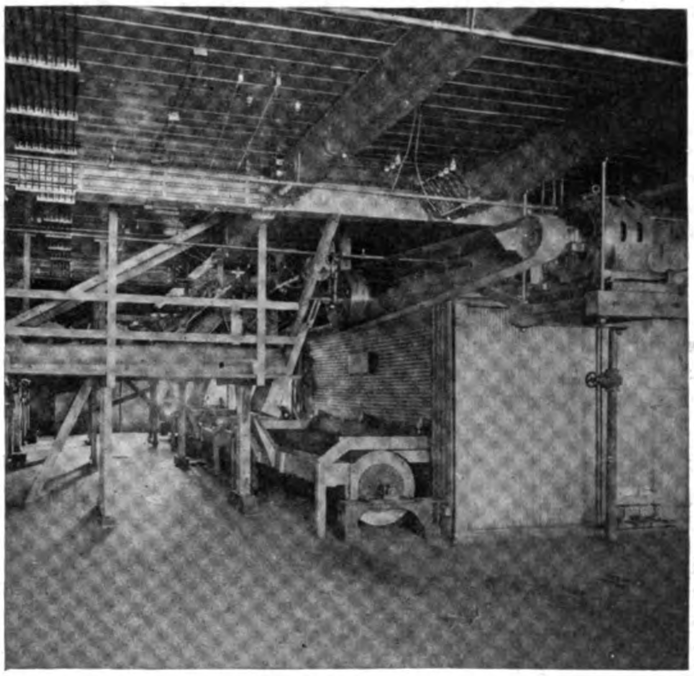
All of the cable used in the motor circuits is rubber-covered to a thickness of 3/32 in. All solid conductors are No. 2 B. & S. gauge, larger sizes being made up of small wires in the manner of standard cables. Porcelain clamp insulators without iron bands are used throughout the building. The average distance between insulators on a straight line is not over 36 ins. Where feeders or wires run through floors, porcelain floor insulators are installed projecting 2 ins. above and below the finished floor. Three feeders run from the switchboard busbars to the motor circuits on the various floors. One feeder supplies the basement, first and second floors; the second feeder supplies the third floor, and the third feeder carries current to the fourth and fifth floors.

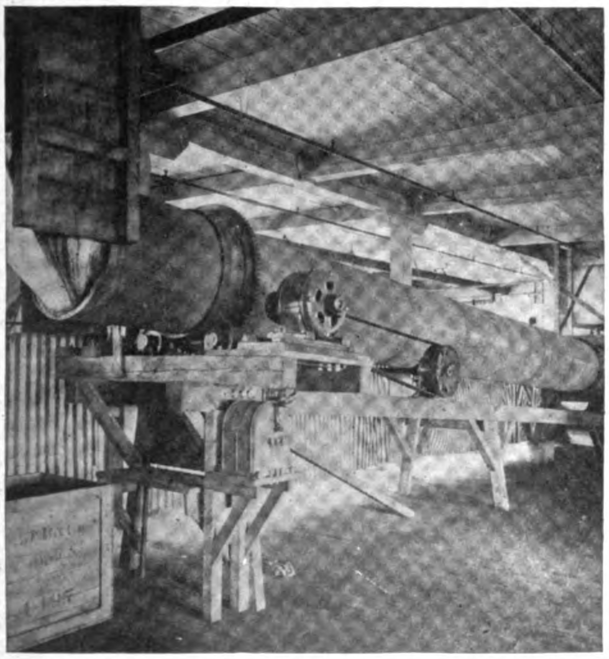
There are installed seventy 6-ampere 125-volt enclosed alternating-current arc lamps, and about 150 16-c.p. 125-volt incandescent lamps. The incandescent and arc lamps are on separate circuits. Four conductors constitute a feeder or riser. One of the four conductors is of proper size to feed one side of all the two-wire circuits; the other three conductors are one-third this size. All branch lines leaving cut-out boxes are two-wire, and equal distribution is made between the three small conductors and the large single conductor which leads out from the junction of the generator armature winding. The connections at switchboard are so arranged that distribution of direct current at night, when the motors are shut down, is effected by combining the terminals of the three small wires into a single leg and using the large wire for the opposite leg.











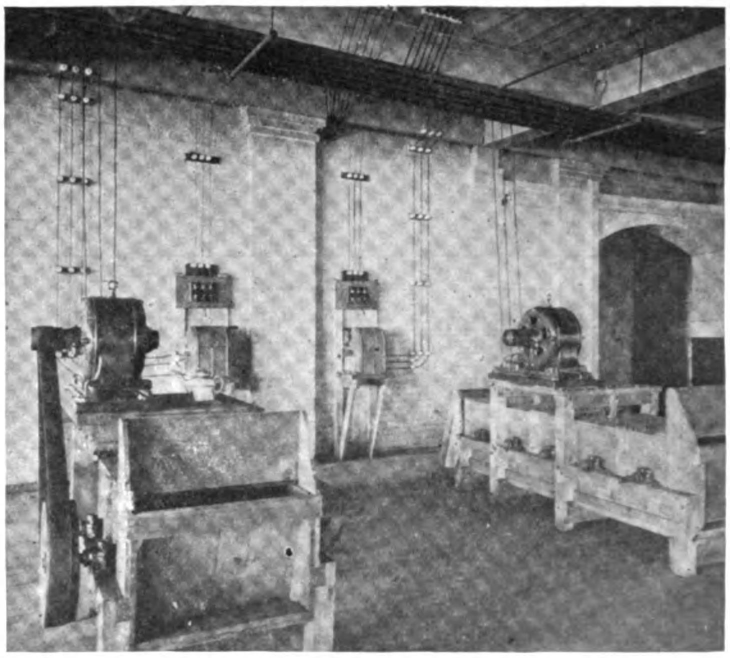


FIG. 4.—10-H.P. MOTOR DRIVING PLUG MACHINES.
FIG. 6.—10-H.P. MOTOR DRIVING FAN.
FIG. 8.—5-H.P. MOTOR DRIVING LEAF STEAMER

FIG. 5.—5-H.P. MOTOR DRIVING WRAPPER CASER.
FIG. 7.—10-H.P. MOTOR DRIVING WRINGERS.
FIG. 9.—3-H.P. MOTORS DRIVING SHAKER MACHINES.

A 5-h.p. motor drives the leaf steamer (Fig. 8), which is a sheet-iron cylinder 35 ft. long by 3 ft. in diameter. In this steamer the initial step in the process of tobacco manufacture is begun. On the basement floor a 15-h.p. motor drives a stem-baling machine, which compresses and binds the stems into the form of a bale for shipment. After the leaf is stripped of its stem it is collected in bulk and dropped through chutes to be automatically dipped, sweetened and passed through wringers on the floor below. A 10-h.p. motor (Fig. 7) drives three wringers, each of 30,000 lbs. capacity. The wringers automatically feed to the belt apron of three driers, 12 ft. wide by 132 ft. long. The belt aprons and cooling fans are driven by three 30-h.p. motors. Leaving the drier, the tobacco drops to an automatic carrier which conveys it into a Cardwell caser, an open copper-lined drum 15 ft. long by 4 ft. in diameter. The caser is belted to a 5-h.p. motor. A small air compressor driven by the same motor discharges into an accumulator, from which, at a pressure of about 35 lbs., an injector sprays the flavor into the caser.

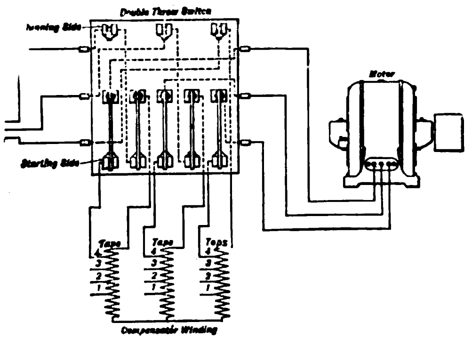

FIG. 10.—COMPENSATOR DIAGRAM.

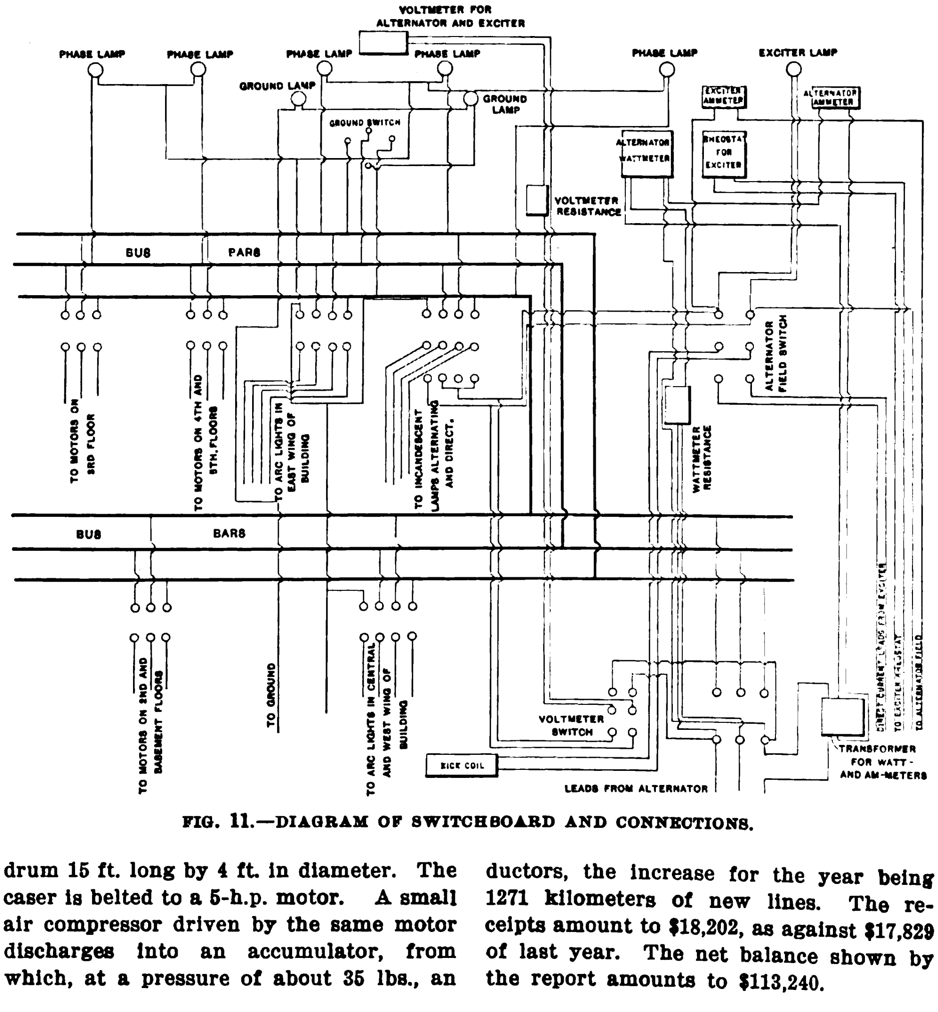

FIG. 11.—DIAGRAM OF SWITCHBOARD AND CONNECTIONS.

Two 5-h.p. induction motors drive two shaker machines, by which the flavored tobacco is loosened up. The plug machines, of the Adams duplex double-header type, are driven from two lines of shafting, belt-driven by two 10-h.p. motors. Two searching tables are also driven through a countershaft by the line shafts.

The tobacco intended for smoking purposes is put through a roller and a No. 3 Pease cutter; a 20-h.p. motor drives a shaft to which is belted the cutter and a 6-ft. grind-stone for grinding the cutter knives. After the tobacco has been cut and thoroughly dried it is passed through a granulator and sieves driven by a 15-h.p. motor. After being cased, flavored and screened in a finer mesh the tobacco is packed in bags by a packing machine driven by a 2-h.p. motor. In the twist tobacco department a fan in the dry-house is driven by a 10-h.p. motor.

The electric light and power equipment ever since its installation has shown a high figure of merit in flexibility, convenience of operation and low cost of maintenance, and the service has been uniformly and entirely satisfactory.

Telephones in Buenos Ayres.—The Buenos Ayres Telephone Company has just published its annual report for 1899-1900 showing the progress made during the year under review. The telephone lines of the capital already amount to 7098 kilometers of overhead and underground conductors, the increase for the year being 1271 kilometers of new lines. The receipts amount to $18,202, as against $17,829 of last year. The net balance shown by the report amounts to $113,240.

LIFTING ELECTROMAGNETS.

BY E. B. CLARK.

The accompanying engravings illustrate the facts emphasized in the general discussion presented in the preceding articles. Fig. 3 shows a section through a magnet built on the principle of a modified horseshoe, having one pair of concentric poles. The horns on the sides are for the purpose of attaching sling chains in case of the disablement of the magnet. Fig. 4 shows a perspective of the same magnet. Though at first glance this seems to be an admirable design, as a matter of fact it was a failure in practical operation. It has the advantage of thorough protection of the winding from external injury, which is important, but it possesses the following disadvantages:

(1) Large size, and therefore low ratio of lifting power to weight. (2) A circular form of pole face, which is poorly adapted to hold a flexible piece such as a steel plate, for a long plate bends down at the ends and strips off from a round pole face. (3) Absolutely no ventilation of the winding. All heat loss in the coil must be dissipated through the outside pole or shell by conduction, and thence to the atmosphere by radiation. The winding must, therefore, be heavy to prevent overheating. (4) High leakage, due to the short distance between poles. (5) High cost of construction. (6) Necessity to take magnet apart in order to repair a broken terminal lead (the fracture in which always occurs close to or inside of the magnet).

Notwithstanding these objections, the performance of this magnet, when tested, looked excellent, on paper. It lifted over 12 tons with 13 amperes at 250 volts, or 3250 watts. Its weight was 1235 pounds, giving a ratio of weight lifted to weight of magnet of about 19.

At this point it might be pertinent to note that the lifting power of a magnet, obtained in a test where every condition is advantageous to high tractive effort, means absolutely nothing from a practical standpoint. The winding of any magnet can be so proportioned that a keeper laid across its poles cannot be detached by a pull of less than 130 to 150 pounds per square inch of pole face, provided the air gap be made small and the keeper be thick enough to carry the magnetic flux. The round magnet described above is an example of high lifting power but small practical value.

Fig. 5 shows a section through the poles and windings of a bipolar magnet in use by the Illinois Steel Company for a number of years for handling plates. Figure 6 shows a side elevation, and Fig. 7 a perspective view of the same magnet. The form of the pole face is well adapted to plate handling; when it is laid across the plate a long surface of polar face is presented to resist the first tearing-off tendency, due to the plate bending down at the ends. The pole faces being some distance apart do not encourage leakage. The magnet will pick up several plates at a time, which is an advantage when loading small sheared plates and a disadvantage when handling long unsheared plates. This magnet, however, as did the round magnet, possesses the disadvantages of large size, lack of ventilation, high first cost, and high cost of maintenance. It must be taken apart to repair a lead broken close to the frame, or to replace a worn eyebolt. The top plate is of steel, the pole pieces are of wrought iron, the casing is of cast brass, and the winding of No. 14 double cotton-covered magnet wire (two coils, 85 pounds each). On test it has lifted 6 tons with 6¼ amperes, at 250 volts, or 1562 watts. Its weight is 1200 pounds, giving a ratio of lifting power to weight of 10.

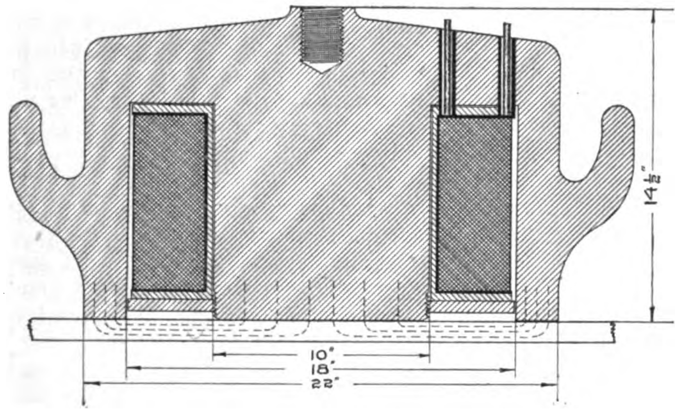

FIG. 3.—CROSS SECTION OF ROUND MAGNET.

A comparison of the data given for these two magnets makes it appear that the round magnet is much better, but, as already stated, the round one was a failure and the long one a success. The conclusion is that the figures usually given for the performance of a magnet, viz., lifting capacity and power consumption, are absolutely valueless from a practical standpoint. The coil of the round magnet has 2904 turns of wire, weighing about 217 pounds; the two coils of the long magnet contain 2952 turns and weigh about 176 pounds. The round magnet, with its compact design, can lift more than twice the load of the long one because of its greater number of ampere turns; yet it was a failure by reason of its shape. The lesson taught is that the shape must be right, the design compact, and the magnet small. With these points in view, the solution seems very simple. It merely consists in properly grouping small magnets into one complete and mechanically well-designed structure.

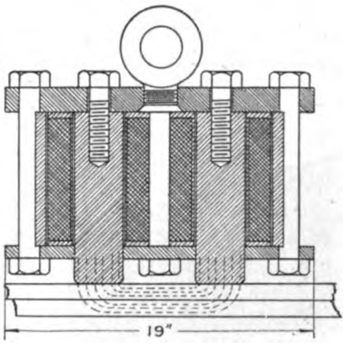

FIG. 5.—SECTION OF BIPOLAR MAGNET.

The writer, after considerable experimenting about two years ago, selected, as the best shape and best size of unit for handling plates, a pole piece having a cross-section of 1 inch by 5 inches, and a length of 3½ inches. Its coils surrounded it to a depth of ¾ in. (including insulation), and covered 2¾ inches of the length of the pole piece. No bobbin was used, the insulation of the coil being sufficient to protect it. The pole pieces were cut from 1-inch by 5 inches bar iron or soft steel and planed to true surfaces top and bottom, in groups of eight or ten at once. When the corners were rounded with a file, and the pole piece drilled and tapped for ½-inch bolts, it was finished. The coils were all alike, being machine wound and interchangeable. In the light of more recent experience this design evidently could be improved, but it is doing, and has done for two years, most successful service. Its small size (requiring small head-room) and its low weight were particularly advantageous in this case.

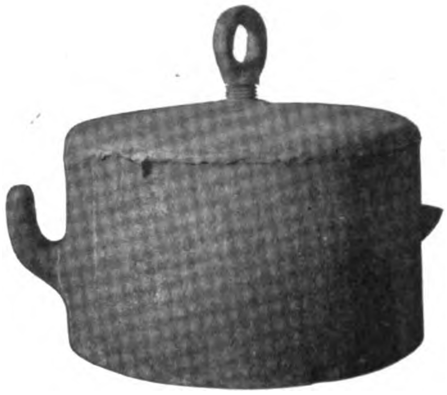

FIG. 4.—EXTERIOR OF A ROUND MAGNET.

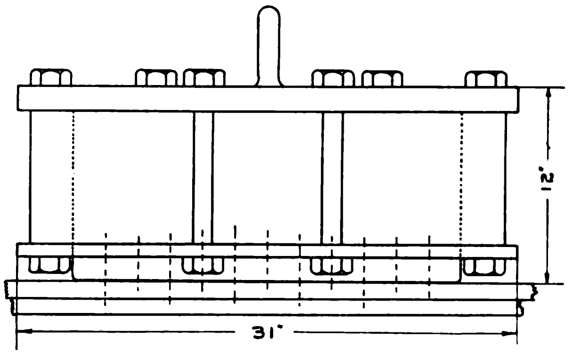

FIG. 6.—SIDE VIEW OF BIPOLAR MAGNET.

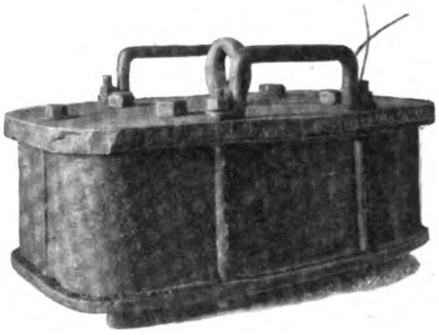

FIG. 7.—EXTERIOR OF A BIPOLAR MAGNET.

Figure 8 shows the side elevation of a magnet built up in this way. Figure 9 is an end elevation, and Fig. 10 a perspective of the same magnet. In this case the service was the handling of long unsheared plates, several magnets being hung from a long beam and operated simultaneously. It is desirable to take a very firm hold on one plate without picking up the floor plates of the "hot-bed." With this object in view, the twelve poles are arranged in two rows of six each, alternating in polarity. The magnetic flux then passes each way from each pole, the result being to reduce the reluctance of each circuit to less than it would be even if used as an independent magnet, and also to avoid carrying the density of magnetization in

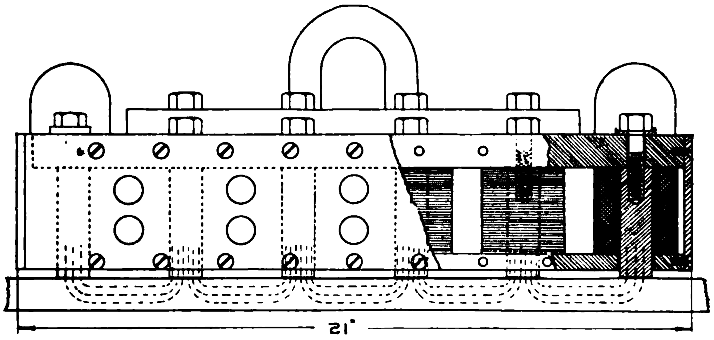

FIG. 8.—A MULTIPOLAR LIFTING MAGNET.

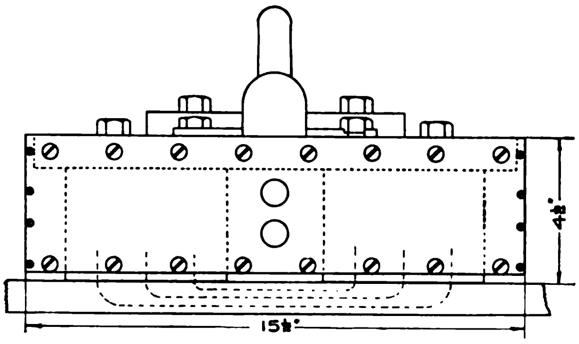

FIG. 9.—END VIEW OF MULTIPOLAR LIFTING MAGNET.

the plate being handled to an excessive point. The plate, therefore, short circuits the lines of force and prevents the leakage through to the lower side, which would pick up the floor plates. A large area of plate surface is covered and a powerful grip taken on that area.

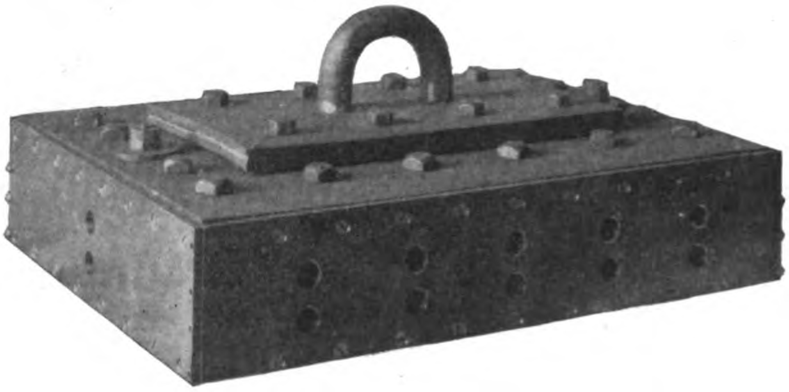

FIG. 10.—PERSPECTIVE VIEW OF MULTIPOLAR MAGNET.

The general form of the magnet face is rectangular, which is the shape best adapted to prevent stripping off. The top is one continuous piece of dead soft-steel plate, finished on the bottom and edges. Tap bolts hold the pole pieces to this plate. Above this is an eye-plate, into which the eye for supporting the magnet is riveted. By this means a worn eye can be replaced quickly and easily without disturbing the magnet proper. The terminal leads are so arranged that they cannot be broken inside of the top plate, being connected externally to terminals which are protected by cast-brass guards, easily removable. Details of this terminal are shown in Fig. 11. The coils are held in position by a bottom plate of cast or sheet brass, which, in turn, is held by side plates of sheet brass; these also afford protection to the sides of the coils. Ventilating holes allow free circulation of air through the interior. In a very wet place these holes could be omitted, but no trouble has been experienced from weather grounds where good insulation is used. The magnet weighs, complete, 300 pounds, and lifted, in a test similar to those given the bipolar magnets previously mentioned, 4 tons, making the ratio of lifting power to weight about 27. It takes 4.4 amperes at 250 volts (1100 watts), but it works with 4 amperes at 230 volts (920 watts).

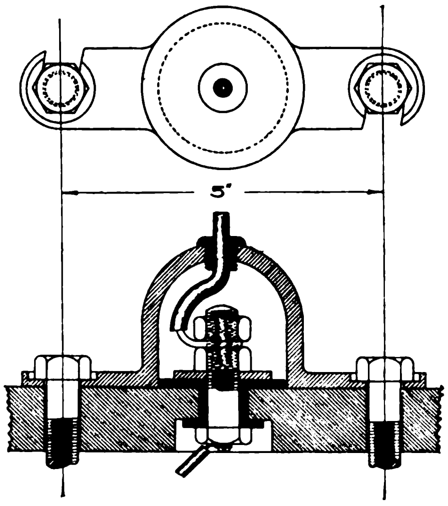

FIG. 11.—DETAIL OF COIL TERMINAL.

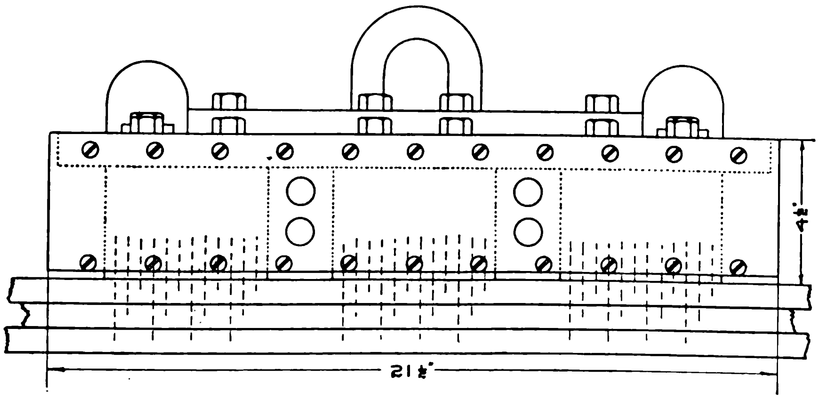
However, as previously stated, these figures really tell nothing of the value of a magnet for actual use. As a matter of fact, the most powerful magnet thus far described, the round type, was absolutely useless as a plate handler; the next one, also powerful, was partly satisfactory; and this least powerful one is the best in this particular case. It weighs about one-fourth as much, uses about two-thirds the power, costs about one-half as much, requires almost no repair, and holds a plate far more securely. The weight lifted per watt expended is not large, but a large figure for this ratio does not necessarily indicate a good design. In ordinary plate handling, a large air gap must be taken into consideration, which means that a large flux must be driven through a high reluctance. If this air gap be reduced to make a big lift on test, the winding will take just as much current, but the flux will not be as much per watt expended because of the decreased permeability at the high density of magnetization in the pole piece, which is above saturation. If it is desired to build a magnet which will show a big lift per watt expended, on a test, the winding should be so proportioned that the poles are not over saturated, and a large area of pole faces should be allowed. But when such a magnet is placed in use where a big air gap is unavoidable, it will suffer a severe impairment of lifting power because of the increased reluctance and consequent decreased magnetization.

To secure this high ratio of lifting power to watt expended, the current density in the coils should also be made very low; that is, a large number of turns of wire should be wound on, which will decrease the current without decreasing the ampere-turns. Of course, though, this will increase the weight of the magnet, both as to iron and copper, and will run its cost up.



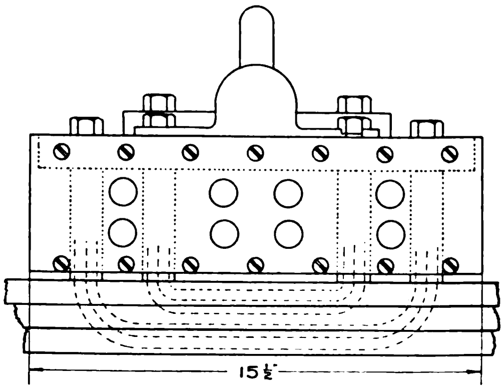


FIG. 12.—MULTIPOLAR MAGNET FOR LIFTING SEVERAL PLATES AT ONCE.—FIG. 13.

In handling sheared plates it is frequently desirable to expedite the work by picking up several small plates at once. If they are very small, say only a couple of feet square, they can be handled on edge, but if larger, they have to be picked up flat, one on top of another. A magnet for this work is built up in the same manner, but the poles are arranged differently. Figure 12 shows a side elevation and Fig. 13 an end elevation of such a magnet. The poles are arranged in four rows of three, each placed end to end. The first and second rows are close together and the third and fourth rows are similarly arranged, but considerable distance is left between the second and third rows. All poles on one side of this space are of one polarity, and all on the other side are of the opposite polarity. Then all the flux must pass over the space between the second and third rows. A plate across the magnet face then becomes saturated and some flux is forced down into the plates below. The result is that several plates are picked up. By connecting the coils in two circuits and bringing the leads out to suitable pole-changing devices, which can be made very simply, the arrangement of polarities here described, can easily be changed to the more economical one first described, for ordinary work, in which it is not desired to handle more than one plate. In the case of each magnet illustrated a plate is shown across the magnet face, and dotted lines are drawn, showing the path of the magnetic flux through the lifted plate. If it is desired to drop a plate from the bottom it can easily be accomplished by the method of quickly opening and closing the circuit, as described in the previous article. In the case of a magnet winding built up of small coils, the flashing is less severe upon opening the circuit.

There are many other arrangements of these small pole units that could be made to meet special requirements. For example, a circular structure would be well adapted for car wheels, while other special shapes to be lifted might require other arrangements. For a straight pull the round pole piece is preferable because it can be wound with a given number of turns with the least amount of wire. The table herewith gives the data for the designs illustrated.

DATA FOR THE DESIGNS ILLUSTRATED.

Type of magnet	Round, Fig. 4.	Long, Fig. 7.	Small, Fig. 10.
Size of wire	No 12.	No. 14.	No. 17.
Turns per coil	2,904	1,476	644
Total turns	2,904	2,952	7,728
Total pounds of wire	217	176	57
Total resistance at 50° C	19.25 ohms.	40 ohms.	56.6 ohms.
Amperes at 250 volts	13	6.25	4.42
Circ. mils per ampere	502	656	465
Total ampere-turns	37,752	18,450	34,158
Amp.-turns per sq. in. of pole-face	482	348	1,138
Area of pole faces, sq. in	204	106	60
Area of magnet face, sq. ins.	380	233	241
Tons lifted on test	12	6	4
Weight of magnet, lbs	1,235	1,200	300
Pounds lifted per pound of magnet	19.4	10	26.7
Pounds lifted per watt	7.4	7.7	7.5

The actual mathematical equations for predetermining the flux and the consequent required magnetizing force are very simple, inasmuch as no actual work is done by the magnet. Its function is simply to resist the force of gravity, and does not involve a space acted through. Therefore, all power absorbed by the magnet is accounted for by losses in the magnet itself. The important feature of design, then, is the correct shaping of the magnet to the work required of it, due attention being paid to first cost, and cost of repair. It always should be borne in mind that a magnet must be built to suit conditions in order to obtain best results. When this is done and a successful design produced, the owner will value his magnet at many times its cost, and generally will investigate the feasibility of putting in more of them. Like every other labor-saving device, a magnet, to be entirely successful, will often necessitate some changes in former methods of operation, but such changes are soon paid for.

The Illinois Steel Company, in this country, and one or two concerns in England, have had magnets in use for a long time, and during the last few months a number of other mills in this country have adopted their use. Where they have been properly built to suit the existing conditions they have been universally successful.

That this field, like every other one promising cheaper methods of doing work, will soon be invaded, cannot be doubted by anyone who has seen the advantages to be gained in many cases by the use of electro-lifting magnets.

METHOD OF MEASURING THE VIBRATION OF A TRANSMITTER DIAPHRAGM.

BY W. L. MERRILL.

The following method of measuring the vibration of a telephone transmitter diaphragm has been tried at the University of Maine (Orono, Me.), and found to give quite accurate results. A silvered mirror, M, Fig. 1, cemented to a steel pinion, J, set in watch jewels, reflects a ray from a source of light, L, on the screen, S. Perpendicular to the pinion and in the plane of the mirror is fastened a steel arm, K, graduated to hundredths of an inch and adjustable by the screw, I. To the center of the diaphragm, D, is soldered a needle, P, which bears against the steel arm, K. The slightest vibration of the diaphragm is transmitted through the needle and arm to the mirror, causing it to oscillate and thus causing the reflected light ray to travel on the screen, S, as from A to A′. A magnet, NS, is placed behind the arm, K, to retract it, when the diaphragm recedes. Any inertia effect due to the mechanism may be equalized by adjusting the damping spring, F, until the transmitter works normally.

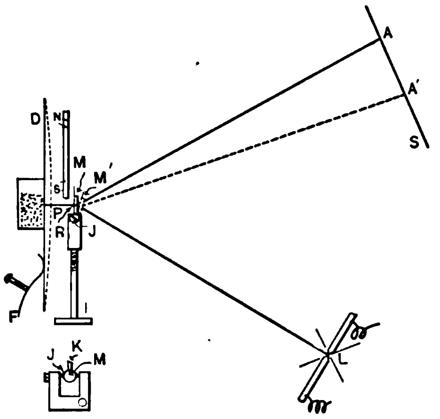

FIG. 1.—MEASURING THE VIBRATION OF A TRANSMITTER DIAPHRAGM.

The travel of the light ray on the screen bears a direct geometrical relation to the travel of the mirror, and hence gives a basis for measuring the magnitude of the vibration of the diaphragm. The calculations based on experiments performed with such an instrument gave a diaphragm excursion of 1/3000 in., where the distance from J to R was 1/10 in., that from R to B 25 ft., and the travel, A, A′, 2 ins. The ticking of a watch gave a noticeable deflection, while sounds of greater intensity caused deflections on the screen of almost 2 ft.

BOILER FEEDING AND FEED-WATER HEATING.

BY L. B. MATHER.

The operation of getting water into a steam boiler is so closely interlinked with the operation of heating it that it is scarcely practical to consider the two separately. It is unnecessary to point out the saving obtainable from heating the feed water; this is amply and strikingly demonstrated by the fact that using live steam to heat the feed water before it enters the boiler is more economical than putting it in cold. But it is frequently perplexing to determine just what method of heating and what means of delivering the feed water will be most economical. The first cost of the apparatus considered enters into the question, of course, as the interest and cost of maintenance form part of the operating expense of the plant, and the class of help obtainable must also be considered, simplicity frequently being preferable to economy.

Speaking generally, it is safe to assert that for all plants of a size too small to justify the installation of economizers, it is good practice to employ heaters in the exhaust pipes of the engines, absolutely regardless of the condensing question. If the plant be non-condensing, it is a self-evident proposition that exhaust-steam heaters are imperative; even if the exhaust steam be used for heating purposes, it will usually pay to put in a heater between the engine and the heating system, taking care, of course, that the steam shall not be robbed of so much heat as to make it useless for radiator service. In such a case, still speaking generally, it will probably be advisable to use some form of steam pump for boiler feeding, in order that the exhaust from the pump or pumps may be utilized for further heating the feed-water in secondary heaters.

It goes without saying that the pump to be used should be of the highest efficiency possible. Ordinary simple direct-acting steam pumps require from 100 to 150 lbs. of steam per horse-power-hour; compound pumps of this type require 60 to 90 lbs.; simple fly-wheel pumps, which are really pumping engines on a small scale, may be had that will develop a horse-power on 50 lbs. of steam an hour; a compound fly-wheel pump requires 30 to 50 lbs. of steam per horse-power-hour. The writer once ran across an odd type of small pumping engine which had one water and two steam cylinders mounted side by side, all three being single acting. There was a single valve between the two steam cylinders which cut off the steam at one-third stroke, no variation of cut-off being provided; the speed was regulated by means of a globe valve in the steam pipe, just as the ordinary direct-acting pump is controlled, and it showed the remarkable economy of 38 lbs. at full load and 45 lbs. at two-thirds the normal speed. The only reason that can be conceived for the failure of this "freak" pump to become an important factor in the market was the cost of building it.

To revert to the specific subject under discussion: In non-condensing plants where the exhaust steam from the main engines is wholly available for heating the feed water, it will generally be found advantageous to employ electrically-driven boiler-feed pumps for regular service and to provide a single auxiliary steam pump for use at such times as the electrical equipment may be shut down. A good non-condensing engine will deliver a horse-power on 28 pounds of steam an hour, and a decent generator will convert this power with an efficiency of 93 per cent; the losses in a motor-driven pump should be somewhere near 40 per cent—say the combined efficiency of the generator and the motor-pump is 56 per cent; then the pump will deliver a horse-power on 50 pounds of steam an hour, which compares with an unusually good compound direct-acting steam pump or a simple fly-wheel pump. Considering simplicity, therefore, as well as economy, the motor-driven pump is preferable, as a fly-wheel pump is a much more complicated mechanism, besides requiring a considerable amount of small piping which has extravagant radiating surface. It seems entirely justifiable, therefore, to say that electric motor-driven pumps are preferable to either of the other types under average conditions for boiler feeding in non-condensing plants where the feed water can be sufficiently heated by the engine exhaust.

In condensing plants, primary heaters will be found advisable under average conditions. Of course if the plant is a very large one, economizers claim consideration, but in a plant of ordinary size an economizer is usually barred by the cost of installation and attention. A primary heater will bring the feed-water temperature from 40 or 50 up to about 110° Fahr.; a higher temperature could be secured by imposing back pressure on the engine, but this is obviously not good practice with a condensing engine. It will be advisable, therefore, to still further heat the feed water by passing it through a secondary heater after it leaves the primary heater. If sufficient heat can be obtained from the exhaust steam of the air, circulating and boiler-feed pumps to carry the feed-water temperature up to about 200° Fahr. without deliberately using pumps of low efficiency for the sake of their exhaust heat, then the combined exhausts from all the pumps should be passed through the secondary heater.

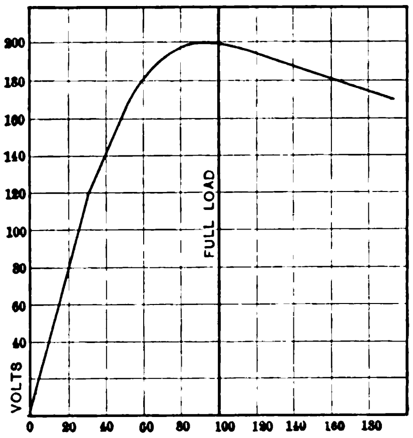
If, however, the efficiency of the auxiliaries is so high that a gain of only 40 to 50 degrees in temperature is obtainable in the secondary heater, it will usually be advisable to run the pumps condensing, still passing the exhausts through the secondary heater in order to extract as much heat as possible before delivering to the condenser, and to reinforce the secondary heater with live steam bled from the receiver or the high-pressure exhaust of the engine. If the engine is provided with a reheater which superheats the receiver steam, then the steam used in the secondary feed-water heater should be taken out from the high-pressure exhaust before that steam reaches the reheater, in order to avoid a waste of superheat. The plan outlined would be almost universally more economical than to sacrifice the efficiency of the pumps in order to obtain sufficient heat from their exhaust steam to give the feed water the proper temperature. Air and circulating pumps should preferably be engine-driven, but whether they are of this type or are ordinary forms of direct-acting pumps, they should be run condensing unless their exhaust steam added to that of the boiler feed pumps will supply sufficient heat for the feed water without bleeding the engine receiver.

Belt-driven pumps are not, as a general rule, commendable for boiler feeding on account of their inefficiency at partial loads when driven at constant speed, as they would have to be in all modern central stations and isolated plants. If it were practical to vary the speed of the pump according to the requirements of the boilers, without interposing a lot of power-consuming gear, the belted type would show the highest efficiency of any form of boiler feeder.

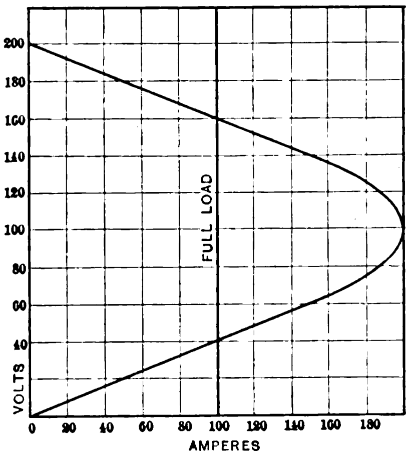
RELATION OF CHARACTERISTIC CURVES OF DIRECT-CURRENT DYNAMOS TO PARALLEL OPERATION.

BY ALTON D. ADAMS.

The action of direct-current dynamos in parallel may be predicted, to a large extent, from their characteristic curves. For this purpose, curves should be constructed showing the voltages at dynamo terminals, on one set of ordinates, and amperes in external circuits on abscissae at right angles to the ordinates plotted to some convenient scale. Such curves are here shown for series, shunt, evenly compounded and over-compounded dynamos. The curve for the series dynamo is from a machine with capacity of 100 amperes at 200 volts, maximum, that part of the curve between the zero point and the full load line covering the total intended range of work. If the resistance in the external circuit of the dynamo is decreased so that more than 100 amperes flow through the armature and magnet coils, the voltage of the dynamo drops as shown by the curve, which will reach the zero line of pressure when the dynamo is on a short-circuit of no appreciable resistance. The internal ampere flow of the series dynamo is greatest when the external voltage is zero.



CHARACTERISTIC OF A SERIES DYNAMO.

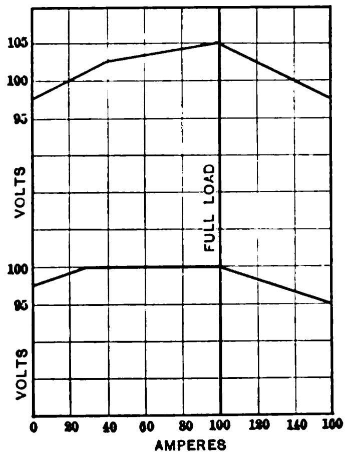


CHARACTERISTIC OF A SHUNT DYNAMO.

The characteristic curve of a shunt-wound dynamo shows some properties that are exactly opposite to those of serise-wound machines. With no current in its external circuit, the series dynamo has no voltage, save the very small amount resulting from the residual magnetism of its frame. On the other hand, a shunt dynamo, as shown by its curve, has the maximum voltage with no current in its external circuit. When the circuit of a series dynamo is closed, its pressure rises with the flow of current; when the circuit of a shunt dynamo is closed the voltage at its terminals drops with the increase of current flow. If the external circuit of a shunt dynamo is reduced so as to allow a flow of current beyond the full load capacity of the machine, the voltage continues to drop for each increase of current, until the external resistance reaches a certain value for each dynamo, corresponding to the maximum ampere output for that machine. Any further reduction of the external resistance results in a fall of both the volt and ampere output of the dynamo, which are brought to zero when the external resistance is zero.

These results are plainly indicated by the shunt dynamo curve shown herewith and may be foreseen from the fact that an external circuit of no appreciable resistance, being in parallel with the shunt magnet winding of high resistance, allows no current to pass through it, and there is only a minute amount of residual magnetism to induce e.m.f. in the armature. If two shunt dynamos having equal voltages on open circuit are connected in parallel on a load not greater than their combined capacities, the curve shows that any inequality of load between them will tend to decrease rather than increase, since the dynamo loaded to the larger part of its capacity will tend to drop in voltage, while the dynamo loaded to the smaller part of its capacity will tend to rise in voltage, the combined tendency being to properly divide the load.

The curve of the compound-wound dynamo shows the combined effects of its shunt and series coils. At the start, with no current in the outside circuit, the dynamo reaches nearly its full voltage, unlike the series-wound dynamo, which has no material voltage until its outside circuit is closed, and unlike the shunt-wound dynamo, which gives its maximum voltage on open circuit. The curve of the compound-wound dynamo rises slightly at the start of current flow in the outside current, but as the saturation of the magnets increases, the contrary effects of the series and shunt coils soon reach a point where they just balance each other, if the dynamo is evenly compounded. For the greater part of its capacity the compound-wound dynamo gives a characteristic curve that is nearly a straight line, but soon after the point of full load is passed, the curve begins to drop toward the line of zero e.m.f. This drooping curve is similar to the first part of the shunt-dynamo curve; but differs from the second half of that curve in that it does not tend toward the zero point of both pressure and current; on the contrary, it follows the general course of that part of the series-dynamo curve beyond the full load line, tending to a very large current on short-circuit.



CHARACTERISTICS OF COMPOUND DYNAMO.

If two similar compound-wound dynamos be connected in parallel without an equalizer and given a load less than the sum of their capacities, the curve shows no such tendency to mutual adjustment as is evident in the characteristic curve for shunt dynamos. Any increase of load on either dynamo does not tend to lower the voltage of that dynamo, but may tend to lower the voltage of the other dynamo, especially if its load falls quite low, and this acts to further increase the differences of load. Adding the equalizer connection, of course, changes this. Any increase of the current in either armature beyond the flow in the series coil of its magnet will leave this dynamo under-compounded, and its characteristic curve will show a drop in pressure for the increased load, like that of a shunt dynamo. Meantime the dynamo, with a smaller current flow in the armature than in its series coil, is for the time over-compounded and consequently tends to increase its e.m.f. and check the unbalancing process.

If the characteristic curves of compound-wound dynamos do not show a nearly equal compounding action, an equalizer connection will not make them work well together.

Convention of the Northwestern Electrical Association.

The ninth annual convention of the Northwestern Electrical Association was held on Wednesday, Thursday and Friday, January 16, 17 and 18, at Milwaukee, Wis. After calling the convention to order, the president, Pliny Norcross, delivered the annual address, which was received with enthusiastic applause and for which a vote of thanks was tendered to him.

In the course of his address Mr. Norcross discussed municipal lighting at considerable length, and expressed the opinion that as municipal ownership becomes more fully understood the desire for it will diminish. A committee appointed by the National Association of Officials of Bureaus of Labor Statistics in the United States, he said, had made a report on this subject which contained many interesting facts. In one municipal plant there were eight private arc lamps of 1200 candle-power and 10 street lamps. The users of the eight private lamps were obliged to pay the city 12 cents per kilowatt-hour, while the city paid nothing for its 10 street lamps. In other words, a few enterprising citizens paid for their own light five or six times as much as they would have paid to a private lighting company, and carried the entire burden of lighting the entire city's streets, which should have been borne by all of the taxpayers. In another plant the cost to the city of operating 75 street lamps was over 12½ cents per kilowatt-hour. In contrast to this a private company was mentioned which furnishes the city and private users light at the uniform rate of 2½ cents per kilowatt-hour. Mr. Norcross closed his address by presenting to the convention a copy of a bill that has been introduced in the United States House of Representatives, the object of which is the conversion of the present Bureau of Weights and Measures into a National Standardization Bureau.

The report of the secretary and treasurer was then made, which covered the entire year's work of the Association since the convention of last January. Applications for membership were presented, and E. L. Debell, chairman of the Legislative Committee, presented his report. In this report Mr. Debell stated that a bill had been presented to the Wisconsin Legislature having as its object the appeal of the present license fee or percentage tax imposed on electric light and power companies. He stated that the tax commissioners in a partial report made to the Legislature had recommended an increase in the license fee, proposing that all companies should pay 3 per cent license instead of 2 per cent where the gross receipts of the company do not exceed $50,000, and where they do exceed $50,000, 1/10 of 1 per cent to be added for each $7,500 of additional income. Mr. Debell stated that the Association's committee had done all that was possible toward persuading the tax committee to retain the present license fee of 2 per cent, and that the only thing left to be done was to appear before any legislative committee which might be appointed for the purpose of considering the matter.

The committee's report was adopted and the committee was continued for further work. The applications for membership were then referred to the proper committee for classification and report to the Association, and letters were read; one from H. W. Frund announcing his inability to attend the convention, one from Henry J. Doherty also expressing his regret at his inability to attend the convention, and suggesting that the Association might advantageously consider the question of three-phase distribution for light and power; and one from the E. P. Allis Company, extending an invitation to the delegates to visit its engine works. After some further routine business a paper from Mr. Doherty was read by Mr. Debell, the subject being

A METHOD OF CHARGING.

Mr. Doherty pointed out that an analysis of flat rates would show a definite charge for a fixed capacity, regardless of the quantity of current used between the limits of no service and constant maximum consumption. Dividing the fixed rate by the maximum consumption under such an arrangement would give the minimum rate per unit of service. An analysis of meter rates would show a fixed charge per unit of current sold, regardless of the capacity demanded. In this case the cost of production at the station would vary from a very low figure per kilowatt-hour if the total capacity were used continuously up to infinity if no current were used. In the abstract, flat rates are preferable but both systems, Mr. Doherty said, seem almost absurd. Theoretically, flat rates can be placed sufficiently high to protect the station from loss, but such rates would drive away much profitable business. Meter rates cannot be placed high enough to prevent loss. Even if the consumer agrees to pay $1 per kilowatt-hour his consumption may be so small that his bill will not equal the cost of reading his meter, keeping books for his account, the core loss of his transformer capacity, and the loss in the meter.

Mr. Doherty cited the practice of a central station with which he was familiar to illustrate the worth of different consumers supplied on a meter basis. A minimum charge of $1 a month was made whether current was used or not. This means a minimum of $1 per lamp per month if the consumer has only one lamp, and 1 cent per lamp per month if the consumer has 100 lamps. At this particular station the average annual bill is $1.96 per lamp; the minimum yearly bill per lamp is 24 cents, and the maximum yearly bill per lamp is $38.46. Assuming that the station represents an investment of $20 per lamp capacity, the length of time necessary for the gross revenues to equal the investment would be ten years and two months for the average consumer; 83 years and four months for the minimum consumer, and only six months for the maximum consumer. If the entire amount paid by the minimum consumer were clear profit the station would be earning only ¼ of 1 per cent on the investment. [This is evidently an error in transcription as 24 cents a year is 1.2 per cent interest on $20.]

A charge of a fixed rate per kilowatt-hour on the meter basis, Mr. Doherty continued, bears no relation to the cost of service. Suppose you should receive an application for a 2000-light connection from an isolated plant to be used only in case of a breakdown, at what rate per kilowatt-hour could you afford to supply the plant with service? The same problem confronts us on a modified scale in the case of each central station consumer. There are certain costs, such as bill-making and meter reading, which are entirely fixed by the number of consumers or meters, and many other costs are virtually fixed by the number of consumers or meters to be cared for, such as meter testing and maintenance, office rent, complaints and gratuitous work, superintendence and inspection. To cover such expenses as these, Mr. Doherty proposed to have a fixed charge for each consumer, regardless of his consumption or the size of his installation, provided no more than one meter is installed.

To cover certain other costs which are fixed by the capacity demanded, such as interest on investment, transformer losses, maintenance, depreciation, etc., Mr. Doherty would make a fixed charge for each lamp the consumer's connection will permit him to demand, without regard to the number of lamps installed, or amount of current used. To cover expenses which vary with the amount of current delivered, such as coal and lamp renewals, a uniform rate per kilowatt-hour should be charged in addition to the preceding fixed charges.

A charge for "readiness to serve" fixed on this basis, and a low kilowatt-hour rate, will bring about many advantages to the central stations, and protect them from loss, unprofitable patronage, and will also probably protect them from undesirable legislation. In view of the fact that it will be inadvisable to enforce this system on old consumers who will be injured by its adoption, Mr. Doherty proposed to adopt it first as a substitute for all special rate consumers, and also for new consumers. Instead of dividing expenses as they exist to-day and apportioning them among the consumers on this basis, the author expected to adopt such charges as will benefit long hour, and therefore profitable, consumers to such an extent as can be readily compensated for by the additional business which can be secured with a lower rate per kilowatt-hour.

In one station where experiments along this line have been made, it had been found more profitable to supply consumers on this rate system, making a fixed charge of $6 per consumer per year, plus $1.80 per lamp demanded per year, to which is added 4 cents per kilowatt-hour for current used, than to sell at a straight rate of 10 cents per kilowatt-hour. It is needless to call attention to the fact that consumers will be much more liberal in the use of current when supplied at 4 cents than at 10 cents per kilowatt-hour. Mr. Doherty advised making all contracts for a year or more, allowing the consumer to contract for any capacity he may choose; the capacity to be increased whenever he desires, but not to be decreased except at the expiration of the period contracted for; the capacity to be limited by a suitable maximum demand cut out to prevent him from demanding more capacity than he contracts and pays for, and one-twelfth of the fixed charge to be included in each monthly bill. Following Mr. Doherty's paper was one by Mr. Loren W. Burch on

PRACTICAL LINE CONSTRUCTION.

In his paper Mr. Burch pointed out the vital importance of allowing only the very best of line construction. The poles, he said, should be well peeled, dressed up, housed and gained. One, two or even more extra gains should be cut while the pole is down, as it is much easier and more cheaply done on the ground. A pole well set and tamped is half guyed. No matter how good your poles may be or how straight the line in which they are set, if they are not properly guyed the result will be a poor piece of work. It is safe to say that properly guying a line will enhance its value fully 50 per cent.

Mr. Burch disapproved of hand-twisted guys. Machine-twisted guys are cheaper, stronger and more easily handled. Guy clamps should be used in all cases, as it permits of coming up with the end and taking the slack out of a guy, if necessary, without cutting it. Guy rods are better than ungainly-looking posts and should be used wherever possible. All guy wires should be fitted with circuit-break knobs placed at a distance of 6 to 8 ft. from the pole end to render the lower part of the guy wire harmless. Guying to trees, buildings, etc., should be avoided absolutely. In the construction of the ordinary plant the subject of guying is an after consideration and if a guy is put up one end is made fast to the pole and the other to some man's house, barn or tree. This is bad practice, even if the permission of the owner is granted, as the ownership of these buildings may be changed at any time. Special attention should be paid to all corner, junction and end poles or there will be no end of trouble when the lines are pulled up taut.

Cross-arms are made in standard sizes and spacings of not less than 18-in. centers and 17 ins. between pins, should be used on all lines carrying 1000 or 2000 volts. Cross-arms should be doubled on all corner, junction or end poles. On 6 and 8-pin arms 9/16 x 9-in. lag screws should be used, and cross-arm braces not smaller than ¼ x 1¼ x 26 ins. The use of galvanized iron throughout is all right, but it is not absolutely necessary in all cases. It depends upon the color the poles are painted. Cross-arm braces should be used on all cross-arms over 3 ft. long and on two pin arms if a heavy wire is carried upon them.

Cross-arming poles is a very particular part of the construction of a good pole line. Great care should be taken to see that the gains are not cut too large in the poles, thus allowing the cross-arms to wabble. The lag screws should be driven in only far enough to give them a start and screwed in the remainder of the way. Cross-arms should be put on the side of the pole opposite to the strain so that they will not be pulled off. In double cross-arming, holes should be bored through the spacing blocks and these should have precisely the same thickness as that of the pole at the gain, so as to prevent bending the cross-arm.

Good live-oak pins are all right to use on straight runs or light wires, but on corner or junction poles locust pins should be used. For wires from No. 8 down to No. 0000 it would be better construction to use iron pins.

Stringing wires over buildings is bad practice, as you are liable to damage the roofs over which they pass. For instance, it is customary to build a "horse" to support a roof line and in time the water will collect and rust the tin under the legs. Leaks result, the water causes damage to the building and its contents, and the owner brings suit.

Mr. Burch pointed out that it was much more economical in streets which were lined with trees to use extra long poles so as to keep the line entirely above the tree tops. This, he said, though a little more expensive in first cost, was considerably more economical in maintenance than a pole line running through tree leaves, which necessitated cropping trees and involved all sorts of trouble with property owners. He also pointed out in conclusion that no line construction should ever be done hurriedly or with a view to temporary use. In laying out new lines it is better to run them with a view to getting future business rather than to take the shortest route to the consumer already obtained. He strongly urged the setting of poles in alleys and on lot lines whenever possible, and the feeding of buildings from the rear.

In the discussion which followed the reading of Mr. Burch's paper George Cutter emphasized the necessity for doing work of only a permanent character, and pointed out that the day had gone by in electrical construction for rushing out work in any sort of fashion and trusting to improving it and beautifying it afterward. There is not a station manager here, he said, who would think for a moment of having his steam pipes leak all over the plant, shoveling more coal under the boiler to make up for the leaks, but he will go outside where there is 10 per cent leakage loss in his lines and pay no attention to it. Regarding the question of insulating guy wires, Mr. Cutter agreed with Mr. Burch that every guy wire should be insulated at the top. He cited a case in which a man was injured by taking hold of the steel hanging cable of an arc lamp, and said that the company in whose plant this occurred has now adopted the practice of inserting a circuit-break insulator in the steel cable as high as possible above the windlass, and thoroughly grounding the windlass. After some desultory discussion of the license tax and the methods of encouraging the discussion of papers the session was adjourned.

The Thursday session was called to order at noon. Several applications for active membership were presented and acted upon favorably; and a communication was read by the secretary from the Jamestown (Ohio) Electric Light Company asking for information concerning a high candle-power gasoline lamp which seemed to have been threatening a serious competition with the company's arc lamps. The letter started quite a discussion on gasoline street lamps. George Cutter expressed the opinion that the lamp referred to was probably a group of Welsbach burners made especially heavy and supplied from a gasoline holder above the lamp, and said that but for the annoyance of starting these lamps electric light companies would find them a serious competitor. Mr. Strong, of Baraboo, said that his arc-light interests had been somewhat threatened by these gasoline lamps, of which there were about 30 in the outskirts of the town. He said that in this case there was one large Welsbach burner on each post using gasoline, and stated that the small self-generators used in connection with these lamps soon destroyed themselves, and that their operation was not profitable. The very best Welsbach lamp will not give more than 60 candle-power when it is new, he said, and deteriorates much more rapidly than an incandescent lamp; moveover, when the weather changes the proportions of air and gasoline change, so that while a Welsbach lamp is a nice thing indoors it must be entirely different from the arrangement at present used to be satisfactory out of doors.

Mr. Gille said that the burner referred to in the Jamestown Electric Light Company's letter was probably the Kern burner, which was being introduced and pushed very hard in this country. He said that his company had felt the effect of the burner in a commercial way to some extent, and he thought the matter was of sufficient importance for consideration. Mr. Debell said that several attempts had been made in Sheboygan to introduce gasoline burners of the Welsbach type, but that none of them had succeeded. Mr. Lord, of Waupaca, said that there was no city gas in his town so that it was either a question of electric light or kerosene. A couple of years ago a party came there to introduce Welsbach gasoline lamps and got permission to install a plant for experimental purposes in one of the stores; the third night the thing exploded and the electric light business has been first-rate ever since. There are still no gasoline burners in Waupaca.

At the close of this discussion the committee on the summer meeting made its report, recommending that the next summer's convention be held in the last week of June at Sheboygan, Wis. After considerable discussion the committee's report was adopted and Sheboygan approved as the place at which the summer meeting is to be held.

Prof. W. E. Goldsborough, of Purdue University, then read a paper on "Synchronous Converters" in which he explained the principle and operation of rotary converters. He presented a table showing the comparative capacity ratios of different types of synchronous converters, which is given herewith:

COMPARATIVE CAPACITY RATIOS OF DIFFERENT TYPES OF SYNCHRONOUS CONVERTERS.

	Direct Current.	Single Phase.	Three Phase.	Two Phase.
Volts between adjacent brushes.	1	.707	.612	.5
Amperes per wire	1	1.414	.944	.707
Ratio of armature copper loss in rotary converter to copper loss of same machine operated as a direct current generator at the same output.	1	1.37	.555	.37
Relative capacity of rotary converter, and same machine operated as a direct-current generator at the same temperature	1	.85	1.34	1.64

The figures given in the table, Prof. Goldsborough explained, were based on the assumption that the currents followed the sine-wave law. A two-phase alternator giving a wave that is comparatively flat with a fairly sharp peak in the center would have a higher e.m.f. ratio than the value in the table. A paper was next read by Mr. P. D. Wagoner under the title of

THE SERIES INCANDESCENT LIGHTING SYSTEM OF THE FUTURE.

Mr. Wagoner pointed out the advances that had been made in the development of the enclosed-arc lamp, and also pointed out that in the central sections or business portions of any city where a considerable volume of light is necessary arc lamps of the greatest illuminating power are required, but as one passes from these districts toward the outskirts the volume of light required is less and less the farther out one goes, until a district is reached where the amount of money to be expended per unit of area illuminated must be considerably below that which is justified in the more densely populated districts. In such a sparsely populated district it would obviously be more satisfactory to use a greater number of lights of lower intensity, as such lights may be placed closer together than would be possible with an expenditure of the same amount of money for lights of greater intensity; consequently, for such a territory the use of a low candle-power source of light, such as incandescent lamps, is advisable.

Considering reliability of operation, Mr. Wagoner presented tests recently made by W. D'A. Ryan, of Lynn, Mass., on fourteen Welsbach street lamps rated at 80 candle-power each. The result of these tests is given in the accompanying table.

WELSBACH BURNER TEST RESULTS.

Mantle Number.	No. of chimneys broken.	Hours run to end of life.	Hours run of mantle to fall to 80% of 80 candle-power.	Hours run of mantle to fall to 80% of 60 candle-power.	Initial candle-power.	Candle-power at end of life.
1	1	418	110	....	70	61
2	1	1069	110	810	71	40
3	4	440	50	....	69	60
4	4	338	90	....	70	67
5	1	129	.	....	60	56
6	3	18	...	....	63	67
7	1	16	...	....	35	35
8	2	109	40	....	66	61
9	1	21	...	....	69	69
10	0	674	175	....	64	58
11	5	420	140	....	76	50
12	1	336	15	....	66	54
13	1	973	160	710	72	39
14	1	451	120	....	73	51
Avg.	1.85	388.7	72.1	109	66.3	54

The tests, Mr. Wagoner explained, were made under laboratory conditions which it would be impossible to duplicate in actual service. The lamps would be subjected to drafts and vibrations and it would be impossible to regulate the gas pressure accurately, as was done during the tests; so that the result of the tests is better than could be expected in practice. Mr. Wagoner pointed out that although the average candle-power of the Welsbach burners which were tested was 66 there was a variation between 60 and 75 candle-power in individual lamps; incandescent lamps showing such a variation in candle-power would not be considered by any lighting company. The author also described some comparative tests of the illuminating power of Welsbach burners rated at 60-c.p. and 50-c.p. incandescent lamps made by W. D'A. Ryan.

A photometric screen was constructed, and a number of cards were printed, having sentences in eight different sizes of type. This instrument was mounted on a tripod midway between the incandescent and Welsbach lamps, which were 200 ft. apart. Each one of seven people took readings of the cards placed in this screen, the object being to read the smallest type possible. It was possible to read type two grades finer with the light from the incandescent lamp than with that from the Welsbach mantle. The next observation gave a more definite idea of the relative illuminating values of the two lights. A given size type was selected and, lining the light up on the center of the card, the observer walked backward until the selected type could be read. When this point was reached, the distance was measured to the lamp. The average results were that the type could be read 150 ft. from the incandescent lamp and 122 ft. from the Welsbach lamp. As intensity of light varies inversely with the square of the distance from the origin, the relative illuminating powers of two lights will be in the ratio of the square of the distance to point of equal illumination, or in this case, 150^2 to 122^2 or 1 to 1.5—the 50-c.p. incandescent lamp, therefore, had 1½ times the illuminating power of a nominal 60-c.p. Welsbach burner.

The foregoing conclusions are based on the actual photometric candle-power of the incandescent lamp and the nominal candle-power of the Welsbach lamp. If the actual candle-power of the Welsbach lamp were 85 per cent of its rated, the illuminating power of one candle-power of incandescent light would be 1.54 times that of the Welsbach. This great superiority of the incandescent light may be partly due to the difference in color of the light rays but it is probably mostly due to the inability to accurately control operating conditions of the Welsbach mantle and to its rapid deterioration and variable initial candle-power. Mr. Wagoner then pointed out that the candle-power of the Welsbach lamp depends upon many more variable conditions than that of the incandescent lamp. The Welsbach candle-power depends upon (1) the pressure of the gas, (2) the amount of gas admitted, (3) the age of the mantle, (4) the quality of the gas, (5) the ventilation of the lamp, (6) the cleanliness of a large globe, (7) the character of glass in the globe, and (8) the physical condition of the mantle. The candle-power of the incandescent lamp depends upon only three variable factors, namely, (1) the amount of current, (2) the age of the filament, and (3) the cleanliness of a small globe.

Mr. Wagoner passed from the comparison of incandescent and Welsbach lamps to a consideration of the various methods of regulating series incandescent-lamp circuits. The shunt-box system of control, he said, is expensive and inefficient, as there is a constant core loss of about seven watts in each shunt-box. The bank-board method of control has a low first cost, but is not automatic and not flexible beyond a range of about six lamps; furthermore, a system using this method of control has a very low efficiency. Figures taken from a plant operating 50 bank boards indicated that an average of three lamps per board were constantly burning. The system which Mr. Wagoner characterized as being best fitted for controlling series incandescent circuits is one which uses an automatic reactive coil consisting of a winding divided into two sections, one movable and the other stationary, and both surrounding a laminated iron core. The movable coil is counterbalanced by weights and shifts its position automatically with changes in the current flow to a position in which the reactive effect is sufficiently greater or less, as the case may be, to bring the current back to its normal value. A modification of this system was also described in which the winding is divided into two parts, one serving to boost the e.m.f. and the other to keep the current flow constant. A coil giving 100 per cent regulation on a 3000-volt 60-cycle circuit carrying 3½ amperes has only 131 watts copper loss and no core loss when the circuit is fully loaded. When all the lamps on the circuit are cut out the total loss would be 131 watts in the winding and 130 watts in the core. The power factor at full load is 98½ per cent.

Mr. Wagoner pointed out that the use of series incandescent lamps was quite extensive in the eastern part of the United States, and gave as usual rates of charge $15 to $20, with an average of $16, per lamp per year for 25-c.-p. lamps burning on moonlight schedule or until 1 o'clock; and from $20 to $30 per lamp per year, the average being $24, for lamps burning all night and every night.

Prof. D. C. Jackson, chairman of the Committee on Correspondence Schools, then presented a report on the "Trade Education of Central Station Employees," which was generally favorable to the correspondence method of increasing the knowledge of central station employees and which contained a suggestion for a central station course of instruction. The report was unanimously adopted and a motion was carried to request the four large correspondence schools to reorganize their courses for central station employees to conform as nearly as possible with the requirements set forth in the report.

After some further discussion of the question of educating central station employees, Mr. Thayer offered an amendment to the constitution to be acted upon at the next meeting. The amendment provides that the programme of the association be altered so as to bring the reading of papers first in order and all other business to be discussed after the papers have been read at each session, with the exception of the afternoon session of the second day in which the report of the Nominating Committee comes first. The convention then adjourned to meet the following morning, at which time, there being no business to transact, the convention adjourned *sine die*. At the election of officers, which was held during the convention, Mr. E. L. Debell, of Sheboygan, Wis., was elected president to succeed Mr. Norcross, and Mr. Thos. R. Mercein was continued as secretary and treasurer of the Association.

On Thursday evening the annual banquet was held at the Hotel Pfister, at which about 100 members and visitors gathered. Secretary Mercein was the toastmaster, and responses to the toasts were felicitously given by General Charles King, Captain George Chase, Prof. D. C. Jackson and Messrs. Almert, Burch, Collins, Cutter, Donohoe, Grier, Lovett, Low, Massey, Munson, McMaster, Pinckard, Searing, Underwood, Whyte and Wolff. The feature of the banquet, however, was the presentation to Mr. Mercein of a very handsome watch by members of the association; Mr. Underwood made the presentation speech.

IMMERSED RHEOSTATS vs. WATER RHEOSTATS.

BY B. PARKS RUCKER.

Though the water rheostat is one of the oldest and most common of all apparatus for the consumption of electrical energy, it is at the same time one of the most troublesome and unreliable. The usual form consists of two metal plates immersed in a barrel of water, and so arranged that the distance between them can be easily regulated. To the water is added common salt, sal ammoniac, or some other substance which will increase the conductivity, but unfortunately at the same time the electrolytic action. The current flowing, assuming the e.m.f. and the distance between the plates to be constant, is dependent upon the conductivity of the electrolyte, and as it is impossible to keep this constant, the rheostat will take a very variable amount of current, and hence is very troublesome when a constant flow is desired.

The accompanying curves show just how this current changes with three of the most common substances used in the water—salt, sal ammoniac and washing soda. Each of these substances was tested under exactly the same conditions. The vessel was of wood, and at the start of each experiment held about 1 gal. of water at 45° Fahr., the electrodes were of sheet iron, 3 ins. by 4 ins. in size, and 3/16 in. thick, and were held in a vertical position just 3½ ins. apart. The only variable factor introduced was the amount of the substance added, just enough being used to give a good starting current. The plates were entirely covered by water and an e.m.f. of 110 volts maintained between them. The curves show how very variable the current is in a rheostat of this style, even under favorable conditions. Should more current be sent through it the boiling and bubbling would be greatly increased, and the bubbling and foaming would make the current rise and fall continuously.

It will be seen also from the curves that the current rises rapidly till a maximum is reached, and then suddenly falls off. This is the boiling point of the solution. The current afterward falls off more slowly and finally reaches a somewhat steady value. The cause of this is easily explained. Cold water has a much higher resistance than hot, so that as the water warms up its resistance decreases; moreover, the substance added becomes much more thoroughly dissolved and distributed, and at the same time the electrolytic action on the plates decreases the resistance of the electrolyte. Finally, the substance added is driven off by the heat and the current falls off, but it still stays pretty high on account of the better conductivity of the now heated water and the results of electrolysis.

When too much current is sent through the solution it boils spasmodically and foams throughout its body and the current becomes too unsteady for any use; sometimes the water boils out of the top of the barrel as fast as it can be put in.

Furthermore, the adding of the salt or other substance and water must be done very carefully; otherwise the cold water will add too much resistance and lower the current or else too much salt will send the current above the safe limit. The practicable continuous capacity of such a rheostat is limited to about 100 amperes at 110 volts for a 40-gal. barrel, or about 15 electrical horse-power, so that in a test of a large plant, where artificial load is used, many more such barrels would be needed than would be practicable.

A series of tests carried out in the electrical laboratory of the Drexel Institute on the carrying capacity of iron wires under water convinced the writer that a most satisfactory rheostat for the purpose could be made on that plan. Wires immersed in water can carry a surprising amount of current without burning off, and, if proper precautions are taken, without much loss from electrolysis. On one test a No. 14 (B. & S.) galvanized iron wire about 15 ft. long was coiled in an open spiral and immersed in about 10 gals. of water; it carried 200 amperes at 110 volts for some time, although the water did boil pretty hard. Another wire 15 mils in diameter carried 50 amperes for several minutes before burning off. Investigation showed that the wire burned off only after a thin film of vapor formed around it, thus preventing the water from coming in contact with it and carrying away its heat by convection.

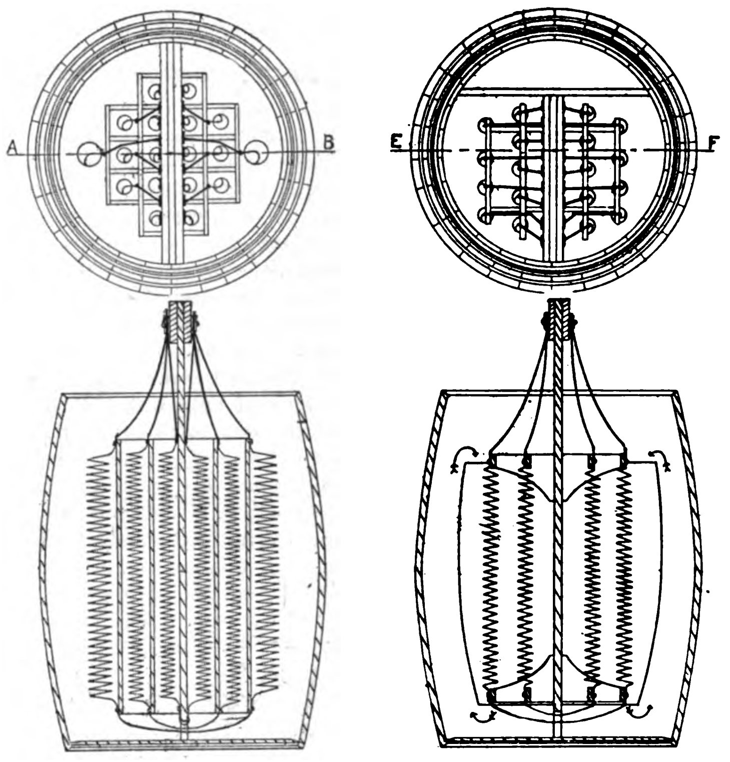


FIG. 2—IMMERSED RHEOSTATS.—FIG. 3.

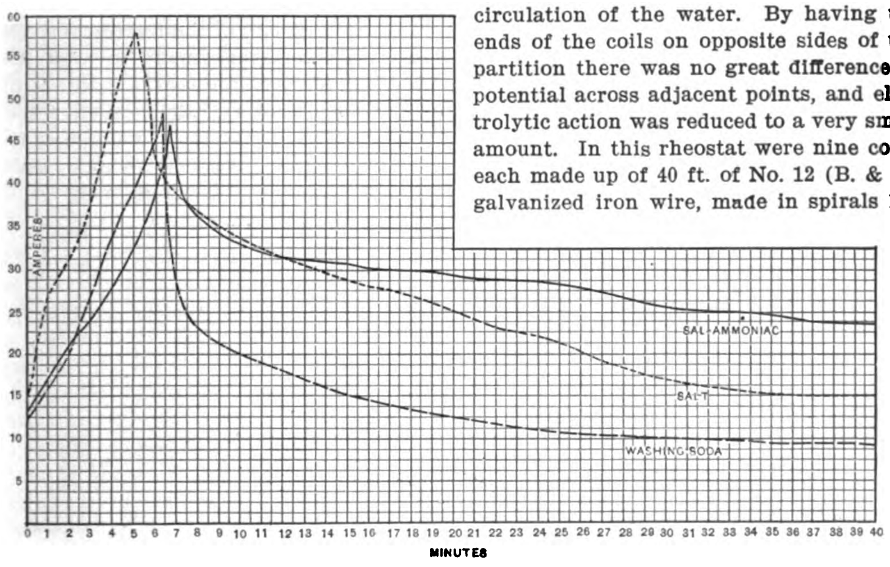

CURVES FROM COMMON WATER RHEOSTATS.

The rheostat shown in Fig. 2 was designed and built according to results of some of the tests mentioned. A barrel of about 40 gals. capacity was divided vertically into three compartments; two of these compartments held the coils of wire and the third one was simply to help the circulation of the water. By having the ends of the coils on opposite sides of the partition there was no great difference of potential across adjacent points, and electrolytic action was reduced to a very small amount. In this rheostat were nine coils, each made up of 40 ft. of No. 12 (B. & S.) galvanized iron wire, made in spirals 1¼ ins. in diameter and drawn out to about 5 ft. in length. The resistance of each coil when cold was 0.55. ohm, and when carrying 145 amperes under water 0.737 ohm. Each of the coils had its own copper leads, and no part of the iron wire carrying current was under less than 3 ins. of water.

Double-pole switches were used in cutting out the coils, as it would promote electrolysis to have all the coils attached to a common connector at one end. When the water becomes heated it starts up a circulation, as shown by the arrows, and a stream of water can be kept playing into the empty compartment with good effect. Small strips of wood run through each coil and are fastened at the ends to catch the coil and prevent it from falling across others should it burn off. This rheostat was used in a 10-hour test of a power plant. Only five coils were used, each taking 145 amperes at 107 volts, or 77.575 watts in all. An intermittent stream of water, about ⅝ in. in diameter, from a tank about 15 ft. overhead, was allowed to run in the barrel, and at no time did the water reach the boiling-point. The other four coils were held in reserve, but were not needed. The writer has not the least doubt that all nine coils could have been used at once without causing excessive boiling of the water, which would have meant passing about 1300 amperes at 107 volts, or about 186 electrical horse-power.

In a later nine-hour test of a dynamo the same rheostat carried a load of 725 amperes at 115 volts for eight hours and 870 amperes for one hour without the least trouble or mishap, and gave an absolutely steady load. When the wire was put in the barrel it was 80 mils. in diameter; after the second test its smallest diameter was found to be 73 mils—a loss of 7 mils in 19 hours' run. This loss was undoubtedly due to cross currents between the wires in use and those which were held in reserve, as the smallest points in the wire were always found to be near the ends, while the middle portions were comparatively unharmed.

A 230-volt dynamo was also tested and a rheostat of the same kind with slight modifications was used. In this a barrel of the same size was divided into two main compartments, as in Fig. 3, and these were each subdivided into eight smaller compartments about 3 ins. square, plan measurement, allowing considerable open space around the coils for the water to circulate. Each coil was thus kept to itself, and cross currents were almost entirely prevented. There were seven coils, each of 75 ft. of No. 14 (B. & S.) galvanized iron wire, one coil of No. 18 wire, each one in its own compartment, and one coil of 80 ft. of No. 12 wire in the open space. As in the first barrel, each coil had its own leads, and in this barrel the leads (No. 8 copper, Underwriters' insulation), went down about 3 ins. below the top of the compartments, thus giving a long path for the stray currents to traverse to reach the next coil. This arrangement was found to work admirably, and after the test the wires were in practically as good condition as before. This barrel carried at times at least 800 amperes at 230 volts, or almost 247 electrical horse-power. Both of these barrels were kept cool with a single ¾-in. stream of water, and at no time did the water boil violently. The water was supplied at a temperature of about 50° Fahr.

Both rheostats proved perfectly satisfactory in every respect except in close regulation, and this could have been secured had wires of different sizes and lengths been used. The rheostat for 110 volts could only be changed in steps of 145 amperes without putting some of the coils in series, which would be impracticable with this construction. In the other form, however, wires can be put in series without the slightest fear of electrolysis or any other serious results, and thus the load can be graded to suit the conditions. The load itself in every case was as steady as a bank of lamps, and in this respect, at least, the rheostat was a great improvement over the old plate and solution form.

TABLE OF SAFE CAPACITIES FOR IRON WIRE IN ORDINARY AND IMMERSED RHEOSTATS.

Size, B. & S.	Circ. mils, d².	Safe cap. in air 0.014 d².	Length for safe cap. in air, 110 volts.	Safe cap. in water, 0.2 d².	Length for safe cap. in water, 110 volts.	Feet per lb. of wire.
20	1018	2.5	594 ft.	36	25 ft.	369.
19	1253	2.9	626 "	42	27 "	293.2
18	1624	3.5	673 "	50	29 "	232.5

11	8234	12.0	990 "	173	42 "	45.8
10	10,380	14.3	1054 "	205	45 "	36.4
9	13,090	17.1	1103 "	245	47 "	33.3
8	16,510	20.3	1354 "	293	58 "	26.0

It is obvious that a rheostat of the type described could be easily adapted for use with polyphase currents by joining the coils in star fashion at the bottom of the barrel. Where a load must be regulated to within a very small amount it is recommended that a plate rheostat be used in between the steps of the main one. Then by careful manipulation and a small load on the plate rheostat the load should be kept very constant indeed.

If the barrels are mounted on wooden bases or blocks about a foot high, any reasonable amount of water can be allowed to circulate through the barrel without danger of seriously grounding the circuit. A column of pure water 1 sq. in. in section and 12 ins. long has a resistance of over 14,000 ohms. The more water is used, the longer the rheostat will last, as the water washes away any metallic particles or other substances set free by electrolysis and keeps the coils cool.

The accompanying table gives the sizes and length of wire which it is practicable to use on 110-volt circuits for ordinary and immersed rheostats. Combination for any voltage can be made, but for immersed rheostats to be used at 500 volts, say, it would be best to put two or more barrels in series. These tables are the results of some tests made on iron wire in the laboratories of the Drexel Institute.

Abstracts from Foreign Contemporaries

Alternating-Current Ammeter and Voltmeter.—Among other instruments described by M. Aliamet in a recent issue of the "Bulletin de la Societe Internationale des Electriciens" is an interesting form of ammeter and voltmeter for measuring alternating currents, the principle of which is shown in Fig. 1. Between the poles of opposite horseshoe electromagnets, F and F', is hung a coil, C, on the vertical arm of an aluminum double bell crank lever pivoted at D. The magnet coils, B and B', are connected in series with each other, and the movable coil, C, which is of fine wire, is connected in shunt to the magnet coils. The connections are such that the movable coil is attracted by the right-hand magnet and repelled by the left-hand one. As shown in the plan view, the air gap between the poles of each magnet is very much smaller than the distance across from the poles of one magnet to those of the other, so that the field through which the coil moves is very uniform. The magnet coils are laminated, of course, and are worked at very low magnetic density, so that the field is proportional to the current flowing in the magnet coils. The movement of the mechanism is damped by means of two air dash-pots, shown in the upper part of the engraving. The travel of the arm, O, is comparatively small, and is amplified by means of the linkages between the end of that arm and the indicating needle, A. A light spiral spring, S, is provided for the purpose of bringing the needle to the zero point and annuling the effect of lost motion in the linkages. The block, P, to which the stationary end of the spring is attached, is adjustable in order to enable one to bring the pointer to the zero of the scale. The ammeters are always used in connection with a small transformer, of which the primary coil, connected in series with the work circuit, consists of a single turn of wire. The secondary winding of the transformer is always given a comparatively large ohmic resistance, in order to minimize the effect of reactance. The instrument is also manufactured as a voltmeter, in which form the coils on the electromagnets are of fine wire and connected in series with the movable coil. The magnet coils of the voltmeters, however, are wound with German-silver wire in order that the resistance of the coil may be much greater than its reactance, so that resistance will be the principal component of the impedance. The instrument is said to be fairly accurate for widely differing frequencies, a voltmeter for 110-volt circuits giving a variation of not over 2½ volts between frequencies of 25 and 80 cycles per second. The voltmeter may be rendered, however, independent of the frequency by using a small transformer, the primary of which has a very great resistance compared with its reactance and is connected in shunt to the magnet coils of the instrument, the secondary being connected to the terminals of the movable coil of the instrument. The result of this arrangement is that the e.m.f. delivered to the movable coil is increased somewhat with the frequency, thus compensating for the lower voltage at the terminals of the instrument which results from an increase in the frequency.

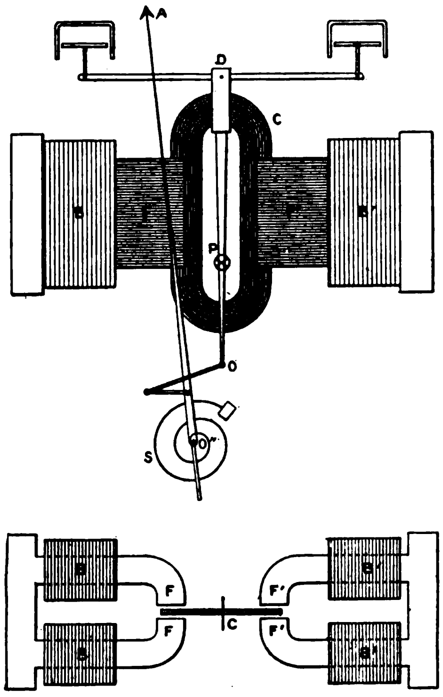

FIG. 1.—ALTERNATING-CURRENT AMMETER OR VOLTMETER.

Simple Modification of a Wehnelt Interrupter.—J. von Pallich, in a recent issue of the "Elektrotechnische Zeitschrift," gives the following simple modification of a Wehnelt interrupter in which the lead plate is replaced by a copper wire, and the platinum anode by a steel wire. A negative electrode of bright copper wire, 0.11 to 0.19 in. in diameter, is passed through a glass tube and permitted to protrude 0.07 to 0.11 in. at the bottom. A positive electrode of steel wire, 0.03 to 0.07 in. in diameter is also passed through a tube the lower aperture of which fits snugly about the wire. At its upper end the steel wire is passed through a cork reamed out to contain mercury, which forms the contact. Both tubes are then passed parallel to each other through a rubber stopper, provided with a hole at the side to permit the acid to flow back in case it should in any way get above the stopper, and placed in a flask of dilute sulphuric acid. When in operation the steel wire should be lowered from time to time as it is slowly consumed, and it will doubtless be found necessary to place the entire apparatus in a cooling tank.

A 350-h.p. Two-Cycle Gas Engine.—A recent issue of the London "Engineer" contains a description of an extremely interesting Koerting two-cycle gas engine of 350 brake horse-power. Fig. 2 herewith is a semi-sectional plan view of the engine, and Fig. 3 is a sort of diagrammatical illustration of the functions of the various parts. It is a double-acting, single-cylinder machine, the piston rod, stuffing box and the piston itself being effectively water-jacketed. The exhaust port of the cylinder consists of a series of slots around the wall, midway of the cylinder, which are uncovered by the piston just before the end of each stroke, as indicated in the upper part of Fig. 3. The admission valves are of the usual poppet type, operated by the air pressure. The air and gas are supplied to the valve chambers by separate pumps, the pump, M, forcing the gas in, and the pump, N, forcing the air. The pumps are double acting and driven by a single piston rod, as shown in Fig. 2, from a wrist pin on an auxiliary crank disc set on the main shaft so that the pin is 110° in advance of the main crank. The pumps are provided with piston valves which are operated by an eccentric on the main crank shaft, and serve to direct the gas and air first to one end and then to the other end of the cylinder, performing the same function that is fulfilled by the admission valve of a steam engine, the inlet valves on the ends of the cylinder being merely check valves to prevent back pressure from the cylinder into the pumps. The air and gas are thus kept separate until they enter the valve chamber on the end of the cylinder. The valves of the two pumps are so set that air is delivered to the valve chamber on the cylinder before gas is admitted, the object of this being to flush out the products of combustion in the cylinder before admitting a charge of gas.

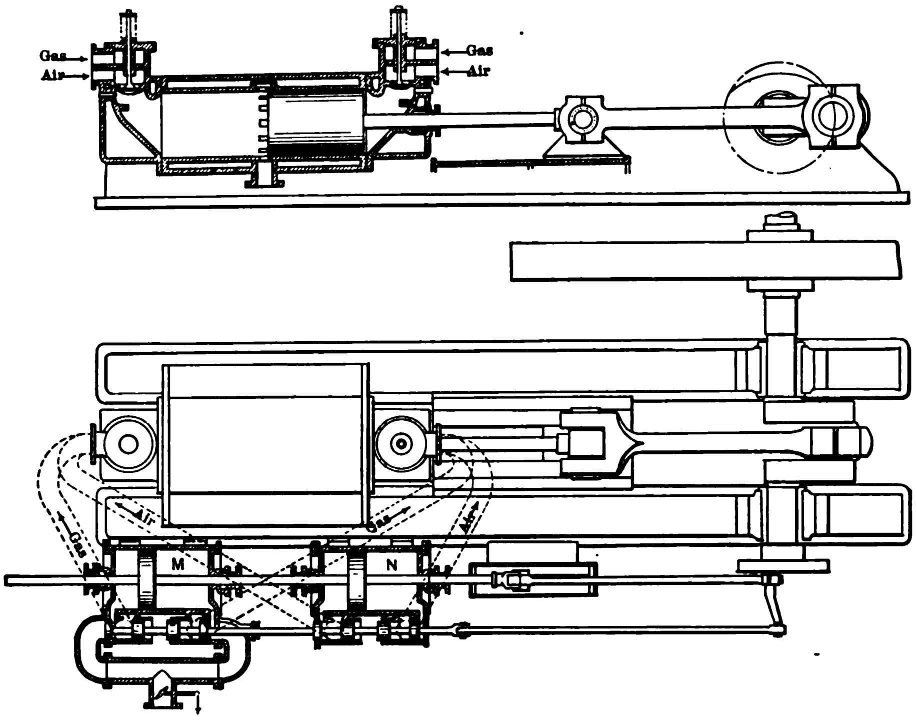

FIG. 3.—DIAGRAMMATIC ILLUSTRATION OF TWO-CYCLE ENGINE.

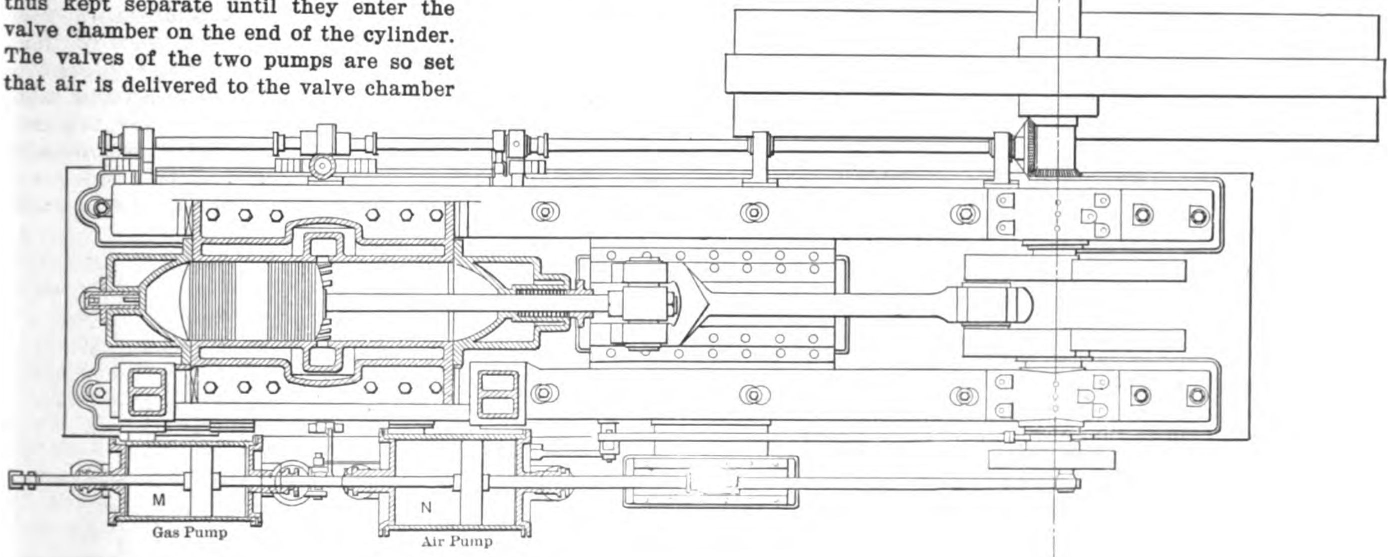

FIG. 2.—SEMI-SECTIONAL PLAN OF 350-H.P. TWO-CYCLE GAS ENGINE.

The working cycle is as follows: At the end of a working or explosion stroke the piston uncovers the exhaust port, allowing the products of combustion to discharge. When the pressure within the cylinder almost reaches the atmospheric pressure, the inlet or check valve at the end of the cylinder is forced open by the pressure of air delivered to the valve chamber by the air pump, and the fresh air forces out the remaining products of combustion. Just as the piston covers the exhaust port on its return stroke the gas valve is opened and the gas pump forces a charge into the valve chamber, where it mixes with the air which is being delivered by the air pump and passes into the cylinder. Compression then takes place during the return stroke of the piston (which is forced through this stroke by an explosion of the previous charge on the other side of it) until the crank reaches its dead center, when the compressed charge, the entrance of which has just been described, is fired. The cycle is the same on each side of the piston, of course. Regulation is effected by varying the amount of gas admitted to the valve chamber. The engine illustrated by Fig. 2 is capable of delivering 350 horse-power from its pulley. The engine cylinder is 21.6 ins. in diameter x 37.7 ins. stroke; the air pump is 24.4 ins. bore, the gas pump 19.6 ins. bore, and both pumps 27.5 ins. stroke. In a test of this engine with producer gas having a calorific value of 129 B. T. U. per cubic foot the engine developed in the working cylinder 544 horse-power. The amount required to drive the pump was 63 horse-power, leaving 481 horse-power for useful work and overcoming the mechanical friction of the moving parts. The friction load was 29 per cent, so that the mechanical efficiency of the engine was 71 per cent, leaving 341.5 horse-power available for useful work. The gas consumed per indicated horse-power in the work cylinder was 58 cubic feet per hour and the gas per brake horse-power was 81.5 cubic feet per hour. The thermal efficiency of the engine considering the indicated horse-power was 37.9 per cent, and the efficiency considering the brake horse-power was 23.8 per cent. The average speed of the engine was 101 r.p.m. At full load the compression pressure, according to the indicator diagram, was 169 lbs., and the explosion pressure 389½ lbs.

A New Form of Calorimeter.—In a paper recently read before the British Association, Prof. John Goodman described a new form of calorimeter which he had designed, and which is illustrated by Fig. 4. The author stated that the wire-drawing calorimeter had recently been discredited by reason of experiments made by Mr. Grindley, of Manchester, which showed that the specific heat of superheated steam, upon which the accuracy of the throttling calorimeter hinges, instead of being 0.48, varies from 0.4 to 0.68. In the new form of instrument Prof. Goodman does not use the wire-drawing principle. The instrument is a condensing calorimeter, consisting of a scale beam, S, from one end of which are hung two scale pans and from the other end two cylindrical tanks, A and B, each 16 ins. in diameter and 24 ins. deep. A small mixing injector, C, is attached to the bottom of the tank, A, and the cold water from this tank passes through the injector and is mixed with the steam, which is supplied by a detachable flexible steam hose attached at the connection, D, which is thoroughly sheathed for convenience in handling and also to prevent radiation. In the pipe through which the condensed steam and condensing water pass to the lower tank is inserted the bulb of a thermometer, H. An outlet cock, E, is provided for the purpose of draining the lower tank. The object in using two scale pans is to keep the steam weights separate from those which counterbalance the condensing water. The tank, A, is filled with water from the pipe, F, until it just balances the weights in the lower scale pan, which are usually two 56-lb. weights. The temperature of the water in A is tnen taken, and the steam pipe, D, after being thoroughly blown through, is coupled up. The steam-supply valve and injector water cock are opened simultaneously, and an observer begins to take readings of the temperature at H at intervals of 10 to 15 seconds. The experiment is continued until the tank, A, is nearly emptied, which usually takes about five minutes; then both the steam and water valves are shut off simultaneously, the flexible steam pipe is disconnected and the incandescent lamp near the thermometer, H, removed. The whole apparatus is again balanced by placing weights on the upper scale pan, which represent the weight of steam which has been condensed. The tank, B, is then entirely drained, and the apparatus balanced up again by changing weights on the large scale pan. The weight of the water which has been mixed with the steam is then easily ascertained. The formula for the calorimeter is as follows:

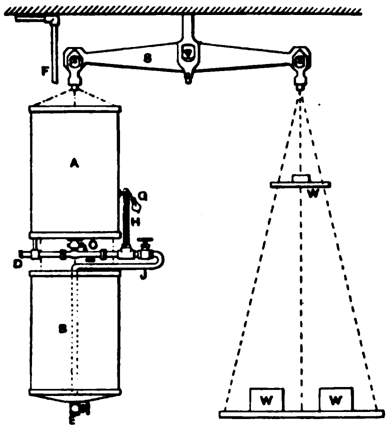

FIG. 4.—STEAM CALORIMETER.

$$Q = \frac{\frac{W}{w}(t_2 - t_1) + t_2 - t}{L}$$

in which "Q" is the quality of the steam; "w," the weight of steam taken into the calorimeter; "L," the latent heat of the steam; "t," its temperature when admitted; "t_1," the temperature of the water in the tank, A; "t_2," the mean temperature shown by the thermometer, H, and "W," the weight of the water used to condense the steam. The chief source of error in the use of the instrument lies in obtaining a reliable sample of steam.

Group-Driven Lathes with Electro-Magnetic Couplings.—To a recent issue of the "Zeitschrift fuer Elektrotechnik" J. Loewy contributes an article showing a compact arrangement of four small automatic turning lathes, provided with quick and convenient means for stopping or starting each lathe individually without the use of complicated switching devices. Four lathes are mounted on a table, as shown in Figs. 5, 6 and 7. Upon a shelf, B, a shaft is mounted which is driven by a belt from a countershaft, not shown. The shaft is equipped with four electromagnetic clutches, K; a sectional view of one of these is shown by Fig. 7. The electromagnet, E, is keyed to the shaft. The magnet is of the "double-crown" type with a single exciting coil, and has 24 poles marked N and S. The cast-iron core, E, carries a vulcanite ring, I, to which are attached two contact rings, R and R, to which are led the coil terminals and on which bear two brushes connected with the source of current. The other part of the coupling is a hollow cone pulley, the steps of which correspond with those of the lathe pulley; this cone pulley is seated on a bushing which is free to rotate and also to move in an axial direction on the shaft. The operation of the clutch is obvious. When the coil is energized the magnet poles pull the cone pulley against the beveled poles, S, which grip it and carry it around. The total resistance of the exciting coil, inclusive of the contact resistance between the brushes and slip rings, is about 430 ohms. The normal e.m.f. employed is about 85 volts, so that each coupling requires about 0.2 amperes, or 17 watts.

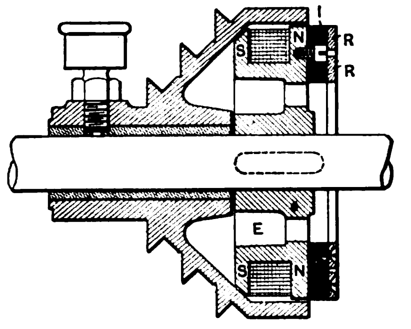

FIG. 7.—MAGNETIC CLUTCH.

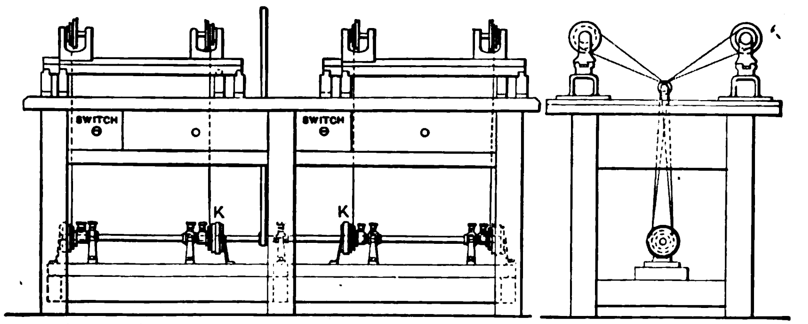

FIGS. 5 AND 6.—A GROUP OF LATHES DRIVEN THROUGH MAGNETIC CLUTCHES

The Behavior of Nernst Glowers.—A recent number of the "Zeitschrift fuer Elektrochemie" contains an article by Messrs. Nernst and Wild regarding the behavior of the electrolytic filament of the Nernst lamp. The samples tested were composed essentially of the oxides of zirconium, thorium and yttrium, together with rare earths, and were in the form of thin, straight rods. A flame was employed to render them conducting at starting, and the temperature necessary for this varied from 900° to 1300° Fahr., according to the composition. The following table gives the result of six experiments with these samples, the three figures in each case representing the observations at the beginning and end of the experiments, and the mean values. The last test in the table was made with a rod supplied by the Allegemeine Elektricitäts-Gesellschaft. To obtain mean spherical candle-power, multiply the candle-power in the table by .78. The watts should be increased by 5 to 15 per cent, if it is desired to take account of the power lost in the series steadying resistance which is indispensable in the actual lamp.

Life (hrs.)	Volts.	Amperes.	Candle power.	Watts per candle.

Wireless Telegraphy.—It is known that for a considerable length of time Prof. Slaby has been devoting his attention to devising a means of Hertzian signaling between several independent stations so that the messages may not interfere with one another. A recent issue of the "Elektrotechnischer Anzeiger" contains an account of the recent experiments of Prof. Slaby in this direction. Upon a lecture table in Berlin were placed two sets of receiving apparatus, both of which were connected to the lightning rod on the chimney of the Schiffbauerdamm electric lighting station, the ground connection of which was not removed. Two stations, one at Schoenweide on the upper Spree, 8 miles distant, and the other in the professor's laboratory at the Charlottenburg Technical College, about 2½ miles distant, were signaled and messages received from each simultaneously. In explanation of the phenomena, the professor said that the arrangements were such that the waves in both cases were of predetermined lengths, and that the two sets of apparatus were each tuned to different wave lengths. At Charlottenburg an aerial wire 52 ft. long was attached to the roof of the college, while at Schoenweide the wire was suspended between the chimneys. In the latter case the waves had to traverse the city of Berlin from southeast to northwest, and hence were necessarily weakened by obstructions, in the shape of chimneys and tall buildings. In the experiments Prof. Slaby used a "multiplikator"—a resonator which increases the potential of the received wave and renders it easier to detect on the receiving apparatus. The invention was worked out by Prof. Slaby some time ago, and turned over to the Allgemeine Elektricitäts-Gesellschaft, which concern has developed the invention, technically, with the assistance of Count von Arco, a former assistant of Prof. Slaby.

Some Recent Electrical Patents

Storage Battery Element.—Storage battery plates of the pasted type are usually made by providing a perforated base plate or grid to which is applied the active material in paste form. In process of applying this paste it is forced into the apertures in the grid, the object being to secure the paste to the grid mechanically. When such a battery is subjected to heavy discharges the active material expands and being rigidly confined by the grid, its expansion tends to mechanical disintegration. In order to minimize this trouble the arrangement shown in Figs. 1 and 2 has been devised by Aubrey G. Eneas. This consists of a central core, *a*, of conducting material, such as lead, which may be either in the form of a rod or a tube; large washers, *b*, of porous material, through which the electrolyte may percolate; smaller spacing washers, *c*, of conducting material; and the active material, *d*, pressed into the annular spaces between the larger porous washers. The whole element is bound together by nuts at each end, and longitudinal expansion is provided for by the use of end washers, *e*, of compressible material. Fig. 1 shows the arrangement with a rod as the central core, and Fig. 2 shows it with a tube fulfilling that function. In the latter illustration the faces of the porous washers are shown grooved in order to provide additional precaution against the dislodgment of the active material between them. The claim is made that as the washers are porous the electrolyte has access to all sides of the active material except the inner face next to the small washers of conducting material which serve as electrical conductors from the central core to the active material. Patent No. 665,195.

Connection for Carbon Brushes.—It is a matter of common knowledge that the principal difficulty in the use of carbon brushes on direct-current generators and motors lies in providing a positive electrical connection between the brush and brush-holder, which will not interfere with the feeding of the brush toward the commutator as it wears. The most common practice is to transmit the current from the brush-holder to the brush by a simple contact between the side of the brush and its holder, a flat spring being ordinarily used to improve this contact. With a view to providing a more reliable connection without resorting to a positive clamp, which has been used in some cases, A. L. Rohrer has devised the simple connection shown by Fig. 3. This consists merely of a sheet-metal clip made to fit snugly over the rear end of the brush, and provided with means for the attachment of the connecting cable. This clip is soldered to the brush, and the joint is subsequently electroplated with copper or some other high-grade material. Those familiar with the progress in the art during the past ten years will remember that the Eickemeyer brush was generically similar to this one. The structural difference, however, is that the Eickemeyer brush consisted of thin spring brass, to which was soldered a short carbon tip, whereas, the present brush consists of a full-size carbon block, to which a flexible, non-resilient conducting lead is soldered. Patent No. 661,669.

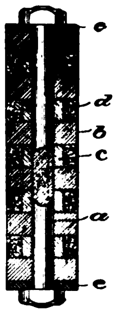

FIG. 1.

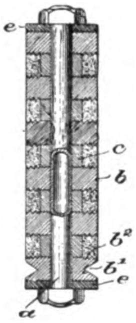

FIG. 2.

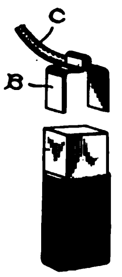

FIG. 3.

Storage Battery Meter.—It is usually desirable in the operation of storage batteries, the work of which is metered, to make a record of the energy supplied to the storage battery as well as that delivered by it. It has been the general custom to provide two separate meters for this purpose, one being switched into circuit when the storage battery is charging, and the other being substituted when the battery is discharging. A simplification of this method has been devised by Caryl D. Haskins, and is illustrated by Fig. 4. Mr. Haskins' method consists in providing two sets of recording gears on one meter and equipping the meter with an automatic polarized relay which shifts the spindle of the meter armature into and out of engagement with the two sets of gears. The relay, which is shown on top of the meter, consists of a magnet, 5, connected in series with the battery and having a polarized armature, 3, which is connected in shunt to a portion of the battery so that it is magnetized always in the same direction. It is obvious that when current is forced through the battery the relay will pull the end of the armature spindle to one side, causing the worm to mesh with the gear train on that side; and when the battery is allowed to discharge, the current flow being reversed, the end of the relay armature spindle will

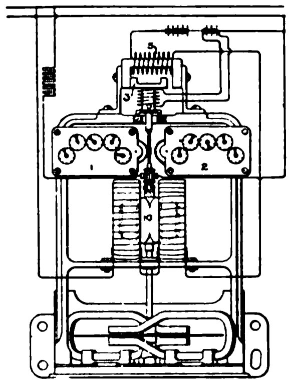

FIG. 4.—STORAGE BATTERY METER.

be thrown over to the other side, causing the worm on the spindle to engage with the other set of gears. Consequently, one set of gears records the energy delivered to the battery and the other set records the amount taken out of the battery. Patent No. 664,948.

Ceiling Rosette.—Fig. 5 illustrates a form of ceiling rosette which has been patented by John H. and Henry Trumbull. The feature of the invention consists in providing eyes, C′, in the line terminal blocks, C, through which the curved ends of the cap terminals pass when the cap is put in position and given a slight twist.

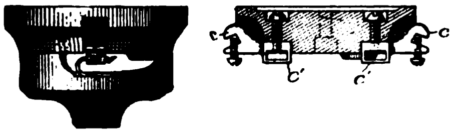

FIG. 5.—CEILING ROSETTE.

The contact pieces in the cap are arranged in the usual manner so as to allow the use of fuses, the only difference from common practice being that two of the contact pieces are provided with extensions which are curved upward, as shown in the illustration, so as to enter the eyes in the main-line terminal blocks. The extreme ends of the curved extensions are bent so as to constitute locking lugs and prevent the cap from untwisting accidentally. Patent No. 664,511.

Railway Motor.—It is well known that designers of railway motors are greatly hampered by reason of the restricted space available for the motor structure parallel with the car axles. In order to increase the axial length of the motor armature it is proposed by Edward D. Priest to do away with the ordinary form of journal box entirely, mounting the armature on a hollow sleeve and arranging this to rotate about a fixed central axle, as shown in Fig. 6. The whole interior of the hollow armature or sleeve, G, constitutes a bearing around the fixed axle, C. Liners, D and D^1, are employed in the usual manner. This construction obviously allows the motor armature to be lengthened by exactly the amount occupied by that portion of the box which projected beyond the armature winding in the ordinary type of machine. Patent No. 664,969.

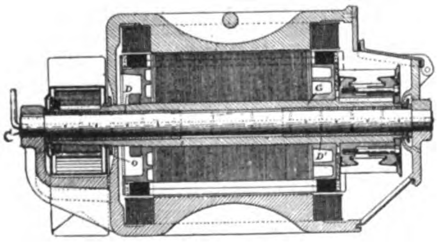

FIG. 6.—SECTION OF ARMATURE.

Arc-Lamp Carbon.—A patent has been issued to Frederick Hachmann for an arc-lamp carbon consisting of a tubular shell of hard carbon, which is filled with calcium carbide in a powdered or pulverized form, the carbide being held together by any suitable binding material, such as tar. The carbide is forced into the carbon tube under slight pressure, and is said to adhere to the walls so as to form practically a solid structure. The claim is made that in operation a certain amount of gas is generated by the calcium carbide, which materially intensifies the brilliancy of the arc formed between the ends of the electrodes. The hard-carbon shell is provided for the purpose of protecting the calcium carbide from the action of the elements. Patent No. 660,852.

NEW BOOK.

Mechanical Drawing and Elementary Machine Design. By John S. Reid and David Reid. New York: John Wiley & Sons. Cloth; 396 pages, 6 x 9 ins.; 301 illustrations. Price, $3.

The avowed mission of this book is to prepare students for advanced machine design by supplying instructions as to the application of the principles of mechanical drawing to the solution of practical problems in machine construction. The preliminary suggestions, relating to drawing instruments and materials and precautions to be observed in preparing drawings, are excellent, but if the book contains any educational matter pertaining to the art of mechanical drawing, that portion was omitted from the reviewer's copy. It does contain, however, valuable instructions as to the design of familiar machine parts and mechanical appliances, such as screws, bolts, nuts, keys, cotters, rivets, shafting and couplings, pipe couplings, journal boxes, hangers, gearing valves, etc. The final chapter on engine details is good as far as it goes, but it is peculiarly incomplete. The cross-head wrist-pin, which is about the easiest part to design excepting the piston rod, receives ample attention, while not a word is said on the subject of crank-pins, crank discs or fly-wheels! However, as intimated above, the matter that is included is excellent; the only serious fault is the failure to consider many vital subjects.

NOTES.

A New Unit of Resistance.—The "London Electrical Engineer" is guilty of the following:

"Erratum—In the answer signed 'E. M.' inserted in our last issue, the resistance of a 100 voltmeter (*sic*) is given at 30,000 watts. This should be 3,000 watts!"

Election of Officers at the Northwestern Convention. — At the recent convention of the Northwestern Electrical Association held in Milwaukee, Wis., the following officers were elected for the ensuing year: President, E. L. Debell, Sheboygan, Wis.; First Vice-President, S. B. Livermore, Winona, Minn.; Second Vice-President, W. Worth Bean, St. Joseph, Mo.; Directors, J. H. Harding, La Porte, Ind.; L. E. Kerns, Madison, Wis.; and Chas. Cuno, of Oconomowoc, Wis.

Practical College Work. — The University of Illinois has issued a manual of instructions, forms and schedules for use in electrical engineering laboratories, prepared by Profs. W. S. Aldrich and W. H. Browne. Full instructions are given, accompanied by diagrams, etc., for making all electrical measurements of a practical character and for testing apparatus, a large space being devoted to alternating currents. Several pages of the book are devoted to a list of book and periodical publications of assistance to students with respect to the subjects treated in the book. We note that many articles in the American Electrician are referred to in the latter, particularly under the heads of inspection of machinery and appliances; compounding machines; efficiency determination; alternating current induction motor and rotary converter working, and other practical subjects relating to alternating currents.

The Pupin Telephone Line Patents. — The patents of Prof. M. I. Pupin, of Columbia College, on improvements to telephone lines have been purchased by the American Bell Telephone Company. According to newspaper accounts, the consideration was a payment variously given at from $200,000 to $500,000 and an annual royalty during the life of the patents also variously stated at from $7,500 to $15,000 per year. These patents, which were issued June 19, 1900, relate to the use of inductances on telephone lines whereby the distance over which telephonic communication may be had may be greatly extended and the line cost diminished. The system, if it can be practically applied to ocean cables, will also render ocean telephony possible. The principle consists in placing inductance coils at equal distances along the line, the distance between consecutive points being equal to or less than one-sixteenth of the smallest wave length which is to be transmitted. According to the inventor's calculations, in the case of a telephone line 3,000 miles long, for example, having a resistance of 4 ohms per mile, one inductance coil of 200 millihenrys would be required per mile. Such a coil using no iron would take 1600 ft. of wire of 2 ohms per mile wound into a coil of 5 ins. internal diameter and 12 ins. in length. The line wire thus corresponds in resistance to No. 9 copper, and the coil to No. 6 copper. Should the method be applied to a submarine cable 2,000 miles long it would be necessary to introduce 8 coils per mile having an aggregate inductance of 300 millihenrys and resistance of 1 ohm per mile. The specifications of the patents state that employing cores of iron or steel, coils of this inductance can be readily made which will be small enough to go within the sheathing of a submarine cable. A coil for this purpose is described having a diameter when finished of 2½ ins. and a length of 4¼ ins. Sixteen thousand of these will be required on a submarine cable 2,000 miles long. The specifications of the Pupin patent state, however, that if iron cores are used for the coils the construction must be such as to keep down the magnetization, hysteresis and eddy current losses and distortion of the currents by the variation of the magnetic permeability of the core during each cycle of magnetization, as otherwise they will work disastrously.

Chicago Electrical Association.—The officers elected by the Chicago Electrical Association for 1901 are as follows: President, R. F. Schuchart; vice-president, Harold Almert; secretary, W. J. Warder, Jr.; treasurer, H. G. Dimick; auditor, G. M. Mayer; librarian, W. B. Hale; directors, L. G. Bassett, J. R. Cravath and H. P. Clausen. The secretary's address is 242 S. Jefferson Street. The association is in a flourishing condition and starts the new century with extremely gratifying prospects.

Wireless Telegraphy in Hawaii.—According to a press dispatch, three wireless telegraph stations have been established in the Hawaiian Islands; one at Honolulu, one at Hilo, and one on the Island of Lanai. There is a cable connection between the Islands of Lanai and Maui, and the establishment of the wireless telegraph service completes means of communication between all the islands of the group except Kauai. It is said that several rigid tests have demonstrated the entire practicability of the system.

Engines Driving Paralleled Alternators.—In the abstract, which was published last month, of Mr. H. G. Reist's paper read before the recent convention of the Engine Builders' Association, the statement relating to the permissible deviation from absolutely uniform rotation, reading as follows: "Mr. Reist stated that all engines designed for this service should not have an angular deviation of more than $\frac{5}{P}$ degrees of a cycle," should have read: "Mr. Reist stated that the rotating parts of engines designed for this service should not have an angular deviation from the position they would have with absolutely uniform speed, greater than $\frac{5}{P}$ degrees of a circle," referring to the circle described by the rotating part and not to a cycle.

The South Carolina Inter-State and West Indian Exposition will be held in Charleston, S. C., opening December 1, 1901, and closing June 1, 1902. The work of constructing the buildings is now in active progress, contracting having already been made for four of the principal structures, of which there will be eleven. The Exposition Company has its agents actively at work in different parts of the country, and it is expected that the exposition will be one of the most attractive that has ever been held in the Southern States. The power plant of the Exposition has not yet been arranged for. A general estimate calls for one plant to maintain 8500 16-c.p. incandescent lamps, a second plant to furnish 600 arc lamps of 500-c.p. each, and a third plant to supply from 1500 to 3000 horse-power for operating the live exhibits of the Exposition. The general plan of installation has been arranged so that power may be provided in every building on the grounds, and wherever practicable, that every machine shall be belted up and operated, and methods of manufacture illustrated throughout the whole range of processes from the raw material to the finished product. In order to carry out this plan, electric power will be furnished to exhibitors who will provide their own motors and connect with the main at the most convenient point. A great number of the mills are now operated by direct-connected motors, and the extension of the system is growing steadily. There is said to be an enormous undeveloped field at the South ready for the influx of machinery and electrical appliances of all kinds, which an exhibit of generators, motors and general appliances would tend to open up.

A Co-Operating Circulating Library and Electrical Laboratory.—The plan which is followed by the Chicago Central Young Men's Christian Association Electrical Club in securing a circulating library of the best practical electrical books is interesting and worthy of imitation. The club started a library fund over a year ago, the first money being the proceeds of a lecture on wireless telegraphy by Mr. Arthur Vaughan Abbott. The fund was further increased by each member of the club subscribing for one year to the American Electrician, at the regular rate; a liberal discount for the entire club subscription was allowed, and this commission was turned over to the library enterprise. With the money thus raised the club has purchased every book (46 in all) listed in the American Electrician catalogue.

The club was organized in March, 1897, and is composed of about a hundred ambitious young men who are employed in electrical or allied industries. During the past three years the club has accumulated a laboratory equipment worth about $2,000, to which additions are constantly being made. Liberal donations from the Western Electric Company, the Chicago Telephone Company, the Chicago Edison Company and other local companies have enabled the club to equip its laboratory with a fine collection of Weston instruments and other testing apparatus. The work in the laboratory is in charge of Mr. W. D. Hale, electrical engineer in charge of the testing laboratory of the Western Electrical Company. Mr. Hale has prepared a course of instruction which is given with the aid of a set of bulletins, and covers practical work with the ammeter, voltmeter, wattmeter and other testing instruments used in every-day work. In addition to the two classes in the laboratory, which meet once a week, there are classes in elementary and advanced electricity in connection with the regular work of the Association College. There are over 125 students enrolled in the electrical classes, and a total of nearly 900 in the other 55 classes of the college. The electrical classes are in charge of Mr. H. R. King, and the text-books used in both classes are Houston & Kennelly's Electrical Engineering Leaflets. The work of this club is a good example of the benefits which can be obtained by ambitious young men with only a reasonable amount of enterprise and co-operation as initial working capital.

Mr. Dooley's Review of the Century.—One of the cleverest and most humorous of skits appears in "Lightning's" first issue of the new century. The celebrated character of fiction, Martin Dooley, is borrowed from Mr. Peter Finley Dunne and made to say, among other funny things:

"Great happenin's has me an' you an' th' ithers seen in these wan hundherd years, an' Great Britain has had so many geenuses that Mack is buildin' a new patent office to Wash'n'ton. * * * * In me toime, Hinnissy, Oi've seen manny wondherful invinshuns interjooced. Oi've seen th' tillyphone put into iv'ry house, be which ye c'n talk to yure naybur acrost th' sthrate whin his number's not ingaged. Th' tillyphone is raysponsible f'r th' prisint overcrowdin' iv hell, an' th' gover'mint had to find a rimidy be diggin' up all th' r-roads an' startin' an opposishun. Oi've seen th' phonygraph invinted twict be th' sage iv Menloo Par-rk, an' no fam'ly's complate without one. Whiniver a man dies he has a wax cylindher put into his corffin with a message to his ancesthors wan thousand years hince. Oi've seen th' gr-reat invintions iv Perfessors Gilbert an' Sullivan in me time fr'm Japanese mirrors to arc lamps. Phwat man don't kape a telpher line in his back gardin f'r hangin' th' close an' bringin' up th' pertaties? Secohmeters are at iv'ry corner iv th' sthrates ladlin' out self-inducshun, an' magnifyin' springs is to be bought in iv'ry sthore. Glory be, an' whin Oi call to moinde th' sthreet kyars pulled be horses which was fur-rust cousins to th' sausages in Schwartzmeister's windy, an' see before me th' electric kyars an' th' ought-to-me-billies toot-tootin' an' runnin' down folks at iv'ry corner, me heart fills with pride, Hinnissy, to know that Oi'm livin' in th' ninetyeth cintury an' assistin' to make th' gr'reat elictric age. * * * * Oi till ye phwat, Hinnissy, th' nixt cintury will be a perspirin' awr-fillin' ixistence, phwat with toobes undher th' earth shakin' th' houses an' makin' their rints to fall—an' flyin' machines knockin' down th' chimley-pots an' dhroppin' folks into th' back yards—an' submar-rines scuttlin' all th' r-river stheamers an' landin' furrin ar-rmies in th' Regent's Canal—an' messages fr'm Mars—an' coal givin' out—an' th' sun gittin' smaller—an' th' Yeller Per-ril—an' ars'nic in whisky—an' compulsory creemayshun—an' sperrits—an'——"

"Merciful hivins!" exclaimed Mr. Hennessy, who was as white as a sheet, "whin do th' new cintury begin?"

ESTABLISHED 1889.

American Electrician,

WITH WHICH IS INCORPORATED
Electrical Industries.

CECIL P. POOLE, Editor.

Long Distance and Ocean Telephony.

The announcement that Prof. Pupin, of Columbia University, had received a large sum of money from the American Bell Telephone Company for his telephone line patents has resulted in considerable sensational matter being admitted to the daily press concerning the subject and scope of these patents. In fact, the great value of the patents in connection with land lines, and which undoubtedly led to their purchase by the American Bell Company, appears to be entirely lost sight of, the newspaper accounts almost exclusively dwelling upon their application to ocean telephony, of which problem they are stated to offer a final solution. A reading of Dr. Pupin's patents, however, shows that some very serious practical and commercial considerations intervene to render such a claim at the present moment unjustifiable. There appears to be no doubt, however, that the system when applied to land lines will enable telephone conversation to be carried on over such lines of any length, with an expenditure of copper relatively small as compared with that necessary for present long-distance lines—which lines, moreover, had reached their limit of length some time ago owing to the enormously increased expenditure for copper that would be required for further extensions in length. Indeed, the purchase of the Pupin patents by the American Bell Telephone Company at a large figure appears to place a stamp on the value of the principles concerned, even though they can be applied only to land telephony.

The principle of the Pupin system is relatively simple. Inductance coils are introduced into the line for the purpose of neutralizing the line capacity, which otherwise greatly distorts and attenuates telephonic currents passing over long lines. This distortion can be partially compensated for by increasing the conductance of the line, but as each addition to the length requires a corresponding increase in cross section of the line wire, a limit is finally reached beyond which further extension is commercially impossible. Long before the day of the telephone it was known that inductance acts to neutralize capacity, and the use of inductance was in early days advocated for counteracting the evil effects of capacity in submarine telegraphy. During the past twenty years or more, the application of inductance coils to telephone lines has been proposed in a number of cases. Dr. Pupin, however, appears to have been the first to attack the problem along the proper lines.

By means of an exhaustive mathematical investigation of the question he arrived at the result that the inductance inserted in a line must not only correspond in value to the capacity of that line, but must be distributed along the line at certain definite intervals. Moreover, he deduced practical formulas whereby the amount of inductance and the distance of the coils apart may be calculated for any given case. His investigation also showed the cause of previous failures in the use of inductances for ameliorating telephonic transmission, for if such inductances are not of the proper value and placed at the proper intervals, they themselves give rise to disturbing effects that still further distort and attenuate the telephonic current. The entire feasibility of the Pupin system for land lines is illustrated by data for such a line given in the specification of one of the patents. For a telephone line 3000 miles long, for example, an inductance coil of 200 millihenrys would be required at intervals of one mile, each coil containing about one-third of a mile of wire—No. 6 in size, if of copper. As the inductance would be a simple coil of wire which, after being connected on the line, would require no attention, the application of the Pupin system to land lines is evidently entirely feasible, from both the commercial and practical standpoints.

Turning now to ocean telephony, this furnished the subject of a remarkably able paper read at the Chicago National Congress of 1893 by Prof. Silvanus P. Thompson. In this paper he showed that the only effective way to annul the retarding effects of the distributed capacity of a cable is to apply inductances along the entire length of the cable, either at intervals or continuously. Unlike Prof. Pupin, Prof. Thompson appears, however, to have failed to grasp the fact that the distance between consecutive coils should be a function of the electrical wave length corresponding to the highest frequency necessary in the transmission of speech. Notwithstanding the establishment of this principle by Prof. Pupin, the question of the applicability of his system to ocean telephony is quite another one from that of its applicability to land lines. According to data given in the patents, eight coils per mile of cable would be required for a submarine cable 2000 miles long, each coil having an inductance of 200 millihenrys. The use of a plain coil similar to that employed on land lines is evidently impracticable. By employing an iron core, the size of the inductances could, of course, be greatly reduced, but Dr. Pupin in his patents states that such coils would work disastrously if they were not constructed so as to keep down the magnetization, hysteresis and Foucault losses and the distortion of the current by the variation of the magnetic permeability for each cycle of magnetization. It will thus be seen that some very difficult problems remain to be solved before the Pupin system can be considered as rendering ocean telephony possible, or applicable even to ocean telegraphy.

Heating and Pumping Feed-Water.

The heating of boiler feed-water and its delivery to the boiler in the most economical manner is a problem involving such a large number of solutions that a general discussion of it is extremely difficult. A practice that may be ideal for one station may be highly inefficient if applied to a station in which some of the operating conditions are different. Readers of Mr. Mather's excellent article on this subject, which appears in another column, should keep this in mind, remembering that the recommendations made in the article are not hard-and-fast rules, but are intended merely as a general guide.

The proposition that boiler feed pumps should be of the highest efficiency is sound in the abstract; any machine should have as high an efficiency as is practical. But there are many cases in practice where simplicity is worth more than efficiency, and where a simple boiler feed pump consuming 150 lbs. of steam per horse-power-hour, but requires no skilled attention, is far preferable to a fly-wheel pump taking 40 lbs. of steam and demanding more or less frequent adjustment and repair. Electrically-driven pumps possess both of the advantages of comparative simplicity and high economy. The pump proper is usually of the very simplest type, and the introduction of a motor should be no drawback in an electrical power house. The freedom from a tangle of small steam pipes is an advantage which can be best appreciated only by those who have to do with the pumps. Wires can be run along out-of-the-way routes, and do not interfere in the slightest with access to a pump; moreover, the pumps may be controlled from any point in the boiler room, so that they themselves may be located wherever most convenient as regards available space in contradistinction to convenience of access for regulation.

Even in a condensing plant, electrically-driven boiler-feeding pumps can usually be installed to advantage. If the plant is not large enough to justify the installation of economizers, the feed water would ordinarily be sufficiently heated by a primary heater in the engine exhaust and a secondary heater warmed by the exhaust steam from the air and circulation pumps. Incidentally, it might be found profitable in some cases to deliver the exhaust steam of the pumps to the main engine receiver after it leaves the secondary heater. This, of course, would depend upon the amount of heat taken out by the feed-water. Where compound engines are operated non-condensing, and steam boiler feed pumps are used, the exhaust steam of the pumps is usually not needed for heating feed-water; it will ordinarily be found profitable, therefore, to deliver that exhaust steam into the engine receiver instead of turning it out into the atmosphere at 30 to 50 lbs. gauge pressure.

Tesla's Latest.

The New Century has already been enriched by two Tesla "discoveries," one of which he announces as his "first gift to the New Century." Several weeks ago he announced through the newspapers that certain electrical disturbances that had come under his observation were, he felt convinced, of planetary origin, which statement was followed up a few days later with another that he had discovered a means which rendered communication with Mars or any other planet not only possible, but easily practicable. Unfortunately for the credence of his claim, he added in a letter to the New York *Sun* some details which contradict all established ideas concerning the transmission of electric radiant energy, though the proposed means of communication with another planet purports to be based upon these same ideas.

The second and more recent announcement is that as the result of continuous effort since his first experimental demonstrations of years ago, he has at last perfected a means of producing "artificial sunshine," the new light being more economical and vastly superior to present forms of artificial illumination. In a letter to the *Sun* the following details are given: "The lamps are glass tubes which may be bent in any ornamental way. I most generally use a rectangular spiral, containing about twenty or twenty-five feet of tubing making some twelve to fourteen convolutions. The total illuminating surface of a lamp is from 300 to 400 sq. ins. The ends of the spiral tube are covered with a metallic coating and provided with hooks for hanging the lamp on the terminals of the source of oscillations. The tube contains gases rarefied to a certain degree, determined in the course of long experimentation as being conducive to the best results." In this instance also Mr. Tesla has been very fortunate in departing from his custom by giving details, for the "gift to the New Century" appears to be merely the vacuum tube light, known now for almost two centuries. The description does not indicate any advance in principle over Hawksbee's work of 1709, nor any advance otherwise over the work of Geissler fifty years ago, or that of D. McFarlan Moore in recent years.

At one time the frequent announcements by Tesla of revolutionary discoveries were a real source of harm to the electrical industry through giving rise to fears in the minds of investors that the current status of the electrical industry is insecure. The lay public appears, however, to have finally become surfeited with promises followed by no fulfillment, and the more recent announcements of Tesla have been received by the newspaper press with few exceptions—mostly of the "yellow" variety—in a changed spirit. Instead of serious consideration being given to his claims, he is rapidly becoming a subject for the irreverent mirth of the newspaper paragrapher, one of whom comments as follows: "Mr. Tesla is thus on the very eve of a discovery even more remarkable than the many others on whose eve he has been so often and so long. It may be asserted confidently that if any one on earth can understand Mars it is Tesla; and conversely, that if any one can understand Tesla, it must be an inhabitant of Mars." To quote sorrowfully an English electrical contemporary: "It is pitiable to see the engineer who invented the polyphase system of power transmission and who has done such valuable original work for other departments of electrical engineering, so fond of the cheap notoriety to be gained by sensational paragraphs in daily papers."

A SPARKING DYNAMO FOR GAS-ENGINE SERVICE.

Although the majority of dynamos and motors of recent design are of the circular-yoke type, with radial poles, the Manchester type of field magnet has many points of merit, particularly in machines designed for amateur construction. The patterns are more easily made, and although there is more actual machine work to be done, it is of a character more easily performed than that on the circular-yoke type, taking into consideration the facilities possessed by most amateurs for this sort of work. An interesting little machine of this type has recently been built by Mr. B. F. M. Weaver, of Wilmington, Del., and is illustrated herewith.

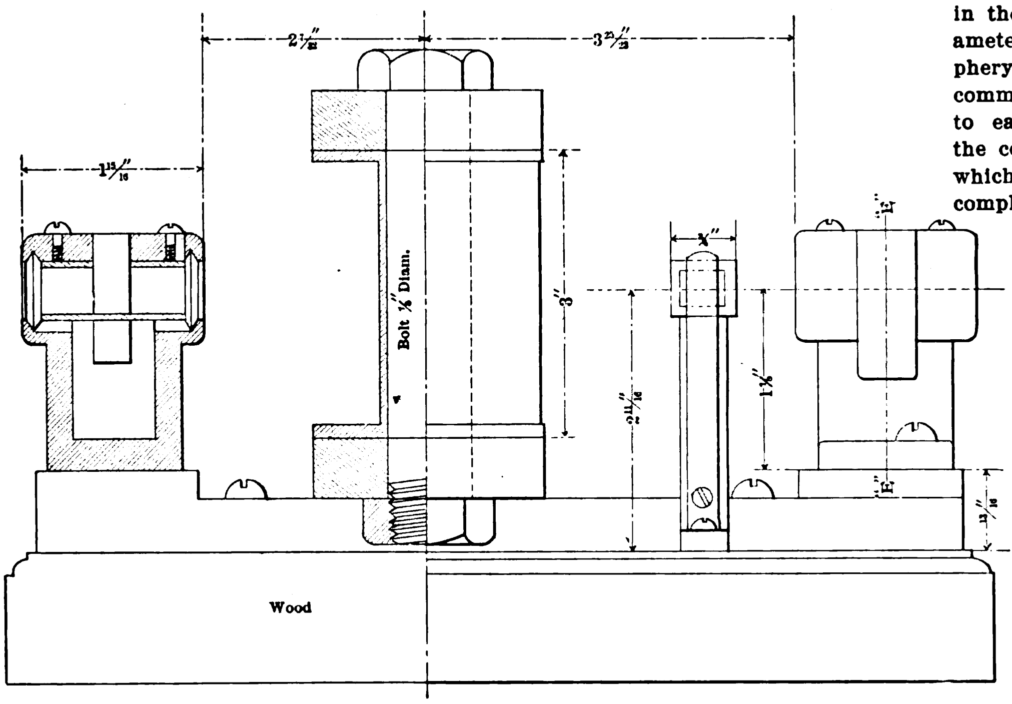

FIG. 1.—SEMI-SECTIONAL SIDE ELEVATION.

Fig. 1 is a partly sectional side elevation of the field magnet frame, base and journal pedestals; the dimensions are all indicated on the sketch. Fig. 2 is a transverse sectional view of the field-magnet pole-pieces and the wood base. The magnet pole-pieces were made of a good grade of cast-iron, and the magnet cores consist of ordinary 7/8-in. wrought-iron bolts, machined just enough to make them fit snugly in the holes of the pole-piece flanges. The distance from center to center of the magnet cores is 6 ins. There are no shoulders on the magnet cores, the pole-pieces being held apart by the magnet coil spools, which may be made of either composition metal or cast-iron. These spools are each 3 ins. long over all, and the barrel is bored out to fit the magnet core snugly. The outside of the barrel is turned down to 1 1/8 ins. diameter. The heads of the spools are 2 3/8 ins. in diameter.

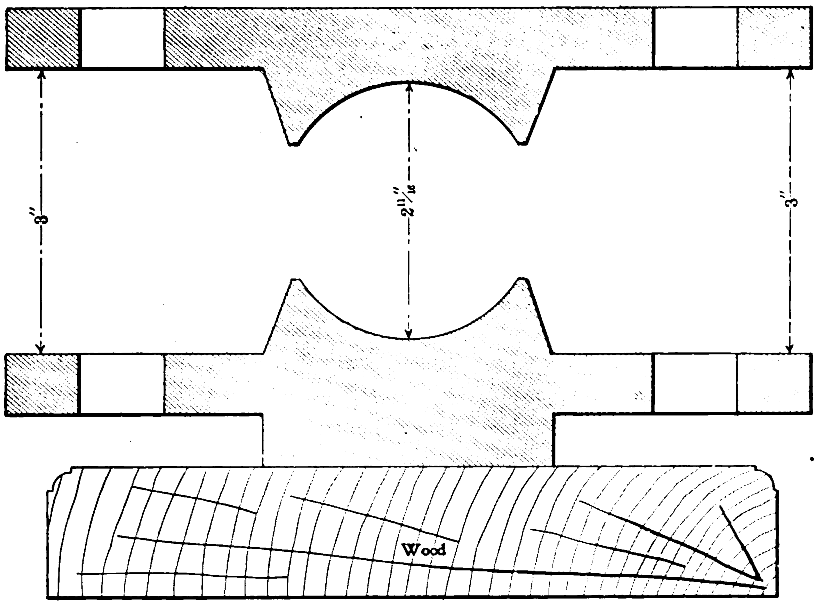

FIG. 2.—TRANSVERSE SECTION OF FIELD MAGNET YOKES AND POLE-PIECES.

Fig. 5 is a sketch of the armature, commutator, shaft, and pulley. The armature core is of the usual laminated type, made of discs 2 5/8 ins. in diameter and of the shape shown by Fig. 4. The coil holes in the armature disc are 5/16 in. in diameter and flared out toward the periphery of the disc, so as to leave a communicating slot through the edge to each hole. It will be noticed that the central hole in the armature disc, which is 5/8 in. in diameter, is not a complete circle, but is flattened on one side in order to form a feather for communicating positively the rotation of the shaft to the discs. The shaft has a corresponding flatted side, of course, so as to fit snugly in the central hole of the disc. The discs are clamped between two brass flanged collars, the flanged portion of the collars being 1 3/4 ins. in diameter and the barrel 1 in. These are screwed on the shaft as shown in Fig. 5, and one of them is provided with an additional outer flange, which serves to prevent oil from finding its way over to the armature core should any of it creep out along the shaft. The magnetic portion of the armature core

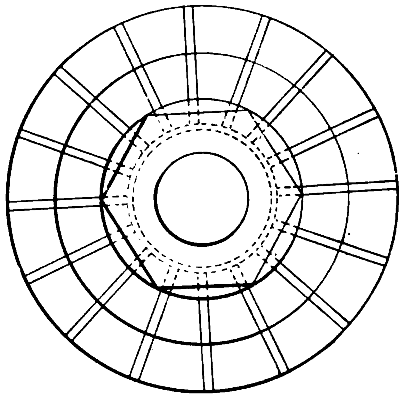

FIG. 3.—END OF COMMUTATOR.

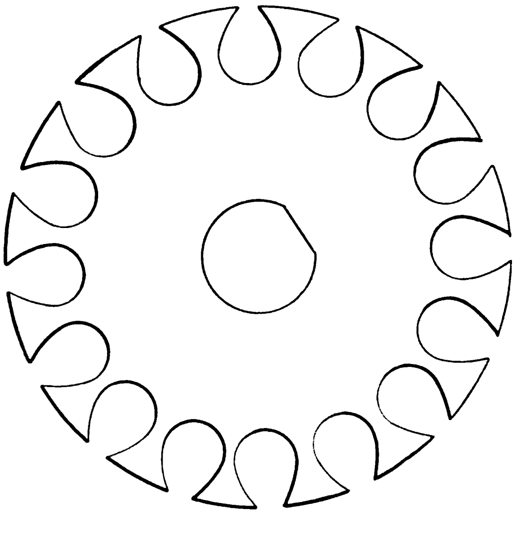

FIG. 4.—ARMATURE DISC.

is 2¼ ins. long and the length over all, including the clamping collars, is 4⅜ ins.

The pulley is of brass, cast with a solid central web instead of spokes, on account of the smallness of its diameter. It is 2½ ins. in diameter and 1½ ins. wide on the face.

The commutator is of the usual type, with the segments beveled at each end for drawing together. The segment is undercut at only one end, however, where the connecting lug extends over the rear beveled collar. The clamping collar at the front end of the commutator fits smoothly over the core, but is not threaded; it is forced into place by an auxiliary nut on the core back of it. Fig. 3 is a front view of the commutator, which is 1½ ins. in diameter at the brush tread by ¾ in. axial length, and 2 ins. in diameter over the connecting lugs, which are 5/16 in. thick axially.

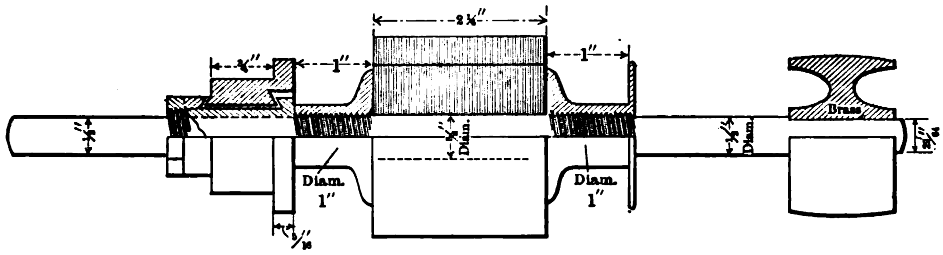

FIG. 5.—ARMATURE, SHAFT, COMMUTATOR AND PULLEY.

The brush-holders, one of which is shown in Fig. 7, are very simple in construction, consisting of a brass standard carrying at its upper end a rectangular box for the carbon brush and provided with a flat phosphor bronze or brass spring screwed to the standard near its base and bent to such a shape as to enable the upper end to press against the back end of the brush. The brushes are ½ in. wide, 7/16 in. thick and 1 in. long.

The journal pedestals are clearly snown in Fig. 1 and by Fig. 6. They are of the self-oiling pattern, having oil rings an inch in diameter outside and 13/16 in. diameter inside; they are ¼ in. wide parallel with the shaft. The oil reservoir is made with parallel sides above the center in order to facilitate the construction of the box by amateurs. The width is 1 1/16 ins. transversely and ⅞ in. axially. The boxes are provided with bushings of ½-in. bore and ⅝-in. outer diameter; they are 1½ ins. long each. These bushings are held in place by small machine screws set into the top of the journal box casting.

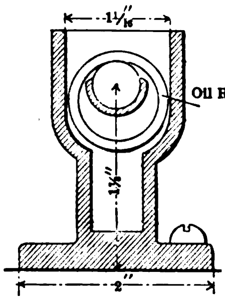

FIG 6.

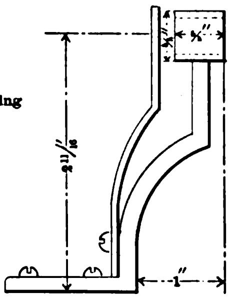

FIG. 7.

The machine has been built with two armature windings, one for 14 volts and 3 amperes, and the other for 32 volts and 1¼ amperes. The 14-volt winding consists of 16 coils of No. 20 double cotton-covered magnet wire, each coil containing 16 turns of wire. The armature winding for 32 volts consists of 16 coils of No. 22 wire, each coil containing 40 turns of wire. Each field coil contains 26 layers of No. 25 double cotton-covered wire, each layer containing 92 turns, so that there are 2392 turns of wire in each coil. The two field coils are connected in multiple when used in connection with the 14-volt armature and in series when used with the 32-volt armature, the fields being connected in shunt with the armature.

The speed of the machine for 14 volts is 2400 r.p.m.; for 32 volts it can run a trifle slower than this. Fig. 8 shows the completed machine, as built by Mr. Weaver, with a pilot lamp on the terminal board. This machine is of the simplest possible construction consistent with practical results, all of the fitting, with the exception of that on the brush-holders, consisting of plain lathe work.

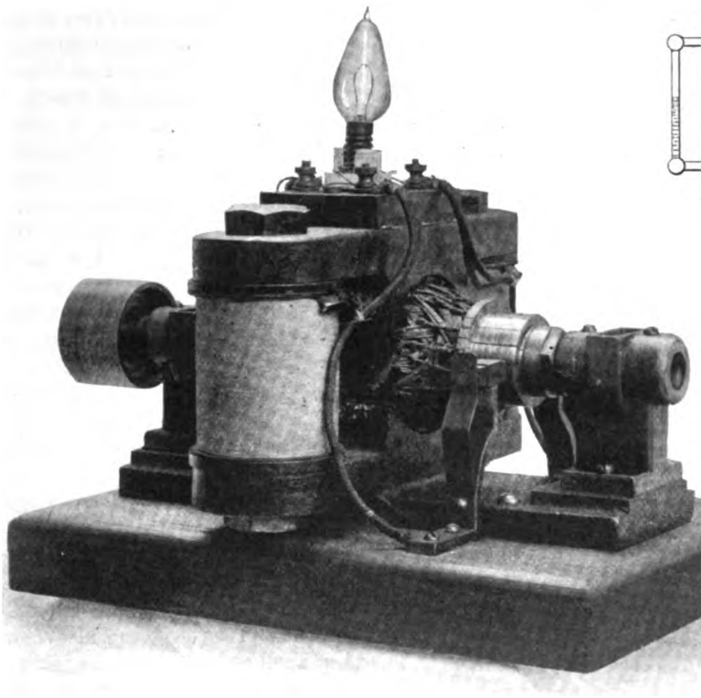

FIG. 8.—THE COMPLETE MACHINE.

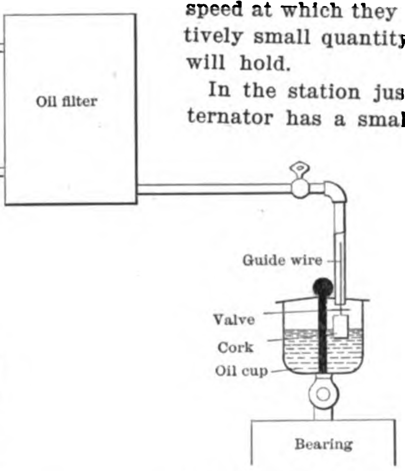
SOME HANDY KINKS.

The writer recently happened in upon E. W. Kramer, chief engineer of the electric light station of the Council Bluffs (Iowa) Gas & Electric Company, and found several wrinkles that will probably be of use to others operating similar small plants. The first one noticed was so simple that it is a wonder it is not more generally used under similar circumstances; it was an automatic oil feeder for old-style bearings. Small alternators built before the days of self-oiling bearings usually require frequent re-filling of oil cups because of the high speed at which they run and the comparatively small quantity of oil that the cups will hold.

In the station just mentioned each alternator has a small oil filter on top of the machine, from which oil feeds by gravity to the oil cups. To prevent the oil from feeding too fast, a cork float is provided in the cup to open and close the inlet. This float is on a guide wire which sticks up into the oil feed pipe, as shown in the accompanying sketch. On the guide wire above the cork is a leather gasket or washer which shuts off the oil flow by closing the end of the supply tube when the oil gets above a certain height in the cup. The cork float automatically regulates the flow of oil to such an extent that the oiling does not need any attention after once being started except to keep the filter on top of the machine full and empty the drip tank underneath. Those who know how often alternator oil cups need filling and what a burden both to mind and body it is to keep them full will appreciate this scheme.



AUTOMATIC OIL FEED.

Another useful little device found in that station was an electro-hydraulic damper regulator. A shunt circuit from the field of an exciter, with a lamp in series, furnishes current for the device. A steam gauge is fitted up so that as the pressure rises to a certain point it closes a circuit through an electromagnet, which in turn opens a needle valve that admits water under pressure from the city mains to a cylinder, moving a piston in the cylinder and so closing the dampers. Regulation of pressure is very close with this device and is so cheap and simple as to be within the reach of any plant.

This station has old-style Westinghouse compensator voltmeters and contacts have been provided so that when the pointer swings more than a predetermined amount to either side of the mark indicating normal voltage a red lamp under the voltmeter lights up; hence, the attendant can see from a distance that the circuit requires regulation.

◆

SMALL TELEPHONE SWITCHBOARD SYSTEMS.

BY W. S. HENRY.

As stated in previous articles, all switchboards should be wired and constructed with complete metallic circuits; that is, with two wires for each telephone circuit and no common wire or ground return. One method of wiring a simple switchboard with two wires for each circuit is shown diagrammatically in Fig. 4. In an actual switchboard the keys would be constructed in a much more compact form than is shown here. In this diagram, D and D′ are two subscribers' annunciators,* commonly called subscribers' drops, and T and T′ are jack tip-springs that normally make contact with a wire running to their respective annunciators. When a plug is inserted in the jack the tip of the plug makes contact with the tip-spring and pushes the latter away from the annunciator contact, and the sleeve of the plug makes contact with the thimble (S or S′) of the jack, as shown at the right side of the figure where the plug, P′, is inserted in the jack. It is better to make S and S′ rubbing contact springs, like T and T′, and this is usually done now on all good switchboards; this will be shown in a later diagram.

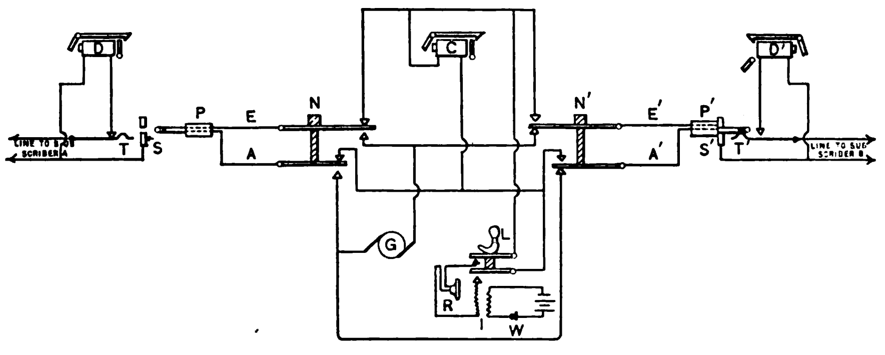


FIG. 4.—DIAGRAM OF CONNECTIONS FOR A SIMPLE SWITCHBOARD.

In Fig. 4, E and E′ are the sleeve strands, and A and A′ the tip strands of the operator's cord circuit; N and N′ are the ringing keys for ringing up subscribers over the plugs, P and P′, respectively; CO is the clearing-out drop, bridged across the tip and sleeve strands of the cord circuit; G is a magneto-generator operated by hand or by an electric motor. Depressing the ringing key, N, will evidently connect the generator, G, to the wires, A and E, and at the same time disconnect them from all other parts of the operator's circuit. Similarly depressing the other ringing key, N′, will connect the generator, G, across the wires, A′ and E′, and disconnect these latter wires from all other parts of the cord circuit. L is the operator's listening key or cam. When the handle of the cam is drawn forward the operator's talking and listening circuit is connected across the cord circuit—i. e., across the two wires running to both plugs. I is the induction coil, W the microphone transmitter, H the battery and R the watch-case receiver. D and D′ are series-wound drops and CO a bridging-wound clearing-out drop.

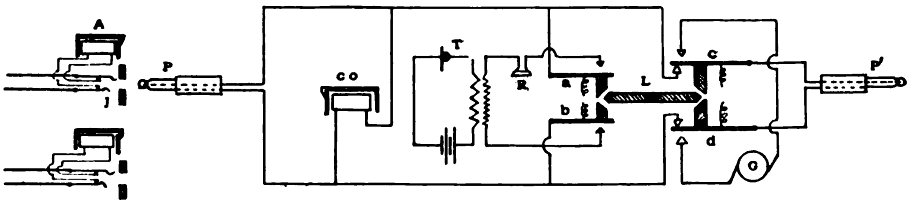

FIG. 5.—DIAGRAM OF SWITCHBOARD WITH COMBINED RINGING AND LISTENING KEY.

The operation of this switchboard is exactly the same as the one described last month. If subscriber B sends in a call, the shutter of the drop, D′, falls, the operator inserts the answering plug, P′, into B's jack, restores the drop now or later, draws forward the handle of the listening cam, asks for and receives the number of the subscriber to whom B desires to talk, inserts the calling plug, P, into that jack (suppose it is A's jack), and depresses the ringing key, N, which sends a ringing current out over the line running to subscriber A only; A having the call and the cam, L, having been restored to its normal vertical position, the two subscribers are properly connected. When the conversation is finished one or both subscribers ring off, causing the shutter of the clearing-out drop, CO, to fall. The operator then removes both plugs from the jacks, and restores the shutter of the clearing-out drop; then the circuits are in their normal position once more.

In the diagram, the ringing key, N, and the listening key, L, are shown in their normal position, and the ringing key, N′, in its depressed or ringing position. Ringing keys should always be constructed so that they will return to their normal position when released, but the listening key must usually be restored by hand.

It will be noticed that by this system of ringing keys the operator can ring out over either plug P or P′; this is convenient, although not absolutely necessary. It is convenient in case the calling subscriber leaves his telephone while waiting for his connection to be made at the switchboard; as a rule, there is really no excuse for his doing so. This provision for ringing out over both plugs requires two ringing keys, and hence twice the number of contacts for the purpose of ringing than if only one key is used and provision made for ringing out over one plug only. The latter method has some advantages; there are fewer contacts for the subscribers to talk through, and the fewer contacts there are the better, for it means fewer points at which there is liable to be trouble, and, of course, less cost in manufacture. On the other hand, where this provision for ringing out through both plugs is not made, the operator would have to reverse the plugs in the jacks in order to ring up the original calling subscriber in case the latter should have left his telephone before the operator had obtained the desired connection.

Fig. 5 is a diagram for a simple switchboard, with a combination listening and ringing key, L; P is the answering plug, and P′ the calling plug. When a subscriber's drop falls, the operator always inserts the front or answering plug, P, into the jack corresponding to the drop whose shutter fell. When the plug has been inserted the tip of the plug makes contact with one spring and the sleeve with the other spring, and the plug also spreads the two springs sufficiently to disconnect both ends of the annunciator circuit, thereby cutting the annunciator entirely out of the circuit and connecting the two line wires with the tip and sleeve strands of the cord circuit. In order to ask for and receive the number of the subscriber with whom the calling subscriber desires to be connected, the operator pulls forward the handle of the combination key, L. This spreads the two springs, *a* and *b*, thereby connecting the operator's telephone across the tip and sleeve strands of the cord circuit. The key is so constructed that it will remain in that position even if the operator lets go of it.

---

*There are, of course, no subscribers in an interior telephone system. The term "subscriber" is used merely to designate the person whose telephone is connected with the system.

After learning what subscriber is wanted, the operator inserts the rear or calling plug, P′, into the proper jack. As in the case of the answering plug, the insertion of the calling plug into the jack cuts out the annunciator of the subscriber called and connects one of the two jack springs with the tip and the other with the sleeve of the plug. The operator then pushes the handle of the key, L, away from her. After the handle passes the middle and normal position, the springs, *c* and *d*, are spread apart, thereby disconnecting the answering from the calling plug, and then connecting the two sides of the calling plug across the generator, G. Thus a ringing current is sent over the line to the second subscriber's instrument. The key, L, will stay in the ringing position only as long as the operator holds it there; the moment she releases it the key automatically returns to its center position.

The ringing current cannot flow in the calling subscriber's circuit and consequently no disagreeable sound, due to ringing up the desired subscriber, is heard in the receiver that the calling or original subscriber is holding to his ear while waiting for the subscriber called to reply. Moreover, this key system has comparatively very few contacts, the voice currents having to pass through only one pair of contacts in the cord circuit. On the other hand, if the calling subscriber leaves his telephone the operator cannot ring him up without first exchanging the positions of the answering and calling plugs. When the handle of the key, L, returns to the middle position the two spring-jacks are properly connected through the cord circuit and the two subscribers may converse. When the conversation is finished, ringing off by either one or both causes the shutter of the clearing-out drop to fall, as before described.

Many switchboards are provided with a switch whereby either a small power or hand generator, as desired, may be connected to the ringing key. Where the subscribers' drops are entirely cut out of the circuit during a conversation they need only be series-wound, and they need not be iron-clad. Iron-clad drops would be more efficient, to be sure, but since they are entirely cut out of the circuit during the conversation, they cannot cause cross talk. The clearing-out drop, however, should be a good iron-clad bridging drop.

In some cases, and at certain times in many small systems, there are not enough calls to require the constant attention of an operator, and, consequently, she may leave the board temporarily to do something else nearby. In such cases an auxiliary feature known as a night-alarm attachment is very desirable. Such an attachment will cause a bell to ring whenever the shutter of a subscriber's drop falls. This is shown in connection with the drop in Fig. 6.

When the shutter, S, falls, the spring, *t*, which is made of very thin spring metal so as to be easily bent, is pressed into engagement with the contact pin, *u*, by the heel projecting from the bottom of the shutter. The spring, *t*, and contact pin, *u*, form the terminals of a circuit containing a battery and an ordinary vibrating bell, and the bell is therefore sounded whenever a drop falls, unless the bell circuit is open at some other point by a switch, which would be the case during the busy part of the day, when enough calls are received to require the entire attention of the operator. All drops can, of course, be connected so as to require only one bell and one battery, and by means of a simple switch the alarm circuit may be readily cut in or out.

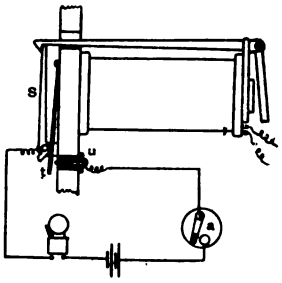

FIG. 6.—NIGHT BELL ATTACHMENT.

SLEET CUTTERS.

BY ARTHUR B. WEEKS.

Electric railway companies in many parts of the country are greatly annoyed by sleet forming on the trolley wires during portions of the winter months, some being hampered even to the point of shutting down. Cast sleet wheels are made to overcome this difficulty, and in some localities may give satisfaction; but the writer's experience with them has not been very encouraging; a wheel does not seem to solve the problem and some sort of scraper device is required to remove the sleet successfully.

A method still employed on some roads is to remove the trolley wheel and allow the fork to drag along the wire. This is satisfactory so far as it goes, and shows that a sliding contact is preferable to a revolving one for cutting off sleet. The wheel with spaced cutting edges is apparently just what is needed, but its edges soon wear smooth and severe flashing, so destructive to wheel and wire, follows. There is no flash with a properly constructed scraper.

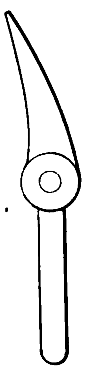

FIG. 1.

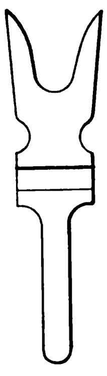

FIG. 2.

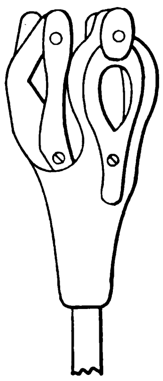

FIG. 3.

Several scraping devices have been suggested at times; but so far as the writer knows, none has yet proved successful, the chief objection being that the projecting parts invariably pull off span wires and hangers. The scraper illustrated in Figs. 1 and 2, however, has been used during the most trying weather for three seasons, and has been found entirely satisfactory on all occasions.

A glance at the cuts will show the construction, but a few suggestions in regard to its use may be advantageous. As soon as there are signs of trouble a scraper should be placed on one car on each line if the line is short; if the line is long or the sleet is very heavy, a scraper should be put on one car going each way. If night cars are not run and the wires must be cleaned before the cars start in the morning, one or more trips on each line a little earlier than usual will accomplish this. Frequently this trip can be made by the sand or salt car. A scraper should not be placed on the sweeper, if it is avoidable, as the sweeper should not be subjected to chances of delay.

To apply the scraper, remove the trolley wheel, put the scraper in its place and re-insert the trolley pin, not neglecting the cotter pins. The scraper should fit loosely on the trolley pin so as to avoid any delay in getting it into place, as nothing is more trying than replacing a wheel in rainy or sleety weather, and nothing is gained by a tight fit. As indicated by the sketch, the lower end of the scraper goes down into the trolley fork, Fig. 3, which thus holds it rigidly in place. Provision should be made for plenty of clearance when in position on the wire, and no attempt should be made to back a car with a scraper attached, or trouble will follow.

The crew should give the scraper their undivided attention while on these trips; the attendant on the rear platform should always hold the rope, and the car should not be run faster than is compatible with absolute safety. It must not be expected that the scraper will remain on the wire at cross-overs, turn-outs or curves; special care should be observed at these places.

These scrapers are made of steel, the cutting edge being drawn to a dark blue. It would seem that a scraper of this kind would cut the trolley wire, but careful tests and close observation prove that it does not harm the wire in the least. The sleet seems to offer all the protection necessary; but as the pressure upon the wire is but from 15 to 40 lbs., it could hardly do much damage, even if run on a dry wire. The scraper should be removed as soon after its work is completed as possible.

STEAM FLUE CLEANERS.

BY JAMES F. HOBART.

As stated in a previous article,* one of the principal methods of cleaning boiler tubes is to blow out the soot and other accumulations by means of steam blowers. Of these there are several types in general use throughout this country. Fig. 1 illustrates one of the best known tube blowers, which is made by the Cleveland Flue Cleaner Manufacturing Company, Cleveland, Ohio, known as the "Old Reliable." The head of this cleaner is so constructed that the jet of steam delivered by it takes a spiral course, the result being that the steam jet wipes the walls of the tube diagonally as well as longitudinally. The nozzle is cone-shaped so that it will fit closely into tubes of different sizes.

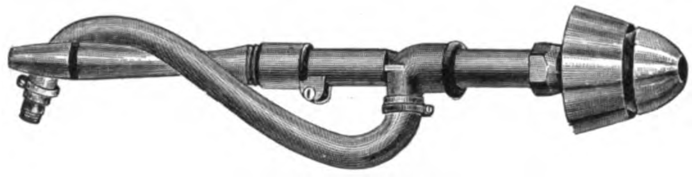

FIG. 1.—"OLD RELIABLE" CLEANER.

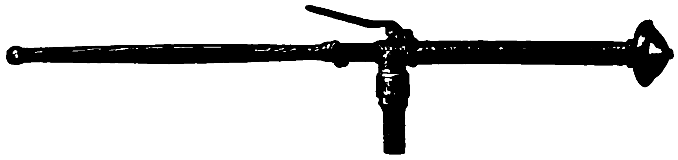

FIG. 2.—FAVORITE TUBE CLEANER.

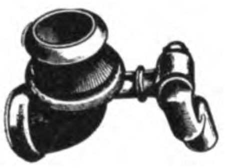

FIG. 6.—TWO-WAY CLEANER.

Fig. 2 represents the Favorite flue cleaner, made by the Haydenville Manufacturing Company, New York City. The nozzle is somewhat similar to that of the "Old Reliable" cleaner in its contour, having the form of a flattened cone, which enables it to be used with different sizes of tubes. The cleaner is provided with a stop valve located in the elbow just above the connection for the steam hose.

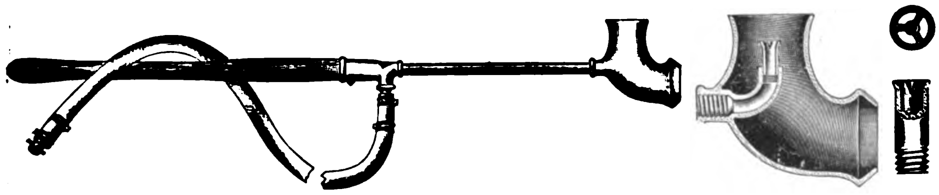

FIG. 3.—THOMPSON SOOT EJECTOR.

Fig. 3 illustrates a unique form of cleaner which operates by suction instead of by blowing. An enlarged view of the cleaner head is shown at the right of the engraving. The right-hand opening of the elbow is applied to the end of the tube and the steam jet discharging upward creates a vacuum in the tube, causing the air to rush through from the other end of the tube and sweep out the soot. An enlarged view of the steam nozzle is shown at the extreme right of the engraving, the upper figure being a plan view of the nozzle. This ejector, which is popularly known as the "soot sucker," is manufactured by Richard Thompson & Co., New York City. This firm also makes a modification of this cleaner which drives through the tube a jet of steam and a column of hot air for use when there is limited space at the uptake, and in the case of vertical tubular boilers.

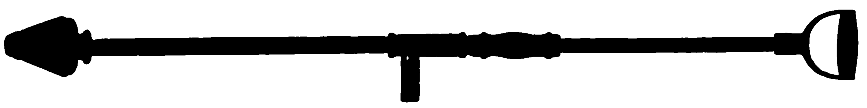

FIG. 4 —COGGESHALL TUBE CLEANER.

Fig. 4 shows a tube cleaner the operation of which is also based upon the production of a partial vacuum in the tube. The head of this tube cleaner, shown by Fig. 5, is cone-shaped, and carries four ribs or flanges, so that when the head is inserted in the end of the tube there is an air space around the shell of the cleaner head through which air can be drawn. The jet of steam delivered by the nozzle forms a partial vacuum in the tube, into which air is drawn through the annular spaces around the cleaner head at a high velocity. The current of air assists in cleaning out the soot and also drives out any moisture which would otherwise be left by the steam. This cleaner is made by the Coggeshall Manufacturing Company, New York City.

A cleaner somewhat similar in design to the Thompson "soot sucker" is manufactured by the Oliver P. Clay Company, Cleveland, Ohio, and illustrated by Fig. 6. This is known as the "Two-way" flue cleaner, being adapted for use either as a soot sucker or as a blower, according to which outlet of the cleaner head is inserted in the end of the tube. The interior arrangement is somewhat similar to that of the Thompson soot sucker.

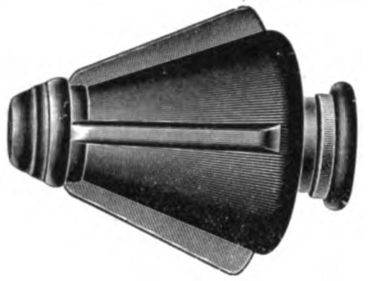

FIG. 5.—COGGESHALL CLEANER HEAD.

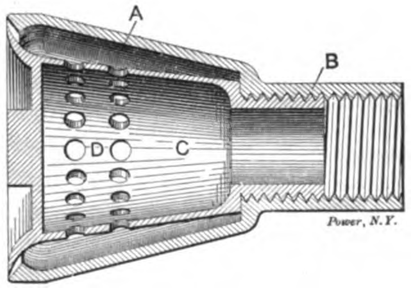

FIG 7.—SEMKE CLEANER HEAD

Fig. 7 is a sectional view of the head of a steam flue cleaner devised by Wm. Semke, Harrison, Kan. The engraving is practically self-explanatory. The steam passes from the inner chamber, C, through the holes, D, into the outer annular chamber, and thence through a restricted annular opening into the tube. The object of this arrangement is to compel the steam to sweep along the wall of the tube instead of passing through its center.

"BUCKING" OF RAILWAY GENERATORS.

BY E. C. PARHAM.

Dynamo tenders and others interested in the care and running of street railway generators, especially in small stations equipped with two or three generators only two of which are required in service most of the time, may have had occasion to notice that when the load is light the dynamos show an inclination to flash violently at the brushes, or as it is usually put, although the name is out of place, to "buck." This action does not take place when there is only one dynamo on the line; there must be at least two machines in parallel; nor is it as apt to take place when there are several dynamos in service, because one of the favorable conditions of the action is a light load, and it is not usual to run three or more machines to carry a very light load. The experience of most power-house men seems to indicate that dynamos do most of their "bucking" just at the time when the load is getting too light for the machines that are running. This is especially the case when two machines are running on a load that one machine can easily carry. Reference to Fig. 1 will help to show why this is so.

In the diagram A and A^1 are the armatures of two generators running in multiple on the outside load indicated by R. The fields of the two dynamos have been left out in order to simplify the diagram. As long as there are any cars running, the circuit, R, is closed and the two dynamos have a common path through which to deliver current. But when the load gets very light there will be a time now and then when the controllers on all of the cars will be at the "off" position at the same time, and the outside circuit will be open so that there will be no common path for the two dynamos to work through, or, what amounts to the same thing, there may be a ground or other fault on one of the cars so that the excessive current will blow a fuse or circuit-breaker situated at some point such as X, in the outside circuit. In either case the common path is broken and the two dynamos are left to fight it out in the local circuit, B, C, F, E. If the two machines have been thrown together properly so that both generate the same e.m.f. on open circuit, no trouble will follow when the line circuit is opened, because the two e.m.fs. being equal and opposed, no current can flow in the local circuit; but if at the time the line current is open the field strength of one machine is such that its armature can generate an open circuit 10 or 20 volts more than the other machine generates, the dynamo with the higher voltage sends a current backward through the armature of the lower voltage armature and runs it as a motor.

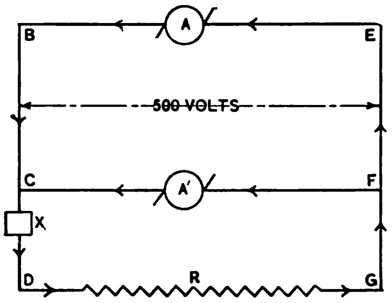

FIG. 1.—TWO GENERATOR ARMATURES IN PARALLEL.

If the machines are highly compounded the series field of the motored machine may be strong enough, if the difference in voltage between the two is great, to try to reverse the direction of rotation of its armature (since series dynamos run in the opposite direction as motors) in which case there will be a short-circuit which gets worse as the magnetizing effect ot the series windings on both machines gets stronger. If the two machines are shunt machines, the demonstration is apt to be less violent, because the shunt machine keeps on running in the same direction as a motor that it did as a dynamo. In either case, however, the brushes spark, and under certain conditions the disturbance is so great that the machine gives out a howl and the current jumps over to the frame of the dynamo or arcs from one brush-holder to the other. The brushes give trouble because they are set ahead to run sparklessly when the machine is a dynamo; as soon as the machine becomes a motor, the non-sparking point shifts, leaving the brushes to short-circuit coils that are in an active part of the field.

Lessons in Practical Electricity

ALTERNATING-CURRENT DIAGRAMS.

If a polarized current indicator could be made so free from inertia as to follow the rise and fall of an alternating current like the piston of a steam engine indicator follows the rise and fall of steam pressure, a pencil attached to its needle or pointer and arranged to move to and fro across a moving strip of paper would trace the "current wave" of the generator when the instrument was inserted in series with the circuit; connecting the instrument across the brushes would cause the pencil to trace the "e.m.f. wave" of the machine. For convenience in calculation, these curves are assumed to have the form of a sine curve, as shown by Fig. 1. In practice many machines do give a wave which approaches very closely to a true sine curve.

In Fig. 1 the spaces along the zero or datum lines may be considered intervals of time in fractions of a second. With a frequency of 100 cycles per second, it requires only 1/100 second for a complete cycle, which consists of one positive and one negative impulse, from zero back to zero. Considering the horizontal divisions as intervals of time, the vertical lines would indicate instants 1/1600 second apart, as indicated by the figures on the diagram. If there were no such thing as phase difference the curve diagram would fulfill all requirements, but when currents or electromotive forces, or both, rise from zero to maximum at different instants of time their mathematical relations cannot be so readily determined from curves as from a system of vectors.

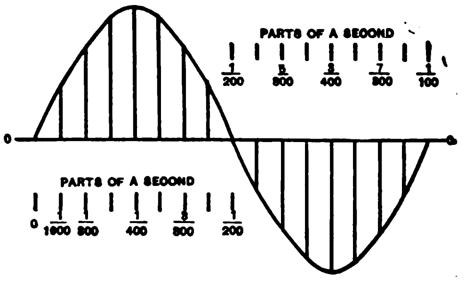

FIG. 1.—SINE CURVE THROUGH ONE CYCLE.

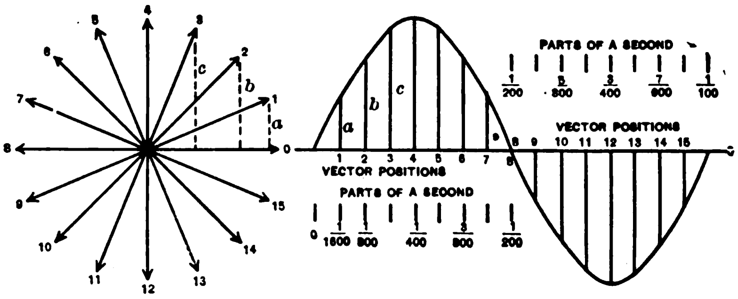

FIG. 2.—SHOWING RELATION BETWEEN E.M.F. VECTOR AND THE SINE CURVE

For convenience, therefore, a cycle, or complete reversal of current or e.m.f. as indicated by Fig. 1, is represented by the rotation of a "vector" about its origin, just as the hand of a clock rotates about the spindle, one revolution representing a cycle. The length of the vector is made to represent the maximum value of the e.m.f. or current, as the case may be, and the distance from the zero line to the outer end of the vector, measured vertically, represents the value of the e.m.f. or current at that part of the cycle indicated by the position of the vector. The latter is usually assumed to rotate left-handedly or counter-clockwise. Fig. 2 shows the relations between the position of the vector and the time intervals of the cycle. Sixteen positions are shown, for simplicity, but it will readily be understood that if the circle described by the vector be divided into 360 parts, as a circle is usually divided, the relation holds throughout, for each degree or fraction of a degree.

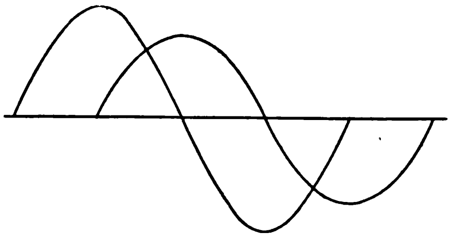

FIG. 3.—CURRENT LAGGING 90 DEGREES.

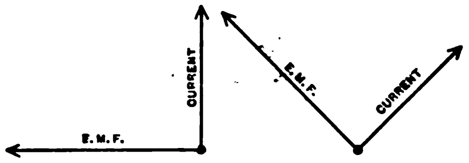
If the current in a line lags behind its e.m.f. to such an extent that it does not attain its maximum value until the e.m.f. has fallen back to zero and is about to reverse, as indicated by Fig. 3, it evidently lags one quarter of a cycle; that is, the e.m.f. passes through zero one-fourth of a cycle ahead of the reversal of the current. This condition is shown by two vectors having a common origin but being angularly displaced by a fourth of a circle, as shown by Fig. 4. The current is then said to lag 90° (one-fourth of a complete circle), or to be "out of phase" with the e.m.f. by 90°. In comparing phases the zero line is usually omitted, as the object of the diagram is to show merely the phase relations and not the instantaneous values. Consequently it does not matter whether the diagram be drawn as in Fig.

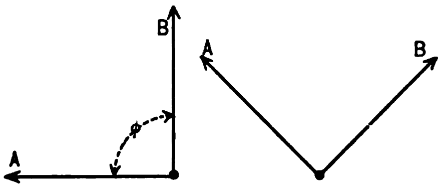


FIGS. 4 AND 5.—VECTORS CORRESPONDING TO FIG. 3.

4 or as in Fig. 5. The main point is the difference in phase.

Differences of phase between two or more e.m.fs. or currents are also represented by vectors. For example, a two-phase (or more accurately, quarter-phase) generator supplies two distinct electromotive forces which are of equal value but a quarter of a cycle apart in phase; that is, when one is at zero the other is at maximum. This relation is shown by two vectors of equal length 90° apart, as in Fig. 6. As in the previous case, it does not matter whether one is horizontal and the other vertical, as in Fig. 6, or whether each forms an angle of 45° with the vertical, as in Fig. 7, or what their position in space is; the point is that they are 90° *from each other.*

The chief convenience obtained by the use of vectors in alternating-current work is in computing the combined effect, or, to express it properly, the resultant, of two or more e.m.fs. or currents which differ in phase. For example, if the two e.m.fs. represented by the vectors, A and B, in Figs. 6 and 7, are connected in series, the resultant e.m.f. may be plotted by drawing two lines parallel with the two vectors, as indicated by the dotted lines in Fig. 8, and drawing in a diagonal across the square thus formed. The diagonal, C, represents both in length and phase relation the resultant of the two original e.m.fs., A and B. If these e.m.fs. are 100 volts each, the resultant, C, will be 141 volts, and it will be ⅛ cycle or 45° ahead of the e.m.f., B, and the same distance behind the e.m.f., A.



FIGS. 6 AND 7.—EQUAL E.M.FS. 90 DEGREES APART.

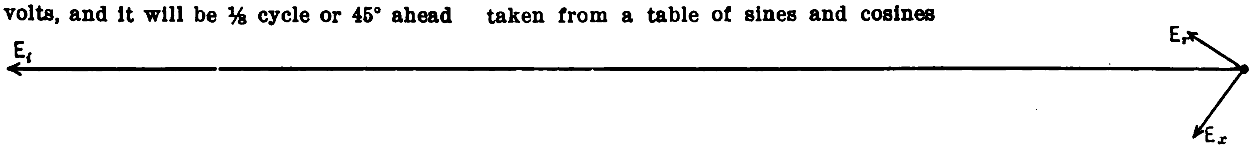


FIG. 12.—VECTOR REPRESENTATION OF THREE E.M FS. HAVING DIFFERENT VALUES AND DIFFERENT PHASES.

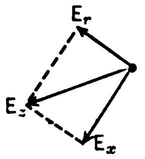

FIG. 13.

The formula for the resultant of two equal e.m.fs. differing in phase and connected in series manner is:

$$2 \times A \times \cos(\tfrac{1}{2}\phi),$$

ϕ being the phase angle between the two e.m.fs. This formula applies regardless of the phase difference, but is only applicable to two e.m.fs. of equal value.

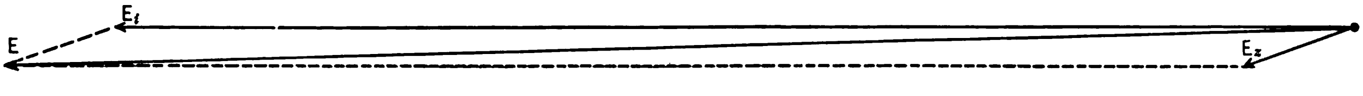

FIG. 14.—RESULTANT OF THE THREE E.M.FS. SHOWN BY FIG. 12.

When two e.m.fs. having different values are combined, as indicated by Figs. 9 and 10, if they are at right angles or 90° apart, the formula for the resultant is:

$$\sqrt{A^2+B^2}=C.$$

This is a case frequently met in practice in calculating the e.m.f. necessary to be applied to the terminals of an inductive load, such as an electro-magnet, on an alternating-current circuit. The vector, B, in the diagrams represents the e.m.f. required to overcome the resistance of the winding, and the vector, A, represents the e.m.f. required to overcome the reactance or inductive opposition, which is always 90° from the resistance e.m.f. The vector sum of these two is the e.m.f. required at the terminals of the coil. For example, the diagram is plotted to a scale of six volts for A and eight volts for B, and the vector sum of these two, instead of being 14 volts, which is the arithmetical sum, would be 10 volts. The scale of the diagram is one-eighth of an inch per volt, and a scale applied to the vector, C, will show that it is 10/8 long, corresponding exactly to the result of the formula.

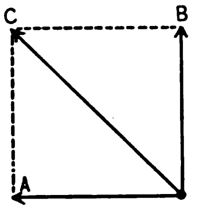

FIG. 8.—COMBINING EQUAL E.M.FS.

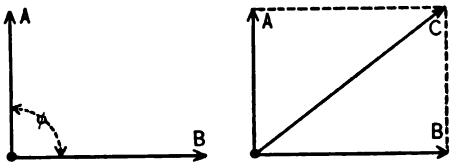

FIGS. 9 AND 10.—UNEQUAL E.M.FS. 90 DEGREES APART.

When the difference in phase between the two e.m.fs. or currents is other than 90°, and the two e.m.fs. or currents have also different values, as indicated in Fig. 11, the calculation is more complicated, the formula being:

$$\sqrt{A^2+B^2+2\,AB\cos\phi}=C,$$

in which ϕ is the angle between the two vectors, A and B, as indicated in the diagrams. The cosine of any angle may be taken from a table of sines and cosines such as the various engineering handbooks contain.

When three or more e.m.fs. of different phases are to be combined, two of them are first combined, then the result of these two is combined with the third, and so on, until all are combined. The commonest case of this kind is found in a transformer diagram. Fig. 12 is a part of such a diagram relating to the primary winding; the vector, E_r, represents the voltage required to overcome the resistance of the primary winding, and which is in phase with the primary current; E_x is the e.m.f. necessary to overcome reactance, which is 90° from the resistance drop, as already explained, and E_i is the e.m.f. required to overcome the counter e.m.f. of the transformer. The resultant of these three will be the e.m.f. required at the terminals of the transformer, as this must balance all of the internal e.m.fs.

The first operation is to combine E_r and E_x; the resultant of these two is E_z, as shown by Fig. 13, and this vector represents not only the strength but also the phase of the resultant e.m.f. Having resolved E_r and E_x into E_z, this must be combined with E_i, as shown in Fig. 14, giving the resultant E, which is the vector sum of E_r, E_x and E_i.

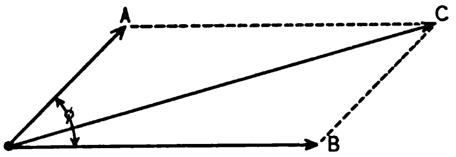

FIG. 11.—UNEQUAL E.M.FS. LESS THAN 90 DEGREES APART.

The reader will find it profitable to make a memorandum of the general rule that vector diagrams and calculations apply to e.m.fs. connected in series and currents combined in parallel; also, all of the currents and e.m.fs. treated in a given diagram or formula must have the same frequency.

Letters on Practical Subjects

Circuit Protection on the Three-Wire System.

To the Editor, American Electrician;

Sir:—The Washington Water Power Company at Spokane, Wash., has its power station near the center of the city and operates an Edison three-wire system for the business part of town. The greater part of the load is carried most of the time by a 750-kw. 300-volt generator connected to the outside of the three-wire mains, two smaller 150-volt generators also being run in order to take care of any unbalancing of the system. If a heavy short-circuit should occur on one side of the three-wire system with such a large generator running connected to the outside mains, the result would be disastrous, as the full 300 volts would be concentrated on one side, which is intended for only 150 volts. To prevent this mishap, John B. Fisken, superintendent of the power and light departments, has inserted in the neutral lead a circuit-closing coil which, upon the occurrence of a short-circuit on either side of the system, will close a local circuit through a magnet, which in turn will trip the main circuit-breaker of the 750-kw. machine.

C. R. James.

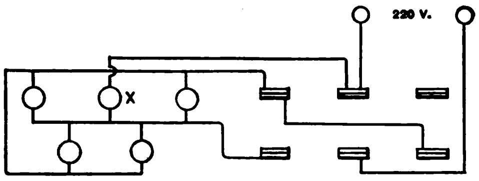
Spokane, Wash.

Another Answer to the Wiring Puzzle.

To the Editor, American Electrician;

Sir:—Regarding the wiring puzzle by Mr. Havens which was published in your December number, I offer the solution shown by the accompanying diagram, which fulfills all the conditions stated in Mr. Havens' letter. Arthur Barthels.

San Francisco, Cal.



WIRING PUZZLE SOLUTION.

[Mr. Barthels' letter and diagram were received several days before the January number containing the other solutions was issued, but were crowded out by lack of space.—Editor.]

Electric Bells on 110-Volt Circuits.

To the Editor, American Electrician;

Sir:—The methods of operating an electric bell from a lighting circuit which have been described recently in this department are very interesting and ingenious. The writer takes the liberty of suggesting, however, that the method shown in the enclosed sketch is rather more practical than the others. The advantages are that the push-button and the vibrator of the bell do not have to deal with a high-tension current, and that the lamp or lamps may be used for illuminating purposes instead of serving as idle resistance. Fig. 1 shows the arrangement for a 110-volt circuit; Fig. 2 shows a similar arrangement for a 220-volt circuit, and Fig. 3 the arrangement for a 500-volt circuit. In all three cases the resistance coil would consist of a few feet of 30 per cent German-silver wire of No. 20 gauge; 15 or 20 feet would be ample. The wire should be wrapped around a stick of porcelain so that it cannot sag and short-circuit its convolutions under the influence of the heat. If the distance from the bell to the point, A, in the diagram is shorter than the distance from the bell to the electric-light mains, then the return wire would be run as shown by the dotted line from A to the bell instead of from the bell to the lighting circuit.

Denver, Colo. Ed. S. Morgan.

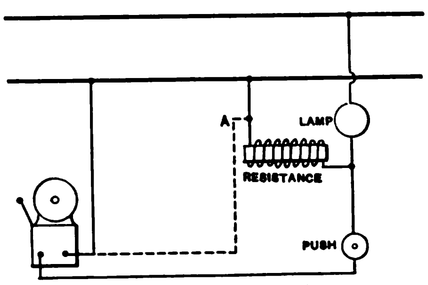


FIG. 1.—BELL ON 110-VOLT CIRCUIT.

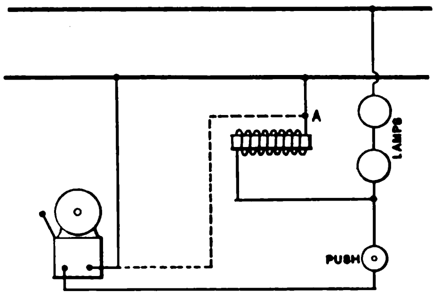

FIG. 2.—BELL ON 220-VOLT CIRCUIT.

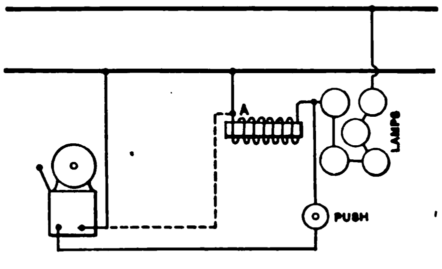

FIG. 3.—BELL ON 500-VOLT CIRCUIT.

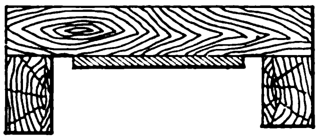
A Plain But Efficient Trolley.

To the Editor, American Electrician;

Sir:—Electric locomotives are used for hauling ore and fuel cars for charging furnaces around the Boston & Montana copper smelter at Great Falls, Mont. In fact, electric power is used throughout, as the company owns the water rights of the falls and built its smelter with that power in view. The locomotives are similar to mine locomotives and the trolley which has been evolved as most suitable for the place is interesting. Nothing exposed so that men would hit it with their iron rods, which they have around the furnaces, would do. The trolley conductor is now a flat copper strip in an inverted wooden trough, and the trolley is simply a flat piece on the end of the trolley pole. The curves are very short, but no attention is paid to the trolley. It stays in the trough and looks after itself. Fig. 1 shows the trolley trough.

Ed. B. Cheatham.



TROLLEY TROUGH.

Exhaust Steam Heating vs. Condensing.

To the Editor, American Electrician;

Sir:—In your January issue appears a note to the effect that the St. Joseph (Mo.) Railway, Light, Heat and Power Company has installed an exhaust steam-heating system for the purpose of serving certain buildings where they can get the contract for lighting and heating, but would be unable to get the contract for lighting alone. In this plant the engines are operated condensing in summer and non-condensing in winter when the exhaust steam is utilized for the heating service referred to. It is further stated that the income from this heating service is about equal to the additional cost of coal required when running non-condensing. The natural inference is that this method is a good one, and that if there is any considerable number of such buildings it would be a profitable investment to go into the heating business for the sake of securing the lighting business, if the income from the heating service will pay for the additional coal required when running non-condensing.

It appears to me that with coal balanced against income, the heating service must results in a very heavy loss, and not improbably a loss that will more than balance the profit on the lighting. In addition to the cost of coal, there is the interest on the investment in the heating mains, together with an allowance for depreciation and repairs. There must also properly be charged the interest and the cost of maintenance and operation for a larger steam plant than would otherwise be required. A compound condensing engine with an economical rating of 500 indicated horse-power and a maximum ability of about 750 indicated horse-power will have an economical rating of about 400 indicated horse-power and a corresponding maximum rating of about 550 indicated horse-power when running non-condensing. The mere fact, therefore, of running non-condensing seriously diminishes the normal capacity of the plant and, still more seriously, its overload capacity. If there is any back pressure due to the operation of the heating service, then the economical and overload capacity is still further diminished.

It follows from this diminution of capacity that if a plant is just able, running condensing, to carry its maximum load—which will usually be imposed during the season when the exhaust steam is most required for heating—its capacity must be increased by at least 25 per cent, and probably more, in order to carry this maximum load when running non-condensing and exhausting against a back pressure not exceeding two pounds by gauge. If, on the other hand, there is sufficient generating capacity to carry this maximum load when running non-condensing, it follows that by running condensing the electrical output can be increased 25 per cent or more, without the investment of a single dollar for generating apparatus. In any event, an excess of generating capacity must be provided if the plant is to be run non-condensing in winter, and that excess of capacity represents an investment on which interest must be paid the entire year, together with a charge for maintenance and repairs.

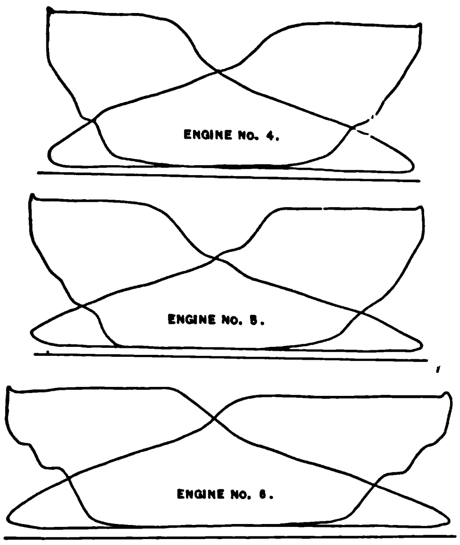
Consequently, in order to derive any profit from the plan under discussion the income from the heating service must cover not only the extra cost of coal required to run non-condensing but the interest on and maintenance of the heating plant, and either the interest and maintenance charges on the excess of generating plant required for the load or the loss of lighting income due to the reduction of the capacity of the generating plant.

New York. A. M. Earl.

Irregular Indicator Diagrams and a Transformer Trouble Remedied.

To the Editor, American Electrician;

Sir:—Referring to the diagrams submitted by L. S. C. in your November number, it seems to me that the wavy compression lines are caused by a sticky indicator movement. They might be caused by the chattering of the valve during compression if the valve was of the plain slide form, but this is not likely. The reason diagram No. 4 is shorter than No. 5 is because the reducing motion was not adjusted exactly the same for both engines. Something must have slipped in changing the outfit from one engine to the other.



IRREGULAR STEAM ENGINE INDICATOR DIAGRAMS.

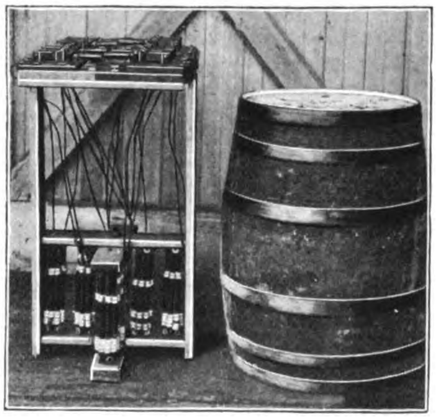
I am running an alternating-current station and was troubled for a long while by the heating of a small three-wire transformer that fed a twenty-four hour consumer. During the day it would run hot enough to boil eggs, but at night, when the full load was on, it would cool down. After burning out two transformers we began a hunt for the cause of the trouble. The lights were tapped off from the three-wire main on two-wire branches and we found that it just happened that nearly all of the lamps that were kept burning in the day-time were fed from the same side of the three-wire main. In the day-time, therefore, the load was almost all on one side and at night it was balanced. By swapping around the taps we divided up the day load as well as the night load and there hasn't been a sign of trouble since. Elmer K. Swift.

A Water Cooled Rheostat.

To the Editor, American Electrician;

Sir:—The writer has noticed in several issues of your paper various descriptions of water rheostats for absorbing large amounts of electric energy. In all of these the water (containing a salt to reduce its resistance) is used as a conductor. The main difficulty with this form is that the temperature of the water rapidly rises, reducing its resistance and keeping the current constantly fluctuating, so that it is difficult to secure accurate measurements. The water rheostat also requires constant attendance, if the current is kept at a fixed value, and is not adapted for operating continuously any length of time.

The writer, in testing some large power meters, met with the difficulties mentioned, and consequently designed a simple apparatus, which is believed to be in some respects an improvement over the form mentioned. It consists of bare German-silver wire 88 mils in diameter wound and secured in sections on a frame, as shown (the coils were originally resistance coils in old-style T.-H. constant-potential arc lamps), with the terminals brought up to double-pole switches on a board above the frame. The frame and coils are submerged in water in a common oil barrel. The water being in contact with the coils absorbs a considerable part of the electrical energy so that the temperature of the coils cannot rise much above 212° Fahr. With a constant e.m.f. the current will remain practically constant for a long period of time, and can be adjusted to desired values by cutting coils in or out and connecting them in multiple series. The immersed rheostat shown in the picture will absorb 150 kilowatts at 220 volts.



WATER COOLED RHEOSTAT.

Chester, Pa. Geo. N. Tidd.

Effect of Reversing a Field Coil on a Multipolar Generator.

To the Editor, American Electrician;

Sir:—The writer recently tried the experiment of running a direct-current six-pole generator with the connections of one of the shunt field coils reversed. The machine was a 125-volt dynamo and was run at a speed which would have given about 150 volts at the brushes under normal conditions. With all the resistance cut out of the field rheostat there was an e.m.f. of 50 volts at the brushes. The machine was run without any load for 10 or 15 minutes without any excessive heating being apparent. It might be that since the field was very weak the current in the armature reacted on the reversed pole in such a manner as to either kill the field there or reverse it. I have erected several machines of different kinds and have frequently found field coils reversed in this way, but have never before made a deliberate test to see what the difference in voltage would be.

Pittsburgh, Pa. B. Graham.

Electrical Catechism

562. *What is the difference between single-pole and double-pole cutouts?*

Cutouts are generally made double-pole —that is, so that there is a fuse on each side of the circuit to give protection against heavy currents whether caused by a "short-circuit" on the line itself, or caused by two ground connections in different parts of the circuit. In the case of large currents at high potentials, it is common to use two single-pole cutouts, in order to maintain a safe distance between the two sides of the circuit. Three-wire systems require a fuse in each of the three wires at each branch.

563. *What is a fuse panel?*

In wiring buildings it is common to use the "cabinet system," in which the various circuits radiate from one or more centers. The fuses and sometimes many of the switches are grouped in the distribution boxes or cabinets. When fuse blocks are used, it is customary to use asbestos lined boxes for the cabinets. In the better class of work, the switch and fuse terminals are mounted upon a marble or slate base, thus reducing the number of connections and making a neater job.

564. *What kind of fuses are used on telephone and similar lines?*

The ordinary currents used on such lines are so small that foreign currents of less than one ampere may cause much damage. The fuses must therefore be very sensitive, so that ordinary electric light fuses are of little or no use. A form frequently used is a small piece of fuse wire mounted on a strip of mica with copper terminals. Another form has a small wire tied in a knot so that its weight will break the fuse if it gets too hot. The McBerty "thermal arrester," illustrated by Fig. 1, is used by the Bell companies; it contains a rubber cylinder, B, in which are a number of turns of fine high-resistance wire

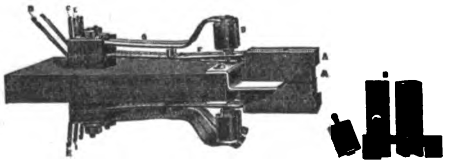


FIG. 1.—McBERTY THERMAL ARRESTER.

in which a stray current will generate so much heat as to melt the special solder and allow a spring, G, to push the central pin against a small spring, F, which connects the line with the earth. A is a lightning arrester with a plug of fusible metal which melts and grounds the circuit if a large current comes in and jumps to the ground across the gap in the mica. The line is connected at D and the exchange or instrument at E, the central iron support being grounded. The cut shows four heat coils for both sides of two circuits.

565. *What sort of fuses do the independent telephone companies use?*

They use a great variety of fuses. One of the best is the form shown by Fig. 2, in which some high resistance wire is doubled up inside a plug of wax in which also is fastened a loop of cord. A grasshopper spring pulls against the cord which is held in place by the wax plug. An excess current will soften the wax and let the plug slip through the ring, when the spring flies out and breaks the fine wire. In an earlier form, the spring tripped a second spring which threw the whole fuse and supporting strip from the holder.

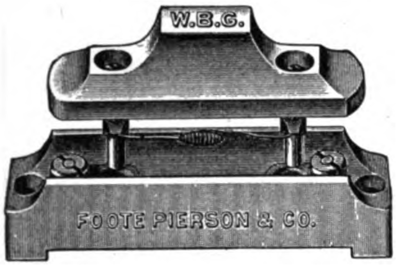

FIG. 2—TELEPHONE FUSE.

566. *Are fuse wires adaptable for fire alarms?*

Fusible metal has been applied in several ways to the extinguishing of fires by opening sprinklers when the temperature exceeds a definite degree. The same idea has been applied in the "Montauk" cable for giving an alarm under similar circumstances. The cable consists of a number of conductors, the inner one of which is surrounded by an alloy that fuses at about 370 degrees Fahrenheit. If the cable is exposed to a high temperature, such as might be caused by an incipient fire, the fusible alloy melts and completes the circuit between the central wire and those near it, thus sending in an alarm through an electric bell or similar device.

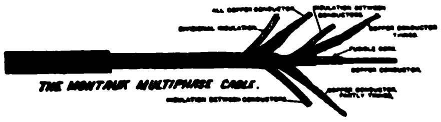

FIG. 3—FUSIBLE CABLE.

567. *For what useful purposes is the heating effect of the current employed?*

The heating effect is used in safety devices such as the fuses noted above (see Q. 550 to 566). Moderate degrees of temperature are used in heaters of various sorts, such as stoves, heating pads, tea kettles, coffee pots, ovens, smoothing irons, curling iron heaters, soldering coppers, solder or babbitt melting pots, glue pots, branding irons, stamp cancellers, surgeons' cauteries and the like. Higher temperatures are used in the tempering of steel, in blasting fuses, in incandescent lamps, arc lamps, electric welding and forging and in various electro-metallurgical processes. Applications of the heating effect of the current are developing continually. The heating effect of the current is used to a small extent in electrical measurements. Heat is developed incidentally in connection with rheostats for regulating or absorbing electrical energy.

568. *What is a blasting fuse?*

A blasting fuse is illustrated by Fig. 4 in which a small platinum wire, E, may be heated by a current and so ignite an explosive mixture, B, which will ignite a still larger charge outside the fuse. Current enters and leaves through the wires, C, which are long enough to extend beyond the surface of the hole. As many as forty of these fuses may be connected in series and fired simultaneously. Current is usually furnished by a small magneto dynamo similar to but more powerful than those used for ringing telephone bells.

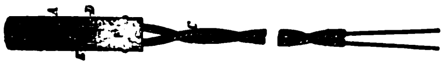

FIG. 4.—BLASTING FUSE.

569. *What is a rheostat?*

A rheostat is a conductor arranged to dissipate electrical energy into heat. It may be used simply to regulate the resistance of the circuit of which it is a part, it may be to regulate the current by changing the resistance of a circuit, it may be to dissipate energy as in a test, it may be to develop desirable heat from electricity. Usually the rheostat is so arranged that its resistance may be changed at will.

570. *For what purposes are rheostats used?*

Rheostats are connected into the field magnet currents of dynamos to regulate the electromotive force of the dynamo; they are used in series with motors to make them start slowly; they are sometimes used in the field circuits of motors to regulate the speed; they are sometimes used to absorb the power of a dynamo while being tested for capacity and efficiency; they are used to regulate the current in a great variety of apparatus supplied from circuits of constant potential. Rheostats are sometimes used to vary the difference of potential between the terminals of apparatus on constant potential circuits.

571. *Of what material are the conductors in rheostats composed?*

Metallic wire is most common, although carbon and graphite are used sometimes; and it is not unusual to employ water made conducting by the addition of salt or acid. Iron is cheap and will stand a high temperature. Copper has high conductivity and is convenient where large currents at low voltage must be controlled. German silver has high resistance and low temperature coefficient, and is used where the resistance must be kept constant.

572. *How are the conductors supported in rheostats?*

Where the energy is small, as in telegraph systems and in standard resistances in wheatstone bridges and similar laboratory apparatus, the wire may be wound in coils directly upon wooden spools. Where there is liable to be considerable heat, the conductors must be supported on noncombustible material, as is required by the insurance rules covering the use of electricity for lighting and power purposes. The conductors may dissipate their heat into the open air directly or through another surrounding medium such as enamel, which carries the heat to cast-iron base plates. The conductors may be wound on slate slabs; on a framework of iron rods insulated with asbestos, or on insulated metallic spools with layers of asbestos between the layers of wire; the wire may be wound into coils which are stretched between insulators on a frame of iron or of insulating material. When the rheostat is to be used for only a short time, the wire is sometimes wound on spools, as such method allows a large amount of wire in small space, and the capacity of such a rheostat depends more on its capacity for taking up heat than on radiation and convection. When spiral coils are employed, provision is made for free circulation of air. Sometimes asbestos tubes are placed inside coils of small wire for the purpose of keeping them still, while the convolutions are close together. In some cases the resistance wire in small rheostats is wound on flat "cards" of mica or fuller board, which are then bent and packed closely together.

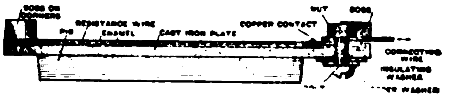

FIG. 5.—SECTION OF RHEOSTAT.

573. *How is the resistance of a rheostat varied?*

The conductors are generally all in series and connections are made at various points with contact blocks upon which a moving arm sweeps so as to include more or less of the resistance, as suggested in the figure. Sometimes the resistance is reduced while the carrying capacity is increased by putting more or less resistance units in multiple, as when a bank of incandescent lamps is used for regulating a current.

Queries and Answers

IMPORTANT.—No attention will be given to inquiries which do not give the full name and address of the inquirer.

What causes some arc lamps to burn with a violet color while other lamps on the same circuit give a yellowish-white arc?
R. L. T.

The difference in the adjustment of the arc. A lamp with a long arc will give a bluish light. In order to get rid of the bluish tinge the arc must be shortened.

Can an electric call bell be connected on a railway circuit of 550 volts, tapping from a group of five incandescent lamps in series?
W. H. B.

The call bell circuit cannot be tapped directly from the series of incandescent lamps. A small resistance of about five ohms should be inserted in series with the five lamps and the call bell circuit connected in shunt to this resistance.

Is there any way by which direct current of 100 volts and 30 amperes can be transformed to 600 amperes and 5 volts without the use of a motor-generator? I wish to make the change for convenience in testing meters.
L. C. S.

The only other way is to use a storage battery of 50 small cells, grouping them all in series for charging and grouping them in multiple-series for discharging. This, however, is vastly more inconvenient and considerably more expensive than to use a motor-generator.

How can I tell the number of kilowatts delivered to a circuit by means of a Thomson recording wattmeter?
G. M. D.

Allow the meter to run ten minutes, then take its net reading, which will be the energy delivered in watt-hours during the ten-minute run. Multiply this reading by 6 and you will have the average number of watts delivered to the circuit; dividing this by 1000, of course, gives you the kilowatts.

Will a ½-h.p. kerosene engine be large enough to drive a small dynamo giving 8 amperes at 45 volts? (2). Is a kerosene engine noiseless, so that it could be used in a house?
A. C. R.

Probably; although it would be safer to put in a ¾-h.p. or 1-h.p. engine. (2). No engine is entirely noiseless. If you are so situated that you can carry your exhaust pipe out into a back yard so as to get the noise of the exhaust out of the house the other noises will probably not be objectionable.

Can storage batteries be charged from a series-wound dynamo; if not, why not?
F. J. P.

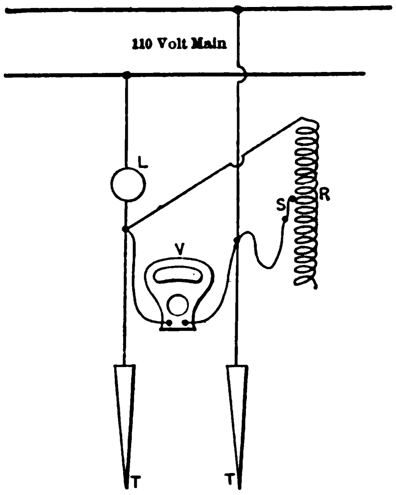
It is not practicable to charge a storage battery from a series-wound dynamo for the reason that as the counter e.m.f. of the storage battery works up it opposes the e.m.f. of the dynamo and reduces the current flowing through it. This weakens the field of the dynamo and reduces its e.m.f., causing a further reduction of the current flow. The operation is cumulative and the ultimate result will be that the battery will discharge through the dynamo. It is possible to counteract this tendency by constantly watching the circuit and strengthening the field of the dynamo as the storage battery increases its counter e.m.f., but this is not a practical method.

I am working in a storage-battery room and find that my clothes are damaged by acid fumes; how can this be prevented?
J. L. S.

The acid spray (not fumes) from a storage battery cannot be prevented from eating cotton goods, but it will not attack woolen; the only remedy, therefore, is to wear woolen clothes throughout.

How is a voltmeter connected up for testing an armature?
H. S. R.

There are several methods of testing for defects in armature windings, one of the commonest of which is shown by the accompanying diagram, in which "T, T" are the testing tips or contacts; "L" is a 110-volt incandescent lamp; "R" is a comparatively small resistance divided into a large number of steps; "S" is an adjustable contact for cutting in and out sections of the resistance coil, and "V" is a low-reading voltmeter. The sliding contact, S, is adjusted along the resistance coil until the voltmeter needle is deflected to the extreme end of the scale when the tips, T, T, are not in contact with anything. The tips, T, T, are applied to commutator segments. In testing for open-circuited coils the plugs, T, T, are applied to successive pairs of segments all around the commutator; one pair will finally be reached which will show a larger deflection at the voltmeter than any of the others; the open coil is the one connected to these two segments. To test for a short circuit coil the tips are applied to the commutator segments in adjacent pairs, as above, until the pair is found which gives the least deflection of the voltmeter needle; the damaged coil will be connected to this pair of segments.



A Westinghouse street-railway motor, after having the armature rewound, ran backward, necessitating the reversal of the armature leads. The coils were wound exactly like the original coils and put on the core in the same way. What was the cause of the trouble?
J. C. F.

Your coils were connected backward to the commutator. That is to say, calling the terminals of the coils right-hand and left-hand, the left-hand terminal was connected to the commutator segment to which the right-hand terminal should have been connected, and *vice versa*.

A direct-current multipolar motor running on a 500-volt circuit blows holes between the commutator segments always at the outer end of the commutator; it has done this with two different commutators. Can you suggest the cause of the trouble and the reason why the holes always appear at the outer end of the commutator?
L. H.

Your trouble is probably due to dampness or else to oil spray on the end of the commutator near the journal; in either case the trouble would appear at the outer end of the commutator because this end is more accessible to both dampness and oil spray than any other portion of the commutator.

I have two small Edison dynamos supplying a three-wire system. Is it practicable to increase the output of the plant by adding a 220-volt dynamo connected to the outer wires of the system, balancing the load by means of two small machines? (2). The two small machines are shunt wound; should they be compounded the same as the large machine, or should the large machine be shunt wound to correspond with the small ones?
W. W. F.

Yes. (2). All of the machines should be shunt wound, as an equalizer cannot be applied between them.

Why does a resistance coil used for reducing voltage waste energy? (2). Is the insulation of a circuit containing thirty 50-volt arc lamps subjected to 1500 volts? (3). Why does a voltmeter made for use on an incandescent circuit fail to indicate when connected to the terminals of an arc lamp in a series circuit?
F. E. O.

Because energy is required to force current through any resistance. If this energy were not absorbed the voltage would not be cut down by a resistance coil on a direct-current circuit. The electrical energy absorbed by the coil is wasted because it is not converted into useful work. (2). Yes. (3). Because it is either damaged or connected up backward. Try reversing the connections between the voltmeter and the arc lamp.

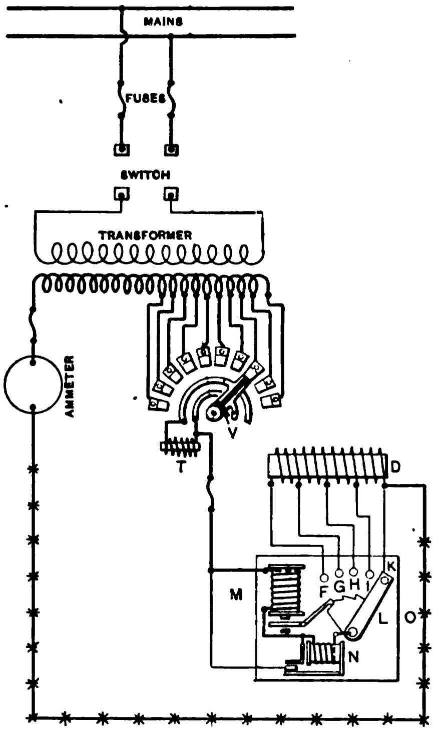
How can I find the number of lines of force passing from the pole piece of a motor to the armature core?
C. C.

Count the number of wires around the circumference of the armature; multiply this number by the revolutions per second of the motor; divide the e.m.f. at the brushes by the product of wires and revolutions, and multiply the result by 100,000,000. The final result will be approximately the number of lines of force, but this will not be accurate because the drop in volts in the armature and brushes has not been taken into account. If you know what the resistance of the armature circuit is from brush to brush multiply this by the current passing through the armature and deduct the result from the e.m.f. at the brushes. This will give you the counter e.m.f. of the motor or the internal e.m.f. of the dynamo, as the case may be; multiplying this by 100,000,000 and dividing the result by the product of the armature wires and revolutions per second will give you the number of lines of force accurately.

A SYSTEM OF REGULATION FOR SERIES ALTERNATING-CURRENT ARC LAMPS.

The rapid adoption of the alternating-current enclosed-arc lamp for operation in series groups from constant-potential primary circuits has resulted in the production of a goodly number of regulating systems, the basic feature of which is a regulator for maintaining constant current through the series of lamps. One of the latest of these systems is that of the Western Electric Company, which is shown diagrammatically by the accompanying illustration. The diagram shows a constant-potential transformer with a tapped secondary winding, the taps being led to contact blocks of a radial switch, the arm of which is indicated by V. This arm is of somewhat peculiar construction, carrying two contact fingers, the ends of which travel over the contact blocks. These two fingers are constantly in connection by means of brushes with the two circular segments shown, to which are connected the terminals of a choke coil, T. The secondary winding of the transformer, of course, is in series with the lamp circuit, and the function of the dial switch just referred to is to vary the e.m.f. of the circuit in accordance with the number of lamps burning. The object of the choke coil, T, is to prevent short-circuiting two adjacent contact blocks of the dial switch as the arm moves from one block to the next.

The arrangement shown in the lower part of the diagram is a combined starting and safety device which is also connected in series with the lamp circuit. It consists of a reactive coil, D, from the winding of which taps are led to the contacts, F, G, H, I and K, of a dial switch, the arm, L, of which is under the influence of a coil spring tending to throw it over to the left, beyond the contact buttons, and thus open the circuit. The lever is held in any position to which it may be moved by means of the ratchet segment and pawl shown in the diagram. The pawl is held in engagement with the ratchet by the magnet, M, so long as current is flowing through the circuit. Should the circuit open or the current supply be discontinued, the armature of the magnet, M, will be drawn downward by a spring, not shown, releasing the lever, L, and allowing its spring to throw it over to the left and open the circuit. The magnet, N, is a release magnet for excessive current flow, its armature being arranged to short-circuit the winding of the magnet, M, when the current exceeds a predetermined value.



SERIES REGULATOR DIAGRAM.

In the operation of the system the circuit is started up as follows: The arm, V, of the upper dial switch is thrown over to the extreme left-hand contact block, so that when the circuit is closed it will be supplied with the minimum secondary e.m.f. of the transformer. The lever, L, of the lower dial switch is then moved to the first contact button, F, and the main switch, shown in the diagram above the transformer, is closed. The lever, L, is then moved gradually to the right, cutting out successively the sections of the reactive coil, D, until it reaches the position shown in the diagram, where the whole coil is cut out; this ordinarily gives the lamps sufficient current to heat the carbons preparatory to the establishment of the arcs. The lever, V, of the main regulating switch is then manipulated so as to deliver the proper e.m.f. to the circuit to maintain the desired current flow.

◆

TESTS OF SINGLE-PHASE MOTORS.

The accompanying curves were plotted from tests of Wagner single-phase motors made under the direction of Prof. W. S. Aldrich, of the University of Illinois. In both cases are given power factor, efficiency, current and speed test results. In Fig. 1 the curves are carried to full load only, while in Fig. 2 the test was carried to about 25 per cent above the rated capacity of the motors.

While these curves show a maximum output of about 25 per cent in excess of the rated output of the motors tested, it should be noted that the makers provide them with a loop terminal, by the use of which a part of the field or primary turns can be cut out of circuit, thus increasing the output about 25 per cent at normal voltage, enabling the motors to take care of temporary loads up to 150 per cent of their rated capacity when operated on this loop. In some tests for power factor and efficiency of a 5-h.p. 60-cycle motor, made at different voltages, the output was almost directly proportional to the square of the impressed voltage within the limits of the tests, and even at the larger outputs, the power factor and efficiency dropped off only a little.

The above and similar test results which have been reported are serving to remove much of the skepticism which many conservative central station men have entertained relative to the commercial practicability of single-phase alternating current motors, and a very general use of motors of this type seems likely to develop rapidly in those fields where a single-phase motor is either necessary or desirable by reason of its simplicity of installation. The Wagner motor does not depend upon the rotary field principle for its starting torque. It has but a single field-winding, which suffices through the medium of the starting construction employed to start the motor under full load, or even more if desired.

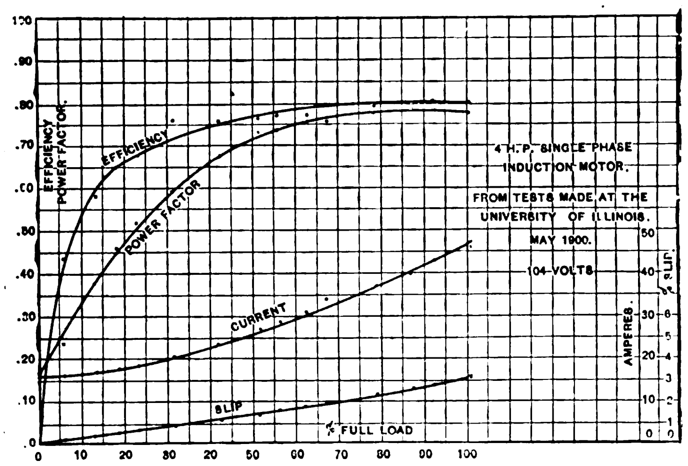


FIG. 1.—CURVES FROM TEST OF 4-H.P. MOTOR.

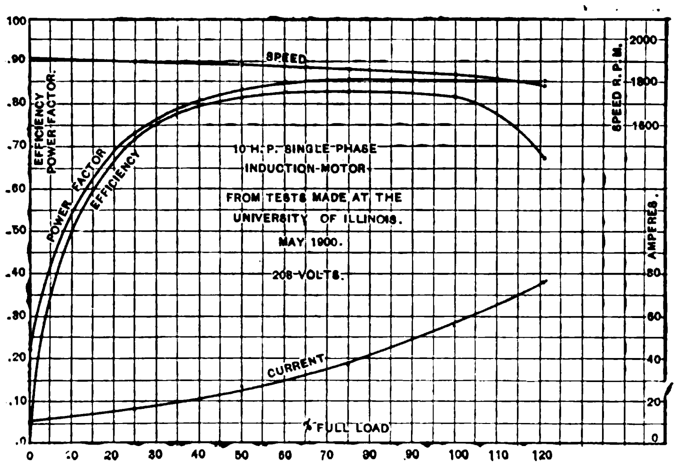

FIG. 2.—CURVES FROM TEST OF 10-H.P. MOTOR.

New Apparatus and Appliances

DIRECT-ACTING PRESSURE PUMP.

Fig. 1 illustrates the latest compound direct-acting pressure pump built by the Stilwell-Bierce & Smith-Vaile Company, of Dayton, Ohio. The pump is one of the largest of its type built, and is designed for a working pressure of 600 lbs. to the square inch. It is intended for mine station work. The valves are of a special bronze and type, seating on steel seats and situated in separate chambers. The water plungers are also of bronze and are of the trombone type, end-packed, reciprocating through deep and accessible glands. The water end is made of a special steel, and is provided with an extension piece having an adjustable shoe for the guidance and support of the plungers. It is mounted on heavy cast-iron feet. The steam end is of the cross-head type, lagged in polished steel, and fitted with Corliss valves. The valve adjustment is on the outside, and the rock-shaft stand which supports the valve gear is so placed as not to interfere with the inspection of the working parts, and also to be free from vibration.

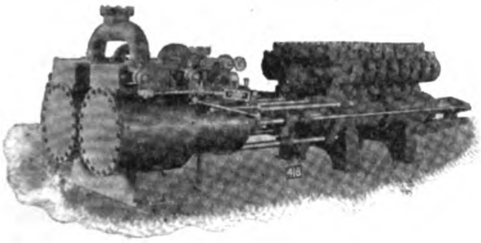

FIG. 1.—DIRECT-ACTING PRESSURE PUMP.

SARGENT GAS ENGINE OILER

The Michigan Lubricator Company, Detroit, Mich., has brought out the oiler illustrated by Fig. 2, and which was designed especially for lubricating the cylinders of gas or oil engines, and also vacuum pumps and air compressors in which the pressure during the induction stroke is slightly below atmospheric pressure. The essential features are a glass reservoir, which is filled through a hole in the top normally covered by the slide A; a needle valve which is adjusted by means of the handle, B, and which controls the feed into the air-tight sight chamber; a ball check valve, D, held to its seat by a spring, the compression of which is adjusted by the nut C. While this is essentially a cylinder oiler, by removing the compression from the spring it may be used in place of the ordinary sight-feed oiler on any other part of the engine. When this oiler is used for admitting oil to the cylinder of a gas engine or air compressor, the check-valve spring is so adjusted that the valve seats when the air pressure above and below the check is the same; but if the air pressure below the check valve is slightly reduced, the check will open and allow the oil in the sight chamber to pass into the cylinder; and the atmospheric pressure on the oil in the reservoir will force the oil down through the needle valve to the sight chamber, from which it will pass into the cylinder every time the check valve opens. When the engine stops, the check valve remains seated and the oil stops feeding through the needle valve, because oil cannot drop into the sight chamber if the air and oil already in there are not drawn out. When compression begins in the cylinder, the check valve shuts and no smoke or pressure from the explosion passes into either the sight chamber or reservoir.

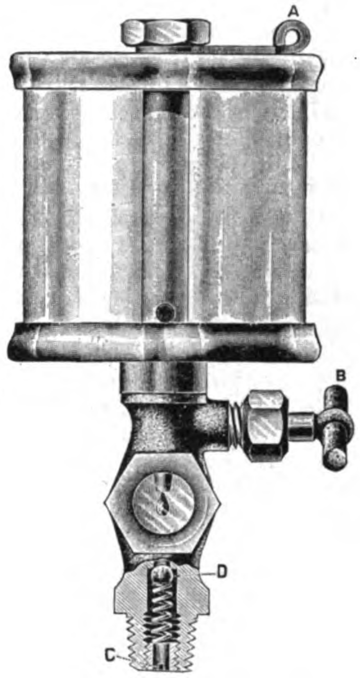

FIG. 2.—GAS ENGINE OILER.

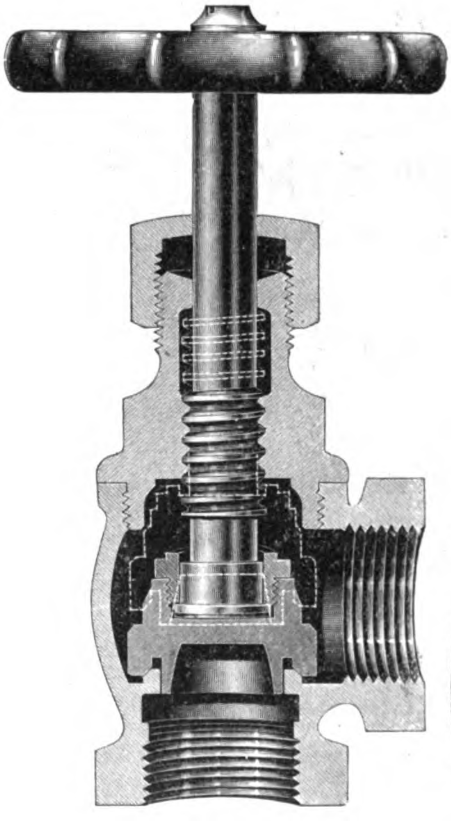

FIG. 3.—BLOW-OFF VALVE

BLOW OFF VALVE AND LOW WATER ALARM.

In order to overcome the trouble generally experienced with the ordinary valves and cocks used at the blow-off, the Crane Company, of Chicago, has designed the blow-off valve illustrated by Fig. 3. It will be observed that the valve seat is situated on the outside, thereby obviating the possibility of sediment lodging at this point. It will also be noticed that there is a projection on the under part of the disc. This projection is added in order to prevent any discharge from taking place until the seats have become widely separated; it also prevents wire drawing. The valves are made in four sizes and in either angle or globe patterns. They should always be connected so that the pressure tends to seat the disc.

The Crane Company has improved its low-water alarm so that it may be readily tested by the inspectors of workshops and factories. A hole is tapped in the top of the boiler to take the bushing, A, Fig. 4. A short piece of pipe is screwed inside of the bushing, and reaches to within 2 ins. of the top of the boiler tubes. The tee, E, is connected by a pipe to the steam space in the boiler. So long as the water does not fall below the low-water line, the water in the pipe, B, prevents the steam from reaching the fusible plug; but when the water does fall below the low-water line steam rushes into the fusible plug chamber, C, fuses the plug and escapes through the hole in the wheel, raising lever, D, which opens the valve in the whistle, F, thereby permitting steam in the pipe, E, to give the alarm. Fusible gaskets are furnished with these alarms, and may be inserted by closing the valve, G, and unscrewing the nut, C. When the

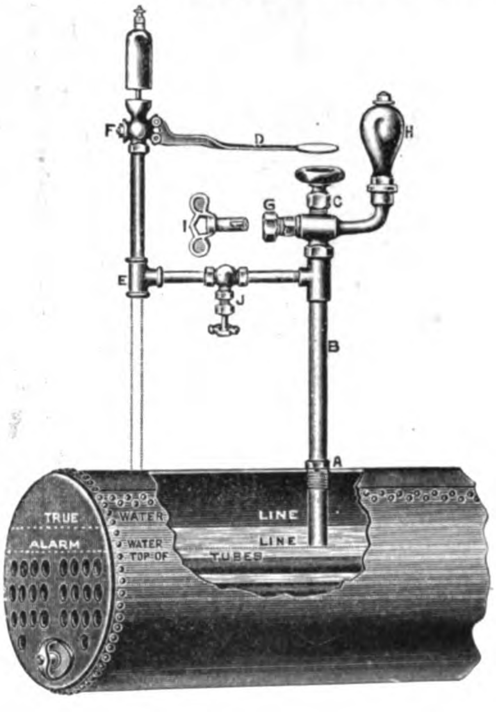

FIG. 4.—LOW WATER ALARM.

parts have been replaced the removal of the key, I, indicates that the valve is open and ready for operation. In testing, the valve, J, is the only one that should be opened. This permits the live steam to pass into B, melt the gasket and give the alarm.

A NEW ENCLOSED ARC LAMP.

Fig. 5 represents the mechanism of a new arc lamp which the National Arc Lamp Company, Lorain, Ohio, is introducing, and which, it is claimed, differs widely from any other type heretofore employed. It is constructed on what is termed the divided coil principle. Around a core of laminated iron is wound a coil in two sections, the larger portion being stationary and the smaller part movable parallel with the core axis. The mutual action of the magnetic fields of the two coils causes the smaller coil to move with reference to the larger one. With this mechanism it is said to be unnecessary to employ an additional choking coil for alternating circuits. It is claimed that this lamp gives as much light on 4½ amperes as is usually obtained from 6 to 7-ampere lamps, and that 100 of the lamps can be operated with the same transformer capacity that is usually allotted for 75 lamps. Another advantage put forward is that the inductive load is greatly reduced. The standard lamp for alternating circuits consumes 4½ amperes at 85 to 90 volts, this being the drop across the arc when the lamp is burning on a 104-volt circuit. The lamp has a power factor of .87. The same type of mechanism is used for direct-current circuits. For 500-volt circuits two 2½-ampere lamps are connected in series and, it is said, will operate successfully on a fluctuating potential within the range of 350 to 650 volts. These lamps are said to be independent of voltage fluctuations on alternating current as well as on direct. The following distinctive claims are made: First, it has no moving iron; second, it has no springs; third, no choke coil is necessary for alternating circuits; fourth, its coils are bolted to the frame, and, fifth, it has a cast aluminum case and hinged outer globe.

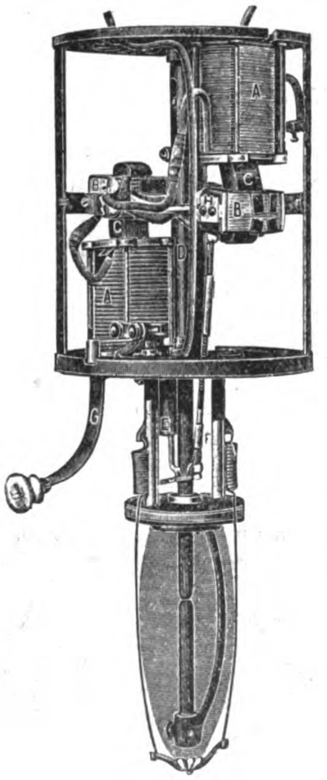

FIG. 5.—ENCLOSED ARC LAMP.

PORTABLE TESTING INSTRUMENTS.

An attractive line of portable testing instruments which should appeal to engineers whose work involves the use of this class of instruments is being manufactured by Elmer G. Willyoung, of New York. Two of these instruments are represented by Figs. 6 and 7 herewith. Fig. 7 is the "P. T." D'Arsonval galvanometer, which is claimed to be the most sensitive galvanometer of this type made in actually portable form. The moving system is mounted between jewels and is dead-beat. The scale is about 2 ins. long and calibrated in 50 divisions. With an e.m.f. of one volt the pointer will show a deflection of one divison when the instrument is working through a resistance from 1 to 1½ megohms. The instrument is provided with three shunts, the connections of which are controlled by the small dial switch shown on the cover of the box. These shunts have ratios of ½, 1/3 and 1/5; four buttons are provided for the switch lever, so that the instrument may be used without any shunt at all or with either one of the three. This galvanometer is also supplied in a box with a battery of test cells, the number of cells being anywhere from 5 to 50, according to the requirements of the user. In this shape the outfit is evidently suitable for insulation tests by the direct reflection method.

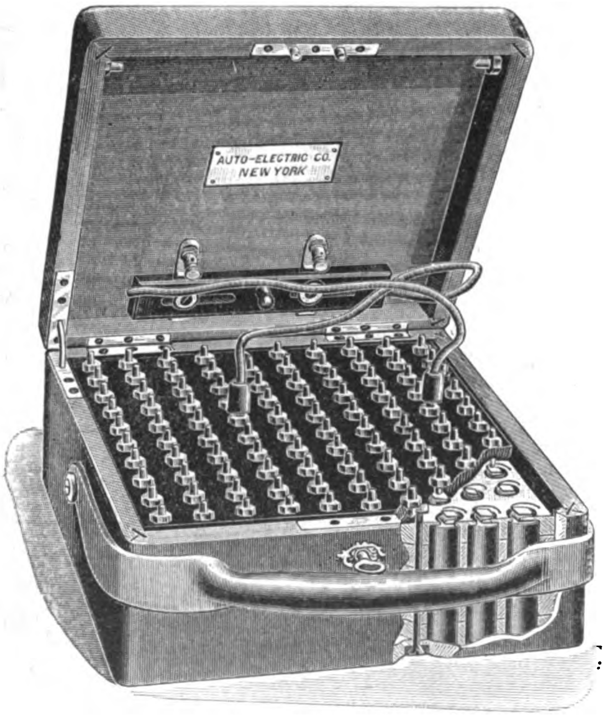

FIG. 6.—"CLOVER LEAF" TEST BATTERY.

Fig. 6 represents the "Clover-Leaf" test battery in the 100-cell size. The individual cell is put up in a drawn (not crimped or soldered) zinc shell ¾ in. in diameter by 2¼ ins. long; this shell constitutes the negative terminal of the cell. The positive electrode is carbon. The e.m.f. of each cell is almost exactly 1.4 volts and this e.m.f. is said to be uniform with all the cells and to remain constant throughout the entire life of the cell. It is stated that there is substantially no deterioration on open circuits, so that the life of a cell is only limited to its service. There is, it is stated, no generation of gases either on open or closed circuit, and therefore no bursting of the cells and possible flooding of delicate instruments with liquid chemicals. Each cell slips into a hole of the proper size in a "built-up" block of light wood. The carbon terminal is a spring brass plate brought out above, and the zinc terminal is a small wire which is carried over to the plate of the neighboring carbon. The external connections are made by means of flexible cords and the usual studs; these are all mounted in a hard rubber plate from which they project below. A suitable number of rods pass through bushings in the bottom of the carrying case and through the built-up block, and are screwed into the under side of the hard rubber plate. By means of these rods the rubber plate is drawn down upon the cell block so as to bring each stud in contact with its own cell plate. Each set is provided with a reversing switch in which the insulation surface is unusually long. The binding posts are all of the double grip pattern, clamping the wire either between flat surfaces or in a hole. Two studs in the lid take the flexible cords when the battery is not in use, thus obviating the unpleasant dangling of cords common with many test batteries.

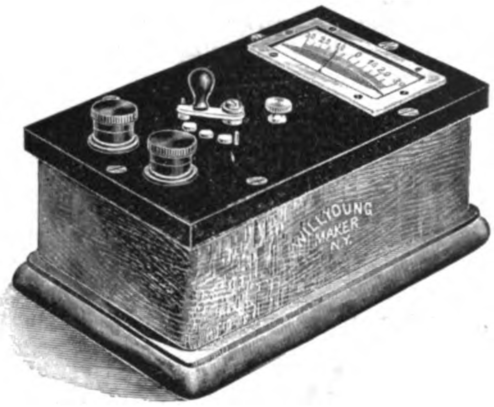

FIG. 7.—"P. T." D'ARSONVAL GALVANOMETER.

GASOLINE TORCH WITH HANDLE AND PUMP COMBINED.

The Clayton & Lambert Manufacturing Company, of Detroit, Mich., has added to its line of gasoline torches a new form known as No. 16, which is illustrated by Fig. 8. The torch is of the standard quart size. The tank is made of heavy drawn brass, fitted with a burner which is said to produce a fine blue flame. The burners are fitted with improved double-shouldered needle points which add to their durability. The pump of the torch is placed within the handle, as may be seen from the illustration. The makers furnish full description with the torch, and a little booklet, valuable to users of gasoline fires.

STEAM HOT BLAST APPARATUS.

A hot blast apparatus which includes an electrically-driven fan and is built by the B. F. Sturtevant Company, of Boston, Mass., is illustrated by Fig. 9. A heater, made up of a series of cast-iron bases into which are screwed steam pipes, is encased in a fireproof steel plate housing. The heads of the sections are bolted together, and either live or exhaust steam is admitted to the common chamber thus formed. A current of air having a high velocity passes over these heated pipes and is distributed throughout the building. In the illustration the fan is also encased in a steel plate housing, drawing air through the heater and having a top horizontal discharge. It is a radial-bladed wheel carried upon an extension of the motor shaft. A special line of electric fans is designed by the company which may be driven independently or in connection with the heating apparatus. The motor in the illustration is of the standard eight-pole type built by the company. According to the conditions and the temperature of the entering air, and of the steam pressure and number of pipes across which the air is drawn, hot air is delivered at a temperature varying from a few degrees above that of the atmosphere to 200° Fahr. The apparatus may also be made to serve as a cooling device in hot weather.

FIG. 9—STEAM HEATED HOT BLAST APPARATUS WITH ELECTRIC FAN.

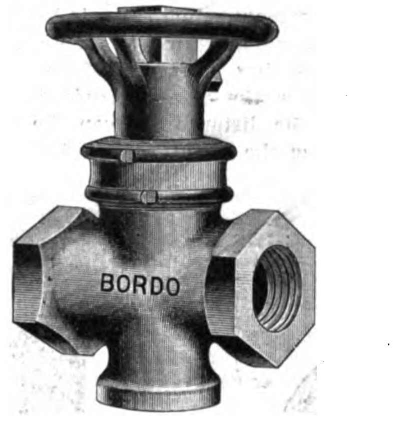

FIG. 10.—BORDO PLUG VALVE.

THE BORDO PLUG VALVE.

The accompanying illustrations show the Bordo plug valve, manufactured by the Bordo Valve Company, of Philadelphia. Its construction can be readily seen from Fig. 11. The plug, which is accurately turned, fits snugly into a tapering seat in the body of the valve. Bearing upon an adjustable bonnet, and fastened with a set screw, is a wheel which is screwed to the stem of the plug. Should this not give sufficient leverage, the stem is furnished with a square head for the application of a wrench. The friction caused by turning the valve is taken up by two brass rings placed around the stem; the upper one, or gland as it is called, being stationary, while the lower one is free to revolve with the gasket. Any wear on the plug may be taken up by simply adjusting the bonnet. The valve is made either flanged or screwed, and in all sizes. Fig. 10 shows an exterior view.

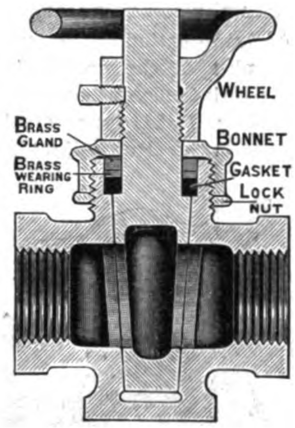

FIG. 11.—SECTION OF BORDO VALVE.

A NEW TIME SWITCH.

Fig. 12 depicts a time switch just placed on the market by J. Jones & Son, of New York, in which the mechanism is entirely mechanical, the current traversing the switch only. In the upper left-hand corner is an eight-day clock movement having two dials, one above the other, the under one of which is calibrated so that every 15° represents an hour. A pin on the front dial engages the front lever which releases a clutch, allowing the switch axle to turn through an angle of 90° and close the circuit. A similar arrangement on the back dial engages the back lever which releases a second clutch, allowing the switch blades to rotate 90° more, and open the circuit. As both dials revolve at the same rate of time all that is necessary to do to set the switch is to place the pin on the front dial so many hours in advance of the pin on the

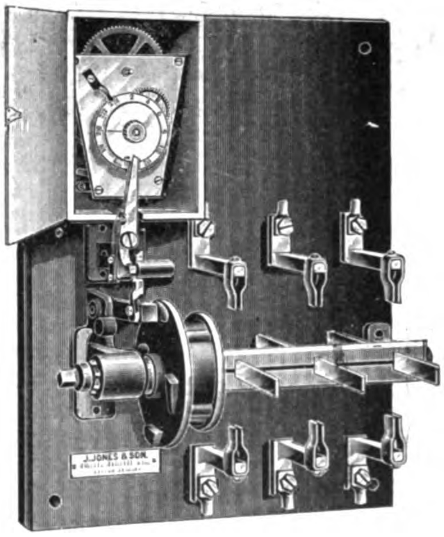

FIG. 12.—TIME SWITCH.

second dial as one wishes to keep the circuit closed. The cylinder to the left of the switch contains a strong spring, which is wound by a key and which furnishes the power to rotate the switch axle. The switch will operate on as heavy a current as 200 amperes.

CREST MOTOR TRICYCLE.

Since the introduction of the automobile quite a number of the progressive electric-light superintendents have recognized the importance of this type of vehicle in connection with the electric-light and electric-railroad industry for the purpose of patrolling overhead circuits, and also for making quick repairs in case of accident. The gasoline motor tricycle illustrated by Fig. 13 is a most convenient machine for this purpose, as it is started instantly by a few turns of the pedal, and a high rate of speed can be maintained. Any speed up to twenty or thirty miles an hour, it is claimed, can be maintained for any distance. The tricycle can be rigged so as to carry a ladder, if necessary, and also coils of wire, or tools for repairs. This machine is built by the Crest Manufacturing Company, Cambridgeport, Mass. It is equipped with an air-cooled 3-h.p. Crest motor, hung on the rear of the frame; the rear axle is provided with differential gear, preventing the grinding of one tire when turning a curve.

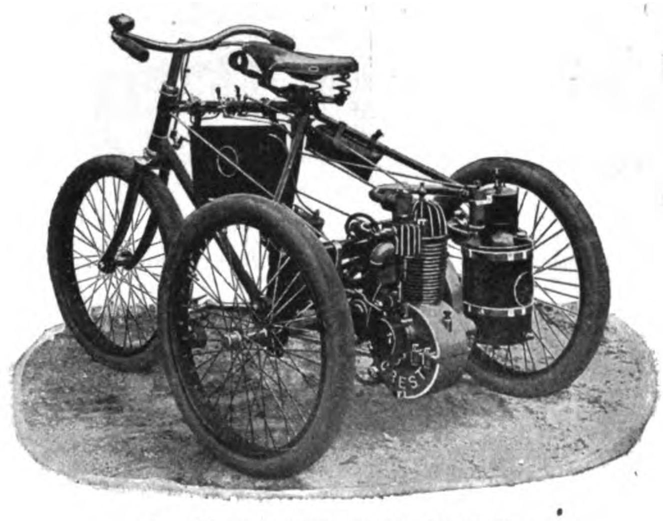

FIG. 13.—GASOLINE MOTOR TRICYCLE.

A NEW MAIN-LINE TELEGRAPH SOUNDER.

Fig. 14 represents a new main-line telegraph outfit comprising a high-resistance sounder and the regular form of steel lever key mounted on a single base which is being manufactured by Foote, Pierson & Co., of New York. The feature of the sounder is the means provided for adjusting the distance between the magnet poles and the armature. A close inspection of the illustration will show that the armature is screwed to a short brass strip which is separate from the sounder lever proper. This strip is pivoted at its rear end to the sounder lever, and the thumb-screw shown immediately back of the armature screw enables the operator to adjust the armature back and forth without altering the adjustment of the sounder lever. The convenience of this arrangement will be obvious to any telegraph operator, although it may not be so to others. Once having adjusted the play of the sounder lever to give the desired loudness of click it is unnecessary to change this adjustment in order to adjust the armature toward and away from the magnet cores; whereas, with the ordinary sounder any adjustment of the armature vitiates the adjustment of the lever play, rendering two adjustments necessary to accomplish a single purpose. With the sounder here shown only one thumb-screw has to be manipulated in order to adjust the distance between the magnet pole and the armature. The sounder coils are wound to 150 ohms resistance so as to work on main-line circuits without an intermediate relay.

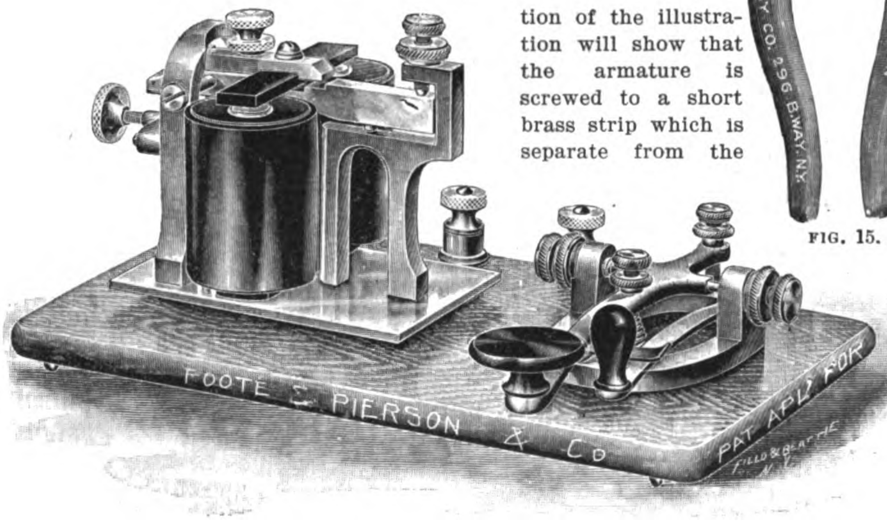

FIG. 14.—MAIN LINE TELEGRAPH SOUNDER.

INSULATED PLIERS.

The Smith & Hemenway Company, of New York, has brought out the insulated pliers illustrated by Fig. 15. The handles are covered with removable rubber shields, and all edges are rounded so that the pliers may be carried in the pocket without injury to the clothes. The advantage of this feature will be entirely obvious to anyone who has carried an ordinary pair of pliers. The tool is of the standard side-cutting type, made of the finest grade of Swedish tool steel.

LEGAL NOTES.

EICKEMEYER ARMATURE WINDING.—The suit of the General Electric Company against the Webster & Dudley Street Railway in the United States Circuit Court of Massachusetts to determine the validity of the Eickemeyer patent No. 377,996, covering the well-known Eickemeyer armature winding, has been decided in favor of the General Electric Company, the Court holding that claim 4 of the Eickemeyer patent was infringed by the defendant's armature construction. This claim reads: "In a dynamo-electric armature winding composed of detachable counterpart coils, each of which is placed in immediate contact with the periphery of the armature core at one side only, substantially as described."

RICE BRUSH-HOLDER.—The United States Circuit Court of New Jersey has rendered a decision sustaining patent No. 394,999, dated December 25, 1888, and issued to E. W. Rice, Jr., covering a brush-holder for carbon brushes, consisting of the usual box, a pivoted finger arranged to force the brush toward the commutator under the influence of a main spring and an intermediate auxiliary spring between the follower and the brush. The suit was brought against the Walker Company, and a perpetual injunction was issued restraining the company from the manufacture and sale of brush-holders of the construction indicated.

OBITUARY.

PROF. ELISHA GRAY.—The electrical fraternity was greatly shocked on January 21 to hear of the sudden death on the preceding night of Prof. Elisha Gray, the well-known electrical inventor. Prof. Gray's death, due to heart failure, occurred at Newtonville, Mass., whither he had gone for the purpose of perfecting a system of submarine signaling. He was born in Barnesville, Ohio, August 2, 1835, and became a carpenter's apprentice in his teens. At the age of 21 he entered Oberlin College, where he paid his expenses by doing carpenter work. Young Gray took the degrees of A. M. at Oberlin College and Ph. D. at Ripon College. His first invention of importance was a self-adjusting telegraph relay, which, however, never came into extended use because the self-adjusting feature was not sufficiently needed to justify its expense. The first invention to become commercially successful was a printing telegraph. He next produced the harmonic telegraph system, which indirectly led to his invention of the telephone. It is generally understood that Prof. Gray filed a caveat, which purported to describe a speaking telephone, on February 14, 1876, and that later on the same day Alex. Graham Bell filed his application for a patent. It is contended by Prof. Gray's friends that the priority which the Patent Office conceded to Prof. Bell's patent application over Prof. Gray's caveat application was due to the fact that Bell's application came in later than the caveat and was therefore taken off the filing hook for entry ahead of the latter; being entered first, it was given priority over Prof. Gray's application for caveat. Of Prof. Gray's inventions, the one which probably attracted the most attention was the telautograph, which was first publicly exhibited at the World's Fair in Chicago in 1893. During the past year or so Prof. Gray had devoted his time principally to the development of a system of submarine signaling, the object of which was to provide for the detection of sounds produced under water several miles away. This system was intended for the transmission of definite signals and also as a means for determining the proximity of submarine vessels. Mr. Gray was for a number of years connected with the Western Electric Manufacturing Company, which is now the Western Electric Company, and during this period he did considerable valuable work on instruments of a minor character, such as annunciators, magneto call boxes, etc. Prof. Gray leaves a widow, two daughters, and two sons to mourn his sudden demise.

PERSONALS.

MR. W. C. KERR, of Westinghouse, Church, Kerr & Co., has returned from a business trip to England.

MR. FRANK J. SPRAGUE has returned from an enjoyable trip abroad. Mr. Sprague was one of the speakers at a recent meeting of the British Institute of Electrical Engineers.

MR. BANCROFT GHERARDI, previously of the engineering staff of the New York Telephone Company, has been appointed chief engineer for the New York and New Jersey Telephone Company.

MR. G. W. HUBLEY, superintendent of the Louisville Electric Light Company, Louisville, Ky., has been appointed representative in Kentucky and Indiana for the Consolidated Telpherage Company.

MR. HOWARD L. DAVIS, recently of the testing department of the General Electric Company at Schenectady, has been appointed superintendent of the Hudson River Gas & Electric Company at Tarrytown, N. Y.

MR. H. P. BROUGHTON, who was for many years engaged in consulting engineering in St. Louis, and is well known throughout the west and southwest, has joined the staff of the Central Electric Company, Chicago.

MR. ROGER W. CONANT, for several years electrical engineer to the Boston Elevated Railway Company, has resigned that position to accept the managership of the New York office of the Gold Car Heating Company.

MR. P. V. VANDEVELDE, Corona, N. Y., who has for some time been interested in electrical matters, recently obtained a patent on an ingenious form of electric burglar-alarm which is considered by many to be superior to previous forms of alarms.

MR. GEO. F. LEMON has resigned the position of superintendent of motive power and electrical engineer of the South Covington & Cincinnati Street Railway Company. Mr. Lemon's plans for the future are not yet completely formulated.

MR. MAXWELL A. KILBERT, of the firm of Wendell & McDuffie, New York, has gone on an extended trip to Mexico for the purpose of closing some important contracts for material and apparatus for projected electric railways. Mr. Kilbert will be absent about three months.

MR. S. FISCHER MILLER, formerly with Milliken Brothers, manufacturers of structural iron, has been appointed manager of the contracting office of the American Bridge Company, vice Mr. Seymour N. Robinson, resigned, with headquarters in the St. Paul Building, New York City.

MR. HUGH H. HARRISON, formerly connected with J. G. White & Co., has joined Messrs. F. Battles and G. G. Heye in forming the firm of Battles, Heye & Harrison. The new firm will deal in municipal bonds and high-grade unlisted securities. Offices will be maintained in New York and Philadelphia.

MR. W. R. MASON, recently manager in St. Louis for the Siemens & Halske Company of America, has been appointed district manager for the Northern Electrical Manufacturing Company and the Stanley Electric Manufacturing Company, with headquarters at 1010 Laclede Building, St. Louis.

MR. ALEX. WYNESS, JR., superintendent of the Geneseeo Gas Light Company, Geneseeo, N. Y., has been elected secretary of the company. Mr. Wyness' election to this office is a well-merited recognition of valuable services which he has rendered the company in other directions besides the mere superintendence of plant operation.

MR. CHAS. H. SCHUM, who has been for the past four years associated with F. A. LaRoche & Co., resigned his position there to accept a similar one with the Bergmann Elektromotoren und Dynamo Werke, of Berlin, Germany. Mr. Schum is a graduate of Cornell University and has had valuable experience in dynamo and switchboard design. He sailed from New York for Germany on January 3.

OSTERBERG & SUTTON. — This well-known firm of consulting engineers dissolved partnership on January 1. Mr. Max Osterberg, formerly the senior member of the firm, will continue to devote his energies to consulting engineering and expert work, and Mr. Frank Sutton will also do electrical engineering work and prepare specifications for heating and ventilating plants, sprinkling, and fire protection systems.

MR. THOS. H. BIBBER and CHAS. E. BIBBER have severed their connection with the Bibber-White Company, of Boston, and will engage in business for themselves. Mr. Thos. Bibber has established an office at 37 Arch Street and will represent various manufacturers under the firm name of Thos. H. Bibber & Co. Mr. Chas. Bibber will engage in contract work in both the electrical light and railway branches; his office is also at 37 Arch Street.

MR. GEO. O. PROCTOR, of the Anchor Electric Company, Boston, who has been for two years the mayor of Somerville, Mass., was tendered a banquet at Young's Hotel, Boston, upon retiring from office recently. Very flattering references to Mr. Proctor's administration were made by those present, his conduct of the city's affairs being characterized as highly efficient, this efficiency being due to the sound business sagacity which has enabled him to make such a success of his private interests.

MR. SEYMOUR N. ROBINSON has resigned his position as New York manager for the American Bridge Company and become interested in a new organization known as the Berlin Construction Company, incorporated for the purpose of designing and erecting steel buildings, bridges, and doing general structural work. Mr. Robinson is treasurer of the new company and the other gentlemen associated with him in the organization were identified for many years with the management of the Berlin Iron Bridge Company before its absorption by the American Bridge Company.

TRADE PUBLICATIONS.

ELECTRO-MAGNETS.—The Varley Duplex Magnet Company, Jersey City, N. J.—A well-illustrated catalogue and price-list of Varley magnets, induction coils, gas-lighting spark coils and gas-engine igniters.

NOISELESS PINIONS.—The New Process Raw Hide Company, Syracuse, N. Y.—A vest-pocket folder setting forth the advantages of rawhide pinions, which are said to be noiseless, durable, cleanly and economical.

CALENDAR.—The American Electrical & Maintenance Company, New York.—A very ornate calendar gotten up in imitation of embossed bronze and bearing a handsome picture dating back in style to continental days.

SILICA GRAPHITE PAINT.—Joseph Dixon Crucible Company, Jersey City, N. J.—A folder pointing out the advantages of protective paint for steel smokestacks, boiler fronts and other metal surfaces subjected to unusual heat.

CALENDAR NOTE-BOOK.—John A. Roebling's Sons Company, New York.—A very convenient soft-leather backing accompanied by 12 sets of leaves, one set for each month of the year, adapted to be inserted in the leather backing.

CALENDAR.—Chas. Weslow, Harrison, N. J.—A small hanging calendar with a monthly-leaf date pad, and an illustration showing three forms of worn-out incandescent lamps, the object being to call attention to Mr. Weslow's business of renewing broken and defective lamps.

CALENDAR. — Chase-Shawmut Company, Boston.—A hanging calendar with the usual form of calendar block divided into monthly leaves and containing also a half-tone engraving showing the various types and sizes of fuse links, enclosed fuses, and electromagnets made by the Chase-Shawmut Company.

CALENDAR.—The H. C. Roberts Electric Supply Company, Philadelphia.—This is the usual monthly blotter calendar of the series which the Roberts Company is sending out. The blotter has on one end a picture of a handsome woman holding a cornucopia, and on the other end an illustration of an incandescent lamp.

STORAGE BATTERIES IN A RESIDENCE PLANT.—The Electric Storage Battery Company, Philadelphia.—This is circular No. 63, containing an illustrated description of an isolated electric lighting plant in a private residence, which includes an outfit of Chloride accumulators having a capacity of 1200 ampere-hours.

SELF-OILING ENGINES.—The Ball Engine Company, Erie, Pa.—A handsome catalogue of standard size illustrating and describing the Ball Engine Company's latest type of self-oiling horizontal engine in simple, tandem-compound, and cross-compound forms. The catalogue is of unusual interest to engine users and should find a place in every catalogue file.

EMERSON FAN MOTORS.—The Emerson Electric Manufacturing Company, St. Louis, Mo.—An extremely handsome catalogue containing illustrations, descriptions and price-lists of the Emerson line of alternating-current fan motors for 1901. The engravings are of the highest grade of half-tone work and the general execution of the book is a model of typographical excellence.

SERIES ALTERNATING-CURRENT ENCLOSED-ARC SYSTEM.—Western Electric Company.—This is Bulletin No. 7009, containing a description of the Western Electric Company's new system of control for series arc-lighting circuits supplied from constant - potential alternating - current mains. The book is fully illustrated with pictures of the apparatus and diagrams showing the various arrangements of circuits.

DYNAMOS AND MOTORS.—Bartz, Evans & Wygant, Hornellsville, N. Y.—Bulletins No. 1, 2, 3 and 4, in which are described the bipolar and multipolar dynamos and motors built by this firm. Bulletin No. 1 describes belt-driven multipolar generators; Bulletin No. 2 describes the same type of motors and includes the starting box; Bulletin No. 3 describes the firm's bipolar dynamos, which are built in sizes ranging from ½ to 2½ kilowatts; and Bulletin No. 4 describes the same type of motor.

SKEPTICISM.—Electric Appliance Company.—An attractive little pamphlet having for its object the dispelling of any skepticism which may exist regarding the performance of the Gutmann wattmeter, and containing a complete explanation of the construction of this meter and the principle on which it operates. The meter is of the induction type, and the Electric Appliance Company, which is selling agent for the meter, offers to send an instrument on trial to any responsible meter buyer.

I. T. E. CIRCUIT-BREAKERS.—The Cutter Company, Philadelphia.—This is an interesting publication prefaced by an explanation of the functions of a circuit-breaker and explaining the meaning of the symbols "I. T. E." which form part of the name of the company's instrument. The catalogue is divided into six sections printed on different colored papers. Part A describes circuit-breakers built to open the circuit under the influence of an overload; Part B describes instruments for opening circuits when the current supply has been shut off elsewhere; Part C describes and illustrates circuit-breakers for storage battery service to open the circuit when the charging e.m.f. falls below that of the battery; Part D relates to combined overload and no-voltage circuit-breakers; Part E describes circuit-breakers for storage battery use arranged to open by either overload or low voltage; and Part F is devoted to the "laminated edgewise" type of circuit-breaker for railway service.

BUSINESS NEWS.

WESTERN ELECTRIC COMPANY, Chicago, has received an order for two direct-current generators of 100 kilowatts each and one of 50-kw. output for the isolated plant in Willard's Hotel, Washington, D. C.

HENRY H. HUMPHREY, of St. Louis, Mo., has removed his engineering offices from the Century Building to suite 1305, Chemical Building, where he will have better facilities for taking care of his rapidly increasing consulting work.

THE HOMER COMMUTATOR COMPANY, Cleveland, Ohio, has moved into its new factory at the corner of Mason and Wilson Streets, which is fully equipped for the production of high-grade commutators and the re-filling of commutator shells.

CATALOGUES WANTED. McKenna Bros. Brass Company, of Pittsburgh, having arranged to establish a switchboard department, as previously announced in these columns, wishes catalogues and discount sheets from manufacturers of switchboard material and appliances.

O. C. WHITE COMPANY, Worcester, Mass., has added to its well-known line of incandescent lamp fixtures a new line of high-grade fixtures designed especially for office, bank and library use. It is the company's aim to turn out a complete assortment of adjustable fixtures for all classes of service.

THE C & C ELECTRIC COMPANY, New York, reports that it is now busier than ever before during its entire history. New orders are pouring in, not only from all parts of this country, but from abroad. For over a year the company's works at Garwood have been running every night with a constantly increasing force, and the large force now employed is pressed to its utmost ability to take care of orders.

AMERICAN ELECTRIC COMPANY, Detroit, Mich., has been dissolved, Mr. W. J. Hartwig, the senior partner in the old concern, having purchased the entire business. Mr. Hartwig will continue the manufacture of the Anthony boring tool, as well as the electrical supply business previously carried on by the American Electric Company. The business will be continued at the old address, 256 Randolph Street.

THE WARREN COMPANY, Chicago, Ill., is rejoicing over the continued receipt of extremely complimentary letters regarding its liquid pulley cover. One user writes to say that the Warren pulley cover is one of the best things ever invented, and that it has saved that consumer at least $150 in belting alone, and enabled it to carry the holiday load on belts that ordinarily would barely carry the regular load.

ABENDROTH & ROOT MANUFACTURING COMPANY, of New York, at its annual meeting, held recently, elected the following officers: Linus G. Read, president; H. C. Kelley, vice-president; F. W. P. Brunig, secretary and treasurer. This completes the reorganization instituted a year ago, and carries with it an association both of thorough factory and engineering equipment and gives the company a sales department which is fully abreast of twentieth-century methods.

THE FILER & STOWELL COMPANY, Wilwaukee, Wis., builder of high-grade steam engines, recently shipped the largest cross-compound engine ever built at its works. The cylinders of the engine were 40 and 76 ins. in diameter respectively by 60 ins. stroke, and the complete engine weighed about 800,000 lbs. The company recently booked an order for a still larger cross-compound engine which will have cylinders 44 and 82 ins. in diameter by 60 ins. stroke.

SPRAGUE ELECTRIC COMPANY, in order to facilitate the handling of its constantly increasing business in the south, has opened a branch office in the Guardian Trust Building, Baltimore, in charge of Mr. W. H. A. Davidson, who was previously connected with the New York office. The establishment of the Baltimore office will enable the company to keep in closer touch with the large amount of government work constantly being done, as well as to handle more conveniently the growing southern business.

THE HOPPES MANUFACTURING COMPANY, Springfield, Ohio, calls attention to the fact that the Brooklyn Electric Illuminating Company's plant, which was described in the January number, is equipped with three Hoppes feed-water purifiers of 1000-h.p. capacity each, which fact was not pointed out in the article. The Hoppes Company also states that the Brooklyn Company "made the mistake of not putting in Hoppes purifiers at the start, but has added them since." The failure to mention the purifiers in the article referred to was, of course, an oversight on the part of the writer of the article.

RICHMONDT ELECTRIC WIRE CONDUIT COMPANY, Milwaukee, Wis., desires to call the attention of conduit users to the fact that the Richmondt galvanized conduit pipe besides being reamed and enameled on the interior is supplied with clean threads which are fully galvanized. In the case of ordinary galvanized pipe the threads are cut after the tubing has been galvanized, which is said to leave each joint unprotected against rust. The company also states that the Richmondt conduit is the only one which can be permanently and thoroughly grounded. The fact that the threads are protected from rust insures a continuous and permanent electrical connection between adjoining lengths of pipe.

TEST OF LE VALLEY VITAE CARBON BRUSHES.—An important test of carbon brushes on railway motors was made some time ago by the Quebec Railway Light & Power Company, which resulted as below:

	Ordinary Brushes.	Le Valley Brushes.
Wear on commutator per 1000 miles	.054	.01
Life of commutator, miles	82,600	278,800
Rel. efficiency on com.	29%	100%
Wear on brushes, 1000 miles	.22	.06
Life of brush, miles	3,680	13,900
Rel. efficiency of brushes	28%	100%

The "Life of Commutator" was limited to a wear of 1½ ins. off the diameter, and "Life of Brush" means the number of miles necessary to wear the brush away ¾ in. Three grades of ordinary carbon brushes were included in the test; the figures given above are the averages shown by these three. The Quebec company stated that during the test the ordinary brushes cut the commutators badly under heavy currents, while the Le Valley Vitae brushes did not cut at all.

CROUSE-HINDS ELECTRIC COMPANY, Syracuse, N. Y., is constantly receiving strong testimonials as to the merit of its switches and switchboard work. Among a recent batch of letters was an extremely

A COMMUTATOR NECESSITY.

For Sale by all Supply Houses.

complimentary one from the Elmira Municipal Improvement Company, Elmira, N. Y., in which the statements were made that the work put out by the Crouse-Hinds Company was of the very highest class possible, that the care and attention which the company showed to every detail was highly appreciated, and that there was not a single instance in which the slightest error was made in following out the Elmira Company's specifications, which is saying a good deal, as that company has had a great deal of work done during the past year.

ALBANUS L. SMITH & CO., Philadelphia, proprietors of the United Flexible Metallic Tubing Company, Ltd., call attention to the fact that the flexible metallic tubing manufactured at their works forms a reliable and indestructible substitute for rubber hose, being capable of carrying steam at all pressures, as well as oils, gas, compressed air, and other fluids. The tubing is said to be absolutely unaffected by either heat or cold and to remain flexible at all temperatures. It does not kink or crush, and consequently the cross-sectional area is always the same. Owing to recent improvements in the manufacture of this tubing it is now possible to supply it in almost every size up to 8 ins. in diameter. Special grades of the flexible tubing are made for extremely high pressures up to 2000 lbs. per square inch.

Northwestern Convention Notes.

THE CHICAGO MICA COMPANY, of Valparaiso, Ind., was represented by Mr. Charles W. Cobb.

MR. CHARLES E. COLEMAN, Chicago manager of Munsell & Company, New York, attended the Convention.

MR. GEORGE S. WHYTE took good care of the friends of the Macomber & Whyte Rope Company, of Chicago, Ill.

THE AMERICAN ELECTRICAL WORKS, of Providence, R. I., was represented by its Western manager, Mr. F. E. Donohoe.

JULIUS ANDRAE & SONS COMPANY, of Milwaukee, Wis., had an exhibit of telephones and other electrical specialties.

THE NATIONAL CARBON COMPANY, of Cleveland, sent its Chicago representative, Mr. Richard O'Connor, to the Convention.

JAMES McCREA & CO., of Chicago, manufacturers of steam joint clamps and boring tools, were ably represented by Mr. M. B. Skinner.

MR. J. G. POMEROY, Western representative of the Adams-Bagnall Electric Company, of Cleveland, Ohio, was a visitor at the Convention.

MR. M. B. KITT, representing the John A. Roebling's Sons Company, of Trenton, N. J., looked after the friends of this company in the West.

MR. JAMES W. HARKINS hospitably entertained the friends of the Dearborn Drug & Chemical Company of Chicago in room 81 of the Pfister.

THE AMERICAN STEEL & WIRE COMPANY, Chicago, sent the manager of its electrical department, Mr. E. J. Pietzeker, to the Convention.

MR. CHARLES F. HART, Western representative of the Skinner Engine Company, of Erie, Pa., attended the Convention in the interests of his company.

THE NORTHERN ELECTRICAL MANUFACTURING COMPANY, of Madison, Wis., had its interests looked after by Mr. D. E. Goe and Mr. F. H. Ford.

THE RICHMONDT CONDUIT COMPANY, of Milwaukee, had an interesting and unique exhibit of its conduits in charge of Mr. C. D. Richmondt.

MR. JAMES WOLFF, the popular Western representative of the New York Insulated Wire Company, was very much in evidence among his friends at the Convention.

THE AMERICAN CIRCULAR LOOM COMPANY, of Chelsea, Mass., was represented by Mr. H. B. Kirkland of New York, and Mr. Thomas G. Greier of Chicago.

THE MANHATTAN GENERAL CONSTRUCTION COMPANY, New York, had the interests of its well-known Manhattan arc lamp ably taken care of by Mr. F. L. Merrill, of its Chicago office.

MILWAUKEE ELECTRIC COMPANY, of Milwaukee, Wis., had three types of motors on exhibition, which attracted much attention from central station men. The company was represented by Mr. Walter Cary.

THE O. C. LITTLE PULLEY COATING COMPANY, of Menasha, Wis., exhibited a machine demonstrating the efficiency of its pulley coating in transmitting power. Mr. O. C. Little represented the company.

MR. A. LOUIS KUEHMSTED, treasurer and general manager of the Gregory Electric Company of Chicago, was present at the Convention and took good care of the many friends and customers of this company.

THE BRYAN-MARSH COMPANY, New York, was represented by its president, Mr. Converse D. Marsh of New York, and its Western representatives, Messrs. Leroy P. Sawyer, George C. Keech and Guy V. Williams.

THE WESTERN ELECTRIC COMPANY, of Chicago, had an extensive exhibit of its alternating and direct-current arc lamps and also showed some of its ceiling and desk fans, as well as several other types of apparatus.

THE COLUMBIA INCANDESCENT LAMP COMPANY'S interests were looked after by Mr. James B. Coale of Minneapolis, Minn., who represents the sales department of this company in the Northwest.

THE WARREN ELECTRIC & SPECIALTY COMPANY, of Warren, Ohio, exhibited through the Illinois Electric Company a line of its Peerless fan motors, transformers and lamps. Messrs. L. K. Cushing and C. W. Bacon had charge of this exhibit.

THE BARTH MANUFACTURING COMPANY, of Milwaukee, had an interesting exhibit of its electric passenger and freight elevator controller. The secretary of the company, Mr. Louis A. Riebs, explained the operation of the machine to all those present.

MR. F. R. BACON, president, and Mr. J. G. Hickcox, secretary of the Cutler-Hammer Manufacturing Company, Milwaukee, attended the Convention and made many new

289 MILES OF BEAUTIFUL AND HISTORIC SCENERY.

The Nashville, Chattanooga & St. Louis Railway offers to the tourist and pleasure-seeker one of the prettiest routes between the North and the South. Its through trains pass at the foot of grand old Lookout Mountain and through the famous battlefields of the Civil War between Nashville and Atlanta. They are equipped with the latest style modern day coaches and Pullman palace sleeping cars and are vestibuled from end to end. If you are going to Florida this winter consult the time-tables of the N., C. & St. L. before deciding upon your route. H. F. Smith, Traffic Manager, Nashville, Tenn.; W. L. Danley, General Passenger Agent.

friends for the well-known line of rheostats and motor starters manufactured by their company.

THE WARREN ELECTRIC MANUFACTURING COMPANY, of Sandusky, O., and the TRIUMPH ELECTRIC COMPANY, of Cincinnati, O., had their interests looked after at the Convention by Mr. B. F. Stewart, of J. Holt Gates & Co., the Chicago agents for these companies.

THE HART MANUFACTURING COMPANY, the well known switch manufacturers of Hartford, Conn., and the BOSSERT ELECTRIC CONSTRUCTION COMPANY, manufacturers of outlet and junction boxes, at Utica, N. Y., were ably represented by Mr. W. P. Crockett, their Western representative.

THE WAGNER ELECTRIC MANUFACTURING COMPANY, of St. Louis, Mo., was represented by its Western manager, Mr. George B. Foster, assisted by Mr. J. F. Begoll. They exhibited to many interested spectators one of the company's many new styles of transformers which excited much favorable comment.

THE HART & HEGEMAN MANUFACTURING COMPANY, of Hartford, Conn., well known to the trade as the manufacturer of "Hart" and "H. & H." switches, was represented at the Convention by Mr. George S. Searing, of Chicago, who also looked after the interests of the Peru Electric Manufacturing Company, of Peru, Indiana.

THE BROWNING MANUFACTURING COMPANY, of Milwaukee, had one of the most interesting and complete exhibits at the Convention. Wires were run into its room and motors connected up in order to demonstrate to visitors the smooth and noiseless operation of the machines, ranging from small dental motors to 3½ h.p. motors.

THE ELECTRIC APPLIANCE COMPANY, of Chicago, sent a full delegation to the Convention headed by its president, Mr. W. W. Low. Others in the party were Mr. B. B. Downs, Mr. W. P. Upham and Mr. S. A. Rall. Among other things it exhibited the Adams-Bagnall arc lamp and the Gutmann wattmeters for which it is sales agent in the West.

THE SAWYER-MAN ELECTRIC COMPANY exhibited some of its incandescent lamps, and by means of a photometer outfit gave convincing proof of their efficiency. These lamps were used in the sign of the Westinghouse Electric Company. The exhibit was in charge of Mr. C. A. Ross, manager of the Chicago office, and Mr. R. S. Mueller.

THE SHELBY ELECTRIC COMPANY, Shelby, Ohio, exhibited various types of its incandescent lamps, and demonstrated by means of a Queen photometer to many interested visitors that the Shelby lamps give an unusual amount of light through the tip. The company was represented by Mr. O. D. Pierce, of Shelby, Mr. W. S. Reynolds, of Detroit, Mich., and Mr. C. A. Meade, of Chicago.

M. B. AUSTIN & CO., of Chicago, had an exhibition in their rooms of the Belden arc lamp manufactured by the Belden-Larwill Electric & Manufacturing Company of Fort Wayne, Ind., and also showed several other specialties, for which they are sales agents in the West. They were represented by Messrs. M. B. Austin, A. H. Friend, C. N. Jackson, C. A. Robinson, A. Meinema and W. A. Browne.

THE ALDEN ELECTRIC COMPANY, of Chicago, was represented by Mr. C. A. Kuhlman. Mr. Fred H. Alden, president of the company, and Mr. J. Geiserowich, secretary and treasurer, were unable to be present. They are exceedingly busy at present moving the factory of the Illinois Insulated Wire Company from Sycamore, Ill., to Chicago. Their new factory will be in operation in a very short time.

THE CHRISTENSEN ENGINEERING COMPANY, of Milwaukee, sent a handsomely engraved invitation to the Convention delegates to visit its new offices and works. Many availed themselves of this opportunity. The company was represented at the Convention by its sales manager, Mr. George J. Caldwell, who received many congratulations from his friends on his recent appointment to this position.

THE GENERAL INCANDESCENT ARC LIGHT COMPANY, PARAGON FAN & MOTOR COMPANY, and CHICAGO RHEOSTAT COMPANY, New York, all had their headquarters in room 8 at the Pfister. Numbers of central station men could be found there at all times examining the arc and incandescent lamps, Wright discount meters, switches and various other specialties exhibited by these companies. They were ably represented by Mr. Francis Raymond, Western sales manager, and Mr. Thomas James of the Milwaukee office of the General Incandescent Arc Light Company.

MR. E. F. KIRKPATRICK, well known as "Kirk" in electrical circles, commenced the new century as Western representative of the McRoy Clay Company of New York. His offices are located in the Chamber of Commerce Building, Chicago. Mr. Kirkpatrick entertained many friends of the McRoy Company at his headquarters at the Convention and received numerous congratulations on his appointment. He will hereafter take charge of the entire business of the McRoy Company in the West. With fifteen years' experience in the electrical business Mr. Kirkpatrick has made a host of friends, all of whom wish him success in his new enterprise.

THE FORT WAYNE ELECTRIC WORKS, of Fort Wayne, Ind., was, as usual, represented by its well-known salesmen, Messrs. Willard Knight and Frank McMaster. Mr. King, chief of the meter department, was also on hand to explain the details of the type "K" meter, which attracted a great deal of attention, owing to its many practical features, such as the interchangeability of all parts. The entirely new features of adjustment in this meter caused a great deal of interest. Mr. Edward A. Wagner was also on hand to explain the leading features of the new "Type A" transformers, which have also some entirely new and useful features. A 5-h.p. Wood automatic starting box, with overload and underload release, was also exhibited, and elicited much merited commendation.

THE WESTINGHOUSE ELECTRIC & MANUFACTURING COMPANY presented a detail exhibit of apparatus, consisting of a Westinghouse wattmeter, which was shown in operation in connection with suitable switchboard instruments, particular attention being called to the company's new line of long-scale indicating instruments. It also exhibited its types of lightning arresters, fan motors, cut-outs, etc. A prominent feature of the exhibit was the new "O.D." type transformer, which represents the most modern practice in construction, and was briefly described in this paper a few months ago. A large electric sign, suspended across the west end of the hall, bore the name of Westinghouse. The officials representing the company during the Convention were W. R. Pinckard, C. C. Burton, T. P. Gaylord, W. S. Rugg and Ervin Dryer. Mr. Arthur Hartwell, manager of the Chicago office, was expected to be present, but was detained by urgent business matters which could not be deferred.

THE GENERAL ELECTRIC COMPANY was efficiently represented at the Convention by Messrs. B. E. Sunny, general Western manager; F. N. Boyer, manager supply department, Chicago office; L. G. Crawford, J. Scribner, S. F. Dibble and Thomas Ferris, of Milwaukee; F. G. Vaughn and P. D. Wagoner, of Schenectady. The General Electric Company's exhibit was unusually interesting to the electrical fraternity, and comprised many new and interesting pieces of apparatus. Probably the most interesting new device exhibited at the Convention was the apparatus for controlling series incandescent lamps for street lighting, which was referred to in Mr. Wagoner's paper read before the convention. This system is similar in principle to the well-known constant-current transformer system for arc lighting, but slightly different in practical application. These regulators have been in use for about a year, but have not been pushed, as it was the desire of the General Electric Company to obtain results of practical operation before pushing the sale of these coils.

SOLID TRAINS TO NORTHERN MICHIGAN.

The Chicago, Milwaukee & St. Paul Railway is now running solid trains of palace sleeping cars, dining cars (serving meals a la carte) and first-class day coaches, through from Chicago to Calumet, Houghton, Hancock and other points in the Copper Country without change of cars, with direct connection for Marquette, Negaunee, Ishpeming, etc., and passengers from the East, South and Southwest will find this a most desirable route.

Vol. XIII. New York, March, 1901. No. 3.

A NOTABLE INDEPENDENT TELEPHONE EXCHANGE.

THE LAMP SIGNAL BRANCH EXCHANGE AT EAST CLEVELAND, OHIO.

BY GEORGE L. BURLINGAME.

THE new branch exchange of the Cuyahoga Telephone Company, which was recently installed as a part of its comprehensive system in Cleveland, Ohio, embodies all of the latest features of the most modern lamp-signal central energy equipments. This branch exchange is known as the "East Office," and is located on Lake Front Avenue in the extreme eastern part of the city, about eight miles from the main exchange. The building, shown in the initial engraving, was erected by the telephone company and is a two-story structure of complete fire-proof construction. The walls are made of pressed brick with gray stone trimmings and the whole is very artistic in design. The operating room is on the first floor and the walls and ceilings are very attractively decorated. This room was designed to accommodate a switchboard of about 2000 lines capacity, disposed in U-shape around three sides of the room.

The distributing room is located in the basement directly under the exchange room, and is large enough to allow the installation of two relay frames, with a capacity of 2160 line and cut-off relays, two 1200-line distributing frames and two terminal frames for twenty-four 100-pair Cook terminal heads. But one frame of each type has been installed. These are securely fastened to the brick partitions and tied together at the top with a cable rack or iron running box in which all of the cables to and from these frames are carried. On one side of the distributing room the power plant and the hot-water furnace for heating the building are located, while the other side has been attractively fitted up as a retiring and locker room. A kitchen and pantry in which there are a gas range and a porcelain sink adjoins the distributing room. These rooms contain many conveniences for the operators when not on duty, such as sofas, rockers, etc., while on the table may be found the latest magazines and papers. This feature is characteristic of the policy of the Cuyahoga Telephone Company, which has always shown the greatest consideration for the comfort of the operating force.

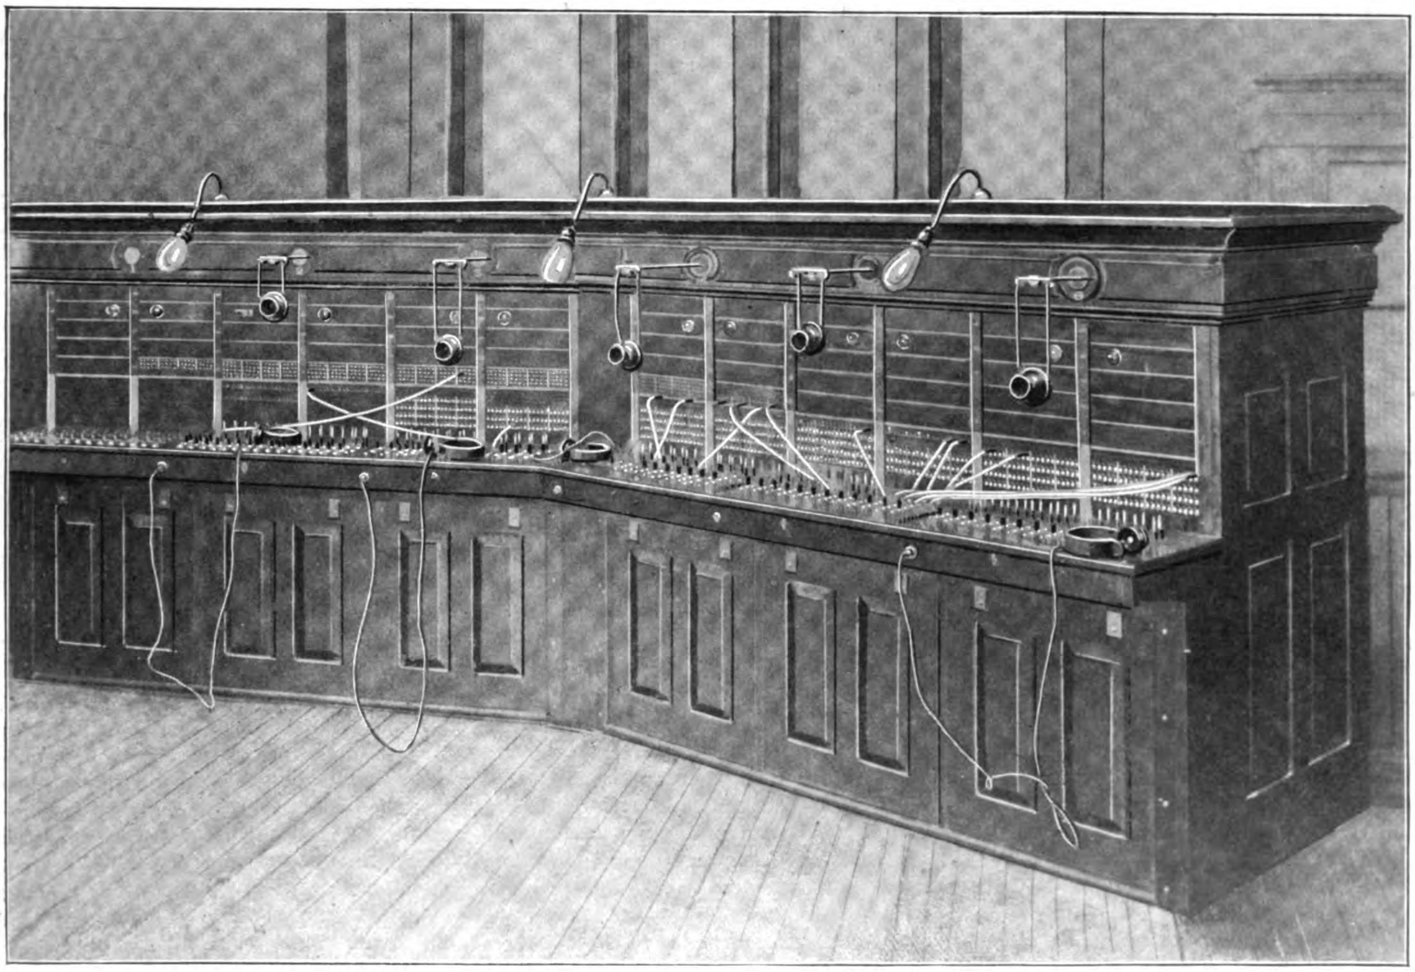

FIG. 1.—TWO SIX-PANEL, THREE-OPERATOR SECTIONS WITH LAMP SIGNALS.

The underground cables leave the manhole about 150 feet from the exchange and enter the basement in a specially designed cement duct about 3 ft. wide and 2 ft. deep, which is covered with iron traps so arranged with flush rings that they can be easily taken up. From this they are led directly to the 100-pair Cook heads, which are mounted on the terminal frame, as shown in the background of Fig. 2. Switchboard cables lead from these heads directly to the line terminals on the main distributing board, shown in the foreground of the same engraving. These cables are made of 102 pairs of No. 24 tinned copper wire, insulated with two windings of silk and one of cotton, the whole being wrapped with several layers of paper and sheathed in a braided covering. These were all treated previously with hot beeswax which penetrates to the paper, leaving a dry core and thus providing a perfectly moisture-proof insulation. All of the cable used within the building was made on this plan by the Kellogg Switchboard & Supply Company, Chicago, who also furnished the telephonic apparatus throughout. The underground cables were made by the Standard Underground Cable Company, Pittsburg.

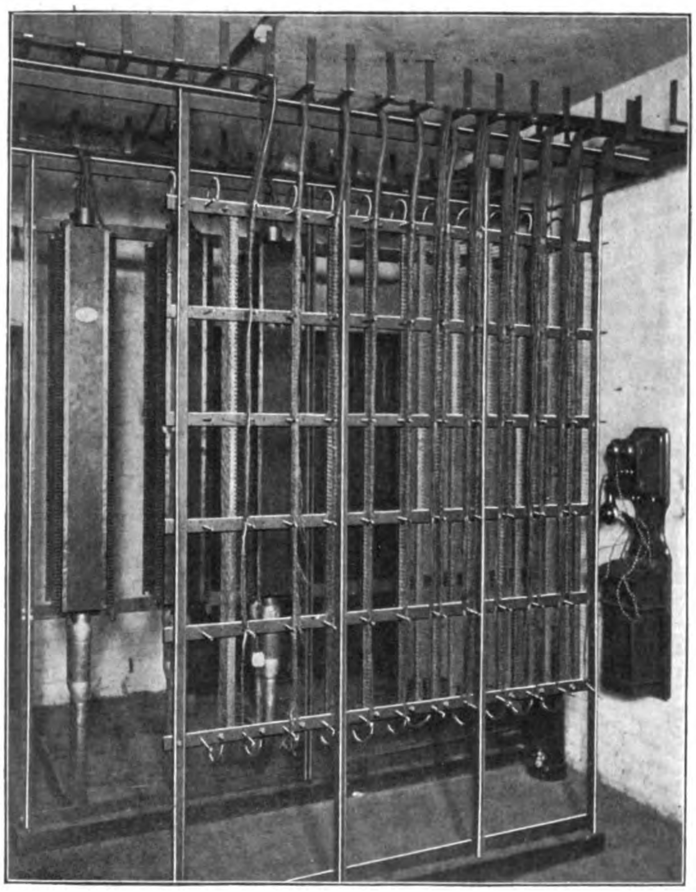

FIG. 2.—REAR VIEW OF TERMINAL FRAME.

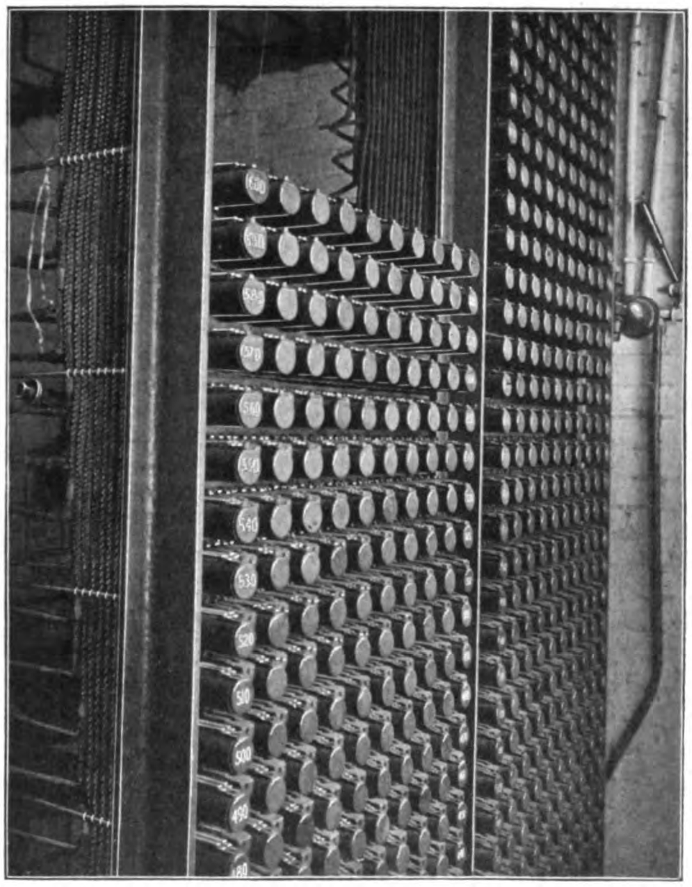

FIG. 3.—FRONT VIEW OF RELAY FRAME.

After being cross-connected or "jumpered" with No. 24 silk and cotton jumper wire from the line or terminal side to the relay side of the main distributing frame, the lines are carried in 21-pair cables on the cable rack at the top, to the line and cut-off relays at the relay frame as shown in Figs. 3 and 4. These relays are mounted twenty of each per strip, there being space on the relay frame for eighteen such strips or 720 relays in each of the three panels or banks. The function of the line relay is to light the line lamp or signal on the switchboard when a subscriber lifts his telephone from the hook and the cut-off relay "cuts off" this line relay when the operator inserts the plug in answering the call, thereby putting out or restoring the line signal.

After passing through these relays the lines are carried by means of 63-wire cable through a running box to terminals on the connecting rack located on the rear of the legs of the switchboard, and are thence carried in 21-pair cables through a box panel at the left end of the first section to the multiple jacks appearing in each section. From these same terminals, but on the inside or front of the connecting rack, 63-wire cables are carried to the answering jacks and line lamps.

Two six-panel, three-operator sections have been installed thus far; these are shown by Fig. 1. The framework is of angle iron construction, rigidly braced and covered with mouldings and panels of mahogany. The line lamp signals are mounted 20 per strip on ½-in. centers, the strips of lamps and answering jacks appearing alternately, as shown just above the key-shelves in Fig. 1.

The first operator's position is not equipped. The second is used as an incoming trunk position. The trunk lines between this office and the 9600-line, 4-division Kellogg board (which was installed during the past two years and is located at the main office) end at this position in single cords. The method of operating these lines will be mentioned later. The third or last position of this section and the middle operator's position on the second section have each answering jacks and line lamp signals for 140 lines, while the first and last positions on the second section are equipped each for 160 lines, making a total of 600 subscriber's lines. Each subscriber's operator's position is equipped with twelve cord circuits, each consisting of a combined ringing and listening key having German silver springs, with contacts of 98 per cent pure platinum, two cords and plugs, each cord having its own supervisory lamp which is controlled by individual dustproof tubular supervisory relays, located in a covered box on the rear of the legs of the section above the connecting rack. This box contains the condensers, two of which are associated with each cord circuit.

The operator's equipment consists of a transmitter arm and solid back transmitter, suspended on two green silk cords, so arranged that the slack in these is automatically taken up as the transmitter is raised or lowered, together with a head telephone and green silk cord with plug attached and a head telephone jack which is located in the front of the key-shelf.

The method of operating is as follows: The subscriber desiring a connection lifts his receiver from the hook. This action operates the line relay above mentioned and causes the line lamp or signal to light, thereby notifying the operator of the call. In conjunction with all of the line signals at each operator's position, there is placed a common relay, known as a "line pilot relay," which is so wired that when any one of the line lamps is lighted the relay operates to light a line pilot lamp having a white jewel or lens, located in one of the blank multiple spaces, and also operates the buzzer located in the box panel. The buzzer is used especially at night, when but few operators are at work, to attract attention to the fact that there is a call, and the line pilot lamp shows at a glance at which position it is. The supervisory or disconnect signals at each position are also provided with a relay of the same description which lights a lamp having a red lens.

As soon as a call comes in, the operator inserts in the corresponding answering jack one of the plugs of any pair of the twelve cord circuits which which she is provided, at the same time cutting in the corresponding listening key. The supervisory lamp associated with this cord and plug does not light, the receiver on the line plugged into being off the hook. As soon as the operator gets the number required by the calling subscriber, if it is for a similar line at the East Office, she picks up the other plug of the pair and with the listening key still cut in, tests the desired line by touching the tip end of the plug to the brass shell of the multiple jack. If the line is being used by some other operator she receives a click in her head telephone, then she immediately tells the subscriber that the line is busy. If she receives no click, she inserts the plug and rings up the party called for by simply pressing forward the cam of the listening key above mentioned. When she inserts the second plug the corresponding supervisory lamp at once lights up, denoting that the receiver is on the hook, and when the called subscriber answers, this lamp immediately goes out. As soon as the two subscribers finish talking and hang up the receivers, the two lamps light up again, which is the signal for the operator to disconnect; this operation puts out both lamps.

In case a connection has been established and one of the parties desires to make another call immediately, he can attract the attention of the operator by simply moving the receiver hook up and down a few times. This will flash the supervisory lamp and the operator will cut in on the line and get the desired number and proceed as before.

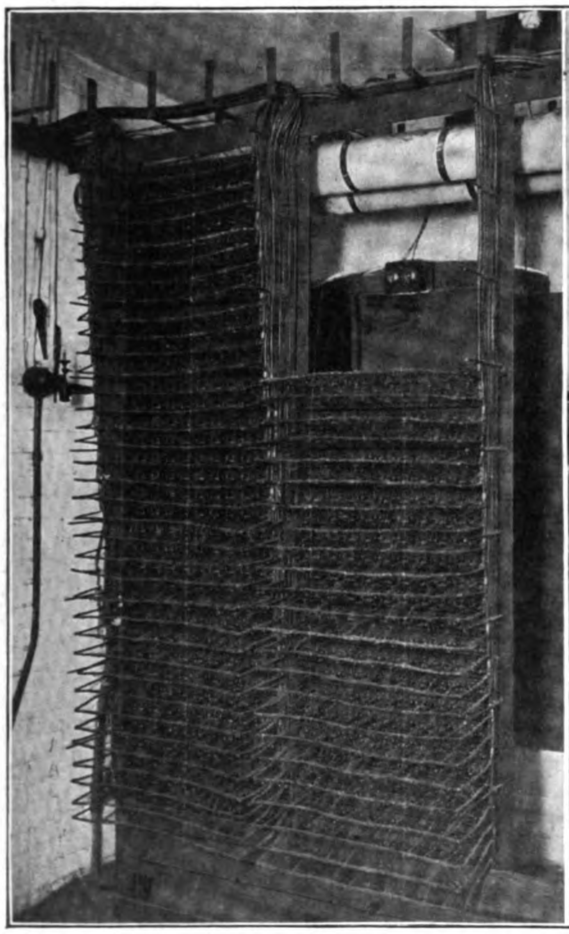

FIG. 4.—REAR VIEW OF RELAY FRAME.

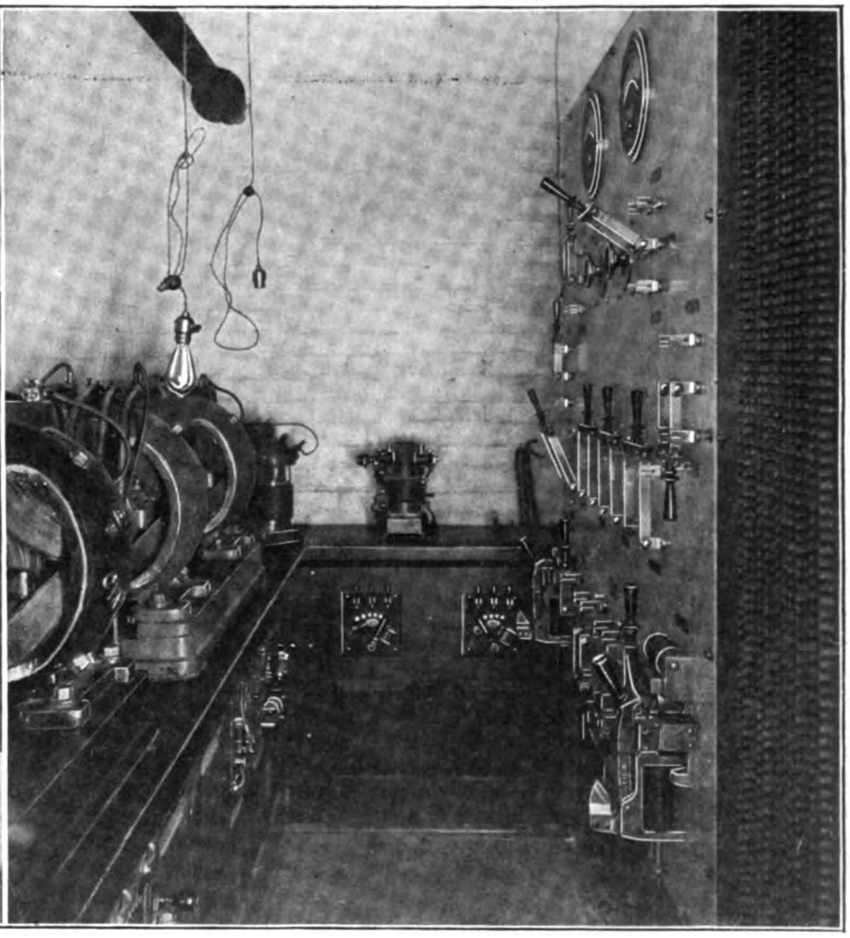

FIG. 5.—VIEW OF POWER EQUIPMENT.

It will be seen that by this method the operator has complete control of the connection and knows exactly whether the parties have answered or are still conversing without the necessity of listening in on the line, and this enables her to handle more lines than she could with the old clearing-out drop system.

Where a subscriber is wanted whose line ends on one of the four divisions in the main office, the operator tests in the usual manner and, if not busy, plugs into one of the forty outgoing trunk lines, which are multipled in the third and fourth panels of each section and which lead to the incoming trunk positions at the main office. By means of an order-wire key which goes direct to the operator's head 'phone at the division wanted in the main office, she tells that operator the connection, and the main office operator designates the trunk. The act of plugging into the designated trunk by the main office operator signals the East Office operator, when the latter rings up the main office subscriber called for in the same manner as if the connection were between two lines in East Office. When the main office subscriber hangs up his receiver after completing the conversation, the corresponding supervisory lamp is lighted at East Office, and when the East Office operator receives both disconnect signals, she pulls down the connection, which action lights the disconnect lamp at the main office incoming trunk position and this operator pulls down her connection. Calls for East Cleveland lines originating in the main office are handled in the same manner at the incoming trunk positions at East Cleveland.

These incoming trunk operators have no occasion to cut in on the talking circuit of a subscriber, and have no occasion to use their listening keys, except to secure a busy test. They have no means for ringing subscriber's bells, for, as above stated, the originating operator does this. The most modern practice decrees that the duties of an incoming trunk operator should be confined to receiving the orders over her order or call wires which are joined to her head 'phone, establishing the connections ordered up, and to disconnect when she receives the disconnect signal. The originating operator is the one who should have complete supervision of the trunking connection, and in case of any special calls, such as calls from pay stations or nickel-in-the-slot machines, this operator is the one who should stay in on the connection to find out whether the calling party has succeeded in securing the called-for party and to see that he deposits his coin in the slot machine. It will be noticed that the trunk circuits installed conform precisely with this rule.

A busy back signal apparatus has been installed at both offices to obviate the necessity of the incoming trunk operator cutting in on a subscriber's line to inform him that the line is busy, for it is plain to be seen that she would necessarily lose many orders for connection while so doing. If a line tests busy, she simply plugs into one of four busy jacks provided at her position and pays no attention to that particular cord until she receives the disconnect signal from the other office.

The power plant shown in Fig. 5 consists of two Roth motor-generators for charging the two sets of ten cells each of American storage batteries. These machines receive current from a 500-volt trolley circuit and deliver 30 amperes at 28 volts. There are also two Roth ringing machines to supply current for ringing the subscribers' bells, one having a 500-volt primary and the other being wound to take current from ten cells of storage battery, both machines giving 100 volts, pulsating and alternating. The busy back signal apparatus is driven by a 1/6-h.p. Roth motor, which is also supplied from the storage cells. These machines are mounted on a specially designed iron frame-work, which is covered with paneling stained to match mahogany.

The power board is an Italian marble slab 60 x 60 x 1¼ ins., with polished surface and beveled face edges, mounted in an iron frame and shown at the right of Fig. 5. On this are mounted a Weston voltmeter of the round pattern, flush type, double scale, reading from 0 to 600 and 0 to 60, dead black finish with copper trimmings, and a Weston ammeter, round pattern, flush type, with six shunts and 100-ampere scale, finished the same as the voltmeter. Each of these instruments is controlled by switches having copper-plated hand wheels with index plates stamped for eight and six circuits, respectively. Two copper-plated Midget, 28-volt under-load and over-load I-T-E circuit-breakers protect the charging circuits. Twelve all copper back-connected jack-knife switches are also provided, eight on the charging and four on the discharging circuits.

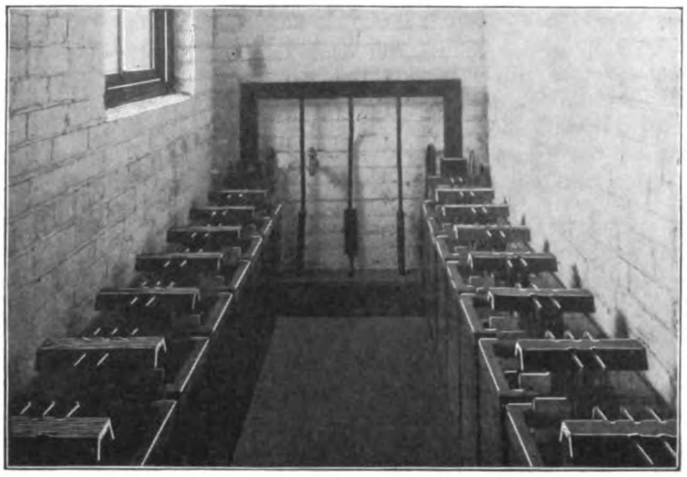

FIG. 6.—VIEW OF STORAGE BATTERY PLANT.

The battery plant consists of two sets of American storage battery, each set comprising ten cells, located as shown in Fig. 6. The elements are Y2 in Y4 lead-lined tanks, and the cells have a capacity of 100 ampere-hours each, which is sufficient for the present line equipment; larger tanks have been provided, however, so that plates may be added as the exchange grows. From the batteries and from the power board leads are carried direct to a fuse board which consists of a slate slab 42 x 60 x 1¼ ins., mounted in an iron frame and located adjacent to the power board, as shown at the extreme right of Fig. 5. On this board are located fuses for all of the circuits. Individual rubber-covered wires, No. 20 B. & S. gauge, are brought from each strip of twenty line lamps, from each set of supervisory or disconnect signals and from each strip of 20 line relays. Each operator's transmitter is fed by a twisted pair of No. 18 B. & S. gauge rubber-covered wires. The battery connection is carried to each cord circuit for talking in 15-pair switchboard cable, each fused on this board. The connections are all soldered to the fuse studs on the rear. These studs project through to the face where each one is fitted with a cap screw, under which the fuse is held. Each set or group of fuses is numbered or labeled so that the "trouble" man may readily locate any circuit which he may wish to open for testing.

The building is lighted throughout by electricity, the switchboard being illuminated on the front with three 110-volt 16-c.p. lamps. The lamp brackets are finished in black and are provided with one-half-green shades. On the rear each section has a porcelain base keyless socket and lamp located in the roof. The power and distributing rooms are equipped with sufficient lamps to thoroughly light the apparatus.

Since the opening of this office a few weeks ago, the number of subscribers has increased so rapidly that it has been necessary for the telephone company to immediately add one section of 480 lines to the present equipment of 600 lines.

THE MODERN HORIZONTAL TUBULAR BOILER.

The horizontal tubular boiler is a peculiarly American type, which has come into general use during the past thirty or forty years. In England, according to an estimate published by Mr. Edward G. Hiller, the horizontal tubular boiler forms less than 1 per cent of the boilers now in use, while in this country it is more common than any other kind. It has a number of features that have conspired to bring it into favor with manufacturers, and probably engineers also. Its first cost per horse-power is comparatively low—lower, perhaps, than for any other boiler on the market. With good feed-water it is easily kept clean and requires very little attention. This much can be said, in fact, of almost any boiler; because good feed-water is a prime essential for any steam plant, and when it can be had, things are always apt to run along pretty smoothly. But it can be said, truthfully and without forgetting the good points of other kinds of boilers, that the horizontal tubular type can be used successfully with water that would bring other types to grief. The vulnerable spot, in this kind of boiler, is the tube ends; and as the back head is the one that is exposed to the flames, it is there that the greatest trouble is experienced.

The shell will often stand a large amount of scale without injury, and yet it must not be neglected. Fragments of scale, wherever formed, fall to the bottom of the boiler when they flake off, and this is the best possible place for them to lodge, as the shell plates present a large area, which is covered by a large body of water. The removal of such accumulated scale must be attended to in an intelligent manner, however, for many boilers have had their days of usefulness shortened by neglect or lack of judgment at this point on the part of the attendant. A case which recently came to the writer's notice illustrates this point very well. A paper manufacturer had two 72-in. horizontal tubular boilers, and as the feed-water was not of the best, he made a practice of opening and cleaning them every two weeks. When they had been in use about three years he changed his fireman.

Some six months later the new fireman summoned the owner and told him the boilers were acting strangely. Upon investigation a well-developed bulge was found on the bottom of one of them, about over the bridge wall. The fire was drawn and the boiler allowed to cool off. The boiler doctor was then summoned by telephone, and was asked to explain the case. He thought the bulge was due to scale; but the owner was positive that that could not be so, as the boilers were emptied and washed out only the day before. The boiler was finally blown off, and when the hand plates were taken out, a large quantity of scale, composed of small particles that had been baked together into one solid mass, was found directly over the bulge. The gaskets on the hand plates were soft and fresh, showing that they had been off the day before, so that the fireman's story that he had cleaned everything out appeared to be quite true.

A little further investigation showed that although the fireman had acted in good faith, he had erred by using the wrong kind of implement for cleaning. He had used a hoe with a handle only four feet long, and had not been able to reach in far enough to draw out the scale that had caused the bulge. The only way to make sure of the condition of a horizontal tubular boiler, when cleaning out, is to make a torch by tying a piece of waste on the end of a pole. The waste is to be saturated with kerosene oil, and then lighted and pushed in through the front hand hole, clear to the back head. This will light up the interior of the boiler and all scale can be located.

It will not be necessary to give an elaborate mechanical description of the horizontal tubular boiler, because its construction is familiar to almost everybody and is well shown in the accompanying engraving. It may be said, however, that there has been a radical change, during the past ten or fifteen years, in the details of the construction of this boiler. The tendency has been, and is, always toward higher pressures and greater capacity. The boiler-maker of to-day is better educated than he used to be, because competition has compelled him to be up to the times, both in tools and in the class of workmen that he hires, in order to get his share of the business. Shell boilers were formerly built with their longitudinal seams single-riveted, except in the case of the larger sizes, and it was not at all uncommon to meet with a 60-in. boiler with all its joints single-riveted. But a change has come over all this, and to-day it is rare to find a boiler even of small diameter (unless used solely for heating purposes) in which the longitudinal seams are not double-riveted, at least.

Formerly boiler-makers had an idea that rivets should be pitched quite close in order to make tight joints, and templets were used for laying off the holes for different sizes of boilers. The same size of rivet and the same pitch were used, in most cases, for all thicknesses of plate; except that when it was found that the rivet did not have body enough to overcome the spring of the plates and hold them properly together, a larger sized rivet was employed. Later it was found that by pitching the rivets further apart a tight joint could still be made; and as this course required less rivets to be driven, which meant a corresponding saving of time and labor, the wide pitch was generally adopted. Some of the makers even went to extremes in this change of practice, and by pitching the rivets too far apart, produced joints that were even poorer than those with the close pitch.

The almost universal adoption of wide pitch has been due, in large measure, to the influence of a few men of advanced ideas, who have given much time and thought to the construction of riveted joints, and to the methods of calculating their efficiencies; and the boilers built by reputable builders of to-day will be found to have the rivets pitched properly in most cases—that is, the shearing strength of the rivets will be found to be substantially equal to the tensile strength of the part of the plate that lies between the rivet holes. The double-strap butt joint is coming into use quite largely now on boilers 60 ins. or more in diameter. It is an excellent joint, far superior to the ordinary double-riveted form, and it may be strongly advised for boilers of even smaller diameter, if they are to carry high pressures.

No bracing is required in the horizontal tubular form of boiler, except on the segments of the head that are not supported by the tubes and the flanges of the heads. In some cases, in which the water is bad, the tubes are set higher than is shown in the engraving, and a manhole is put in the front head, under the tubes. In such cases it is necessary to brace that part of each head which lies below the tubes; but ordinarily the segment of the head that lies below the tubes is not large enough to require any bracing.

There are several different kinds of bracing in use, some of which are favored by one maker, and some by another. The so-called "longitudinal brace," which runs straight through the boiler from head to head, is met with more frequently than formerly. It is made in two styles, one of which is fastened with a jaw and bolt to stiffening bars that are riveted to the heads. This is a very effective brace, but it has the disadvantage of rendering the interior of the boiler less accessible than it would be with the oblique shell braces, shown in the engraving. The other style of longitudinal brace passes through channel bars on the heads, and is fastened with nuts on the outside of each head, and lock nuts on the inside. If this brace is properly put in, it has all the advantages and disadvantages of the other form just described; but there are some points about it that call for additional consideration. Great faith must be placed in the judgment and intelligence of the workmen who screw up the nuts. How much strain does it take to make them tight? And what will be the effect upon these nuts, in the course of time, of the heat to which they are more or less exposed? It is not easy to answer these questions, and yet they represent uncertainties that are of great importance.

Diagonal bracing, in which the braces run from the head to the shell, as shown in the engraving, is met with more commonly than the longitudinal style. Here, also, there are several methods of arranging the details. Sometimes the brace is fastened with a jaw and bolt to tee-bars, or angle irons, that extend across the head horizontally. Sometimes it is secured in the same way to bars that are riveted to the head radially. Sometimes, too, the brace is forged up with a solid crowfoot, which is riveted to the head directly, without the use of tee-bars. Any one of these forms is good, provided the workmanship is satisfactory and the braces are numerous enough.

The methods of setting the horizontal tubular boiler are as numerous as the kinds of bracing; yet they may be all classified, in a general way, under the two headings of "overhung fronts" and "flush fronts," according as the front end of the boiler does or does not project out into the fire room, beyond the setting. The flush front makes the neater appearance, but there is more chance of injury to the boiler from it than from the other style. The bricks that lie in the space over the fire door and under the front end of the boiler must be kept in place, or there will be serious danger of burning the dry sheet, and many boilers have been badly damaged by carelessness in this particular. When the overhung front is used, the dry sheet projects out beyond the setting, and hence if any of the bricks

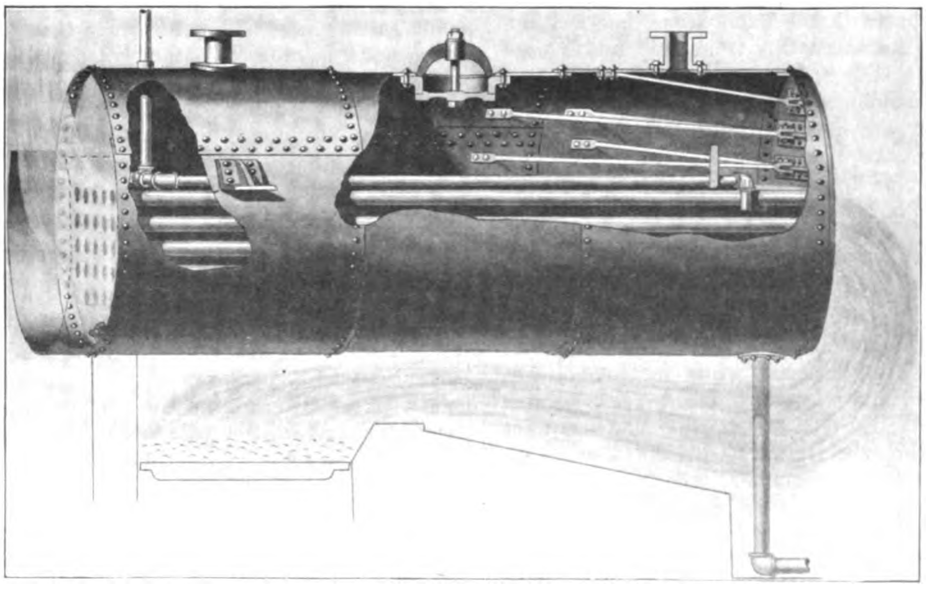

FIG. 1.—MODERN HORIZONTAL TUBULAR BOILER.

fall away from over the fire doors, the boiler itself is not injured, although the cast-iron front is by no means improved by exposure to the heat of the furnace.

The feed pipe may be led into the boiler in various ways, but the method shown in the engraving is one of the best. It here enters at the top of the shell, through a bushing. The internal part is screwed into the bushing, and it then drops down to within two inches of the tubes. At its lower end this pipe is fitted with a tee, from which branch pipes extend toward both sides of the shell, where they turn and pass backward along the shell to within about 18 ins. of the rear head. To prevent the two branches of the feed-pipe from chafing the tubes, they should be supported at the back end of the boiler by hooks forged from flat bar iron and attached overhead to a brace, or secured directly to the shell by a rivet. One of these hooks is suggested in the engraving. This method of introducing the feed from the top of the shell appears to have a material advantage over the commoner one of passing it in through the front head, as in the latter case the gases in the front connection affect the brass pipes that are usually employed for feed connections, and the life of the feed pipe at this particular point is shorter than elsewhere. In flush front settings, too, the brickwork has to be torn away to some extent in making repairs to the pipe, in case it enters through the front head; while in the construction here shown all parts of the pipe can be easily reached.

The blow-off pipe, if it is to answer the purpose for which it is intended, should be attached to the bottom of the shell, and not to the back head, as is sometimes done. Much trouble is often given by blow-off pipes becoming burned by direct exposure to the flame from the furnace; and, to avoid this trouble so far as possible, it is recommended that the floor of the combustion chamber be arranged substantially as shown in the engraving. The cavity or depression into which the blow-off pipe drops, will protect the elbow and the horizontal pipe from the hot gases. This same object is sometimes achieved by continuing the pipe still further down, so as to bury the horizontal part below the paving. The construction shown in the engraving is believed to be superior, however, because, while it accomplishes the same purpose, it also leaves the pipe perfectly free to expand and contract without straining itself, and also leaves it quite accessible. The sooty matter which lodges in the combustion chamber will soon cover the elbow and the horizontal part of the pipe, and protect them quite as effectively as a layer of brick.

The course of the gases, as they pass from the furnace under the boiler and back through the tubes, is sufficiently indicated in the illustration. In some cases an arch is sprung over the top of the shell, so as to provide a third return for them; but since this invites overheating of the shell, and does not add much to the efficiency of the boiler, it is not good practice.

THE ELECTROLYTIC PRODUCTION OF SODA AND CHLORINE.

BY ERNEST FRANKE.

If a solution of sodium chloride (common salt) be treated electrolytically with an insoluble positive electrode and a negative electrode of mercury, sodium will combine with the mercury, forming an amalgam, while chlorine will be evolved at the positive electrode. The amalgam will readily part with this sodium in water or steam as caustic soda. Pure caustic soda being obtained by this method, a saving of sodium chloride is effected, and a difficult and expensive refinement of the caustic soda lye obviated. Sodium being strongly electro-positive, has a tendency to oxidize, although combined with mercury as an amalgam, and forms caustic soda if it remains in the electrolyte for a definite time, even if separated from it by a porous wall. This tendency is especially noticeable shortly after closing the circuit of the cell, in the diminished current and increased voltage. In order that the sodium, combined with the mercury, may not be redissolved by the electrolyte from which it was formed, thus causing a loss, the amalgam must be removed from the electrolyte as quickly as possible. It may then be freed from the sodium and the mercury replaced in the cell.

While the principle is simple, the method is not easily followed in practice, and for this reason many inventors use diaphragms in connection with the mercury cathodes. The principal requirements for processes which use mercury as cathodes are the following: 1. Small quantities of mercury used, to reduce the first cost. 2. Rapid circulation—that is, rapid removal of the amalgam from the cell. 3. The anode should have a larger surface than the cathode, in order to obtain great current density on the cathode and thus prevent a loss of sodium. 4. No waste of mercury. 5. Tenacity of the cell-material against the influence of the sodium amalgam and chlorine. A considerable advantage would be gained by dispensing with the diaphragm and avoiding all the trouble connected therewith.

In using mercury as a cathode, the size of its surface is the main feature. The larger the surface, the greater will be the current passed through the cell at a given e.m.f.; if we also enlarge the surface of the anode, the smaller will be the quantity of mercury required per unit of work done. It would be impossible to use a cathode consisting of a thick cylindrical stream of mercury, but by spraying it the inactive portion of the mercury will be reduced to a minimum, while the effective surface will be made a maximum. This method possesses many advantages. The vertical position of the electrodes facilitating the escape of the chlorine gas, while the distance between anode and cathode may be made so small that the cell will require very little space. The internal resistance of the cell will be unusually low and its capacity large, it being possible to locate the mercury cathode between two anodes, thereby utilizing it to the highest degree. In large cells both sides of the intermediate anodes can also be used.

The amalgam, which falls to the bottom of the cell, may be protected from reduction by a layer of some inert liquid, such as sulphide of carbon, chloroform, etc. During its entire flow the mercury is under the influence of an anode having a considerably larger surface; a reduction of the amalgam during the flow is therefore out of the question; and since one layer of the amalgam is immediately covered by another, the inert liquid may be entirely dispensed with, if the quantity of amalgam leaving the cell is equal to the amount of mercury entering it. The result of rendering impossible the reduction of the amalgam is the highest obtainable production of caustic soda and chlorine. Experiments with free flowing mercury electrodes have given an efficiency of 98 per cent. The cells are very simple, as the mercury only falls through the electrolyte; they may be made from such material as stoneware, and require but little attention. There is scarcely any chance for them to get out of order, and no possibility for any waste of mercury, as a union of the metal with the separated chlorine in the cell is completely prevented by the large surface of the positive electrode.

A most important item is the quantity of mercury required to maintain continuous streams so as to obtain certain results. Experiments show that 2 grams (about 0.0705 oz.) of metal per second are necessary to maintain the flow in a concentrated solution of sodium chloride with an average length of 6 to 8 centimeters (2⅜ to 3.15 ins.). Such a stream being delivered between two carbon anodes in a warm concentrated solution, the current from the carbon to the mercury is about 0.7 ampere with an e.m.f. of 4 volts. The distance from anode to anode in this experiment was about 3 centimeters (1 3/16 ins.). By using platinum anodes, the current required was 1 to 1.2 amperes. For a current of 160 amperes at about 4 volts, 500 grams (1.1 lb.) mercury per second were required with carbon anodes; but with platinum anodes the quantity of mercury required was reduced 100 to 150 grams (3½ to 5.3 oz.). These extraordinary results are due, in the first place, to the rapid escape of the amalgam falling to the bottom of the cell, which prevents the formation of counter e.m.f., and also the fact that the amalgam was unable to take up much sodium during its short fall.

Owing to the rapid circulation of the mercury-stream through the cell, the amalgam formed is not rich in sodium and is thus easily reduced outside the cell. Cells may be made of glazed stoneware, about 0.8 meter (31½ ins.) square, with alternate anodes and cathodes, the anodes consisting of a composition of platinum-iridium. Such cells will pass about 3000 amperes at 4 volts.

SOME OF THE SPECIAL FEATURES OF THE SYSTEM OF THE PORTLAND GENERAL ELECTRIC COMPANY.

The power plant of the Portland General Electric Company at Oregon City, Oregon, was among the first electrical water-power plants to be built for transmitting power to a large city on a large commercial scale. This plant was built in 1893 and has ever since been one of the largest, most substantial and most satisfactory in operation of any of the water-power transmission plants in the United States. The plant was described in the technical press at the time it was built, but a few words about some of its special features and the distribution system it feeds will not be out of place at this time.

In few hydraulic plants is there such a varying head as at Oregon City. The power-house is 14 miles above Portland on the Willamette River. A few miles below Portland this river flows into the Columbia and at some seasons of the year the freshets in the Columbia back up the water in the Willamette so that the head at the Willamette Falls at Oregon City is greatly reduced. At other times freshets on the Willamette increase the head. Taken altogether, the head is likely to vary from 18 to 40 ft. Turbines large enough to drive the generators at the lowest head would be hard to govern with the small gate opening that would be necessary at the highest head. Therefore to meet these varying conditions two turbines were installed on each generator, a large turbine for low head and a smaller one for high heads. The generators and turbines are on vertical shafts. The small turbines are directly connected to the shafts of the generators and the large turbines are at one side of the small ones, and when in use are belted to the generators. These belts are short and are thrown out of use simply by loosening a belt-tightening idler pulley.

The weight of the generator armatures is 16 tons and special provision is made for carrying this weight. The shaft has two different thrust bearings. One is a bearing in which the thrust is taken by a number of bronze rings lubricated by having oil forced under them at high pressure and the other is a revolving piston under which oil is forced at sufficiently high pressure to sustain about half the weight of the armature, the other half being sustained by the thrust bearing. The floating bearing was designed as a safety precaution to relieve the thrust rings in case they began to heat, but it is employed regularly to take about half the weight, as it is just as easy to run it so and saves some power that would otherwise go to waste in friction. The generators are 450-kw. machines and run at 200 r.p.m. It has been found, by running the armature with a small motor, that the thrust bearing used alone absorbs 25 horse-power with the 16-ton weight upon it, and when relieved of half its weight by the floating oil bearing the friction loss in the bearings is reduced to 10 or 12 horse-power. Oil for the lubricating and floating is supplied by an electrically driven oil pump, supplying the whole station. In case the pump fails and the oil pressure drops, a pump driven by a water wheel is automatically turned on. The oil pressure is maintained at from 150 to 175 lbs. per sq. in. In addition to the forced lubrication all bearings of any size are water jacketed. The provisions against shut-down are very complete.

The efficiency of the turbines in this station at full load as near as can be determined is given by hydraulic engineer Sullivan as a little less than 75 per cent.

The governors in the plant are all the Replogle electric relay type. The electric circuit on the magnets which close the gates is run up from the wheel pit into the dynamo room and in case a machine is to be shut down in an emergency the circuit can be closed down so the governor will shut the gate in about 18 seconds. The results obtained in regulation are good. As plenty of fly-wheel effect is absolutely necessary to the successful regulation of a turbine-driven dynamo on account of the impossibility of stopping the flow of water suddenly with safety or starting it quickly, it is common practice to run the large turbines of this plant idle when the small ones are doing the work, for the sake of the fly-wheel effect.

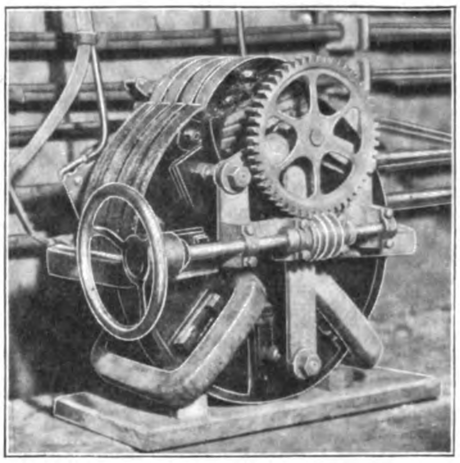

FIG. 1.—INDUCTIVE REGULATOR.

The station now has six direct-connected, 33-cycle, 450-kw., 3-phase, 6000-volt generators and three 600-h.p. turbines geared by bevel gear to a horizontal line shaft to which are belted some 5800-volt 125-cycle single-phase alternators brought from an old station. Besides this there are two 375-h.p. turbines direct-connected to 500-volt direct-current generators which serve for exciters and supply current to neighboring electric railway lines. The 6000-volt and 5800-volt machines supply direct a sub-station in the center of Portland, which will be mentioned later on. The machines supplying incandescent lighting circuits and those supplying railway and power circuits are run separately, but those on three-phase lighting circuits are run in multiple and those on the railway load in multiple. In operating the plant 24 hours 11 men are employed.

The company has two pole lines into Portland, one on the west side of the Willamette River and one on the east. The 6000-volt lines are run on glass insulators on pins 12 ins. apart. About the only trouble experienced on this line is an occasional cross during a storm.

The sub-station in Portland was laid out to meet conditions existing when it was put in, one of which was a 4-wire 330-volt system for low-tension distribution around the center of the city. This system has been continued. It is not considered an ideal one to operate by any means because of the difficulty of keeping the balance between the three circuits. It is fed from the three-phase generators and each transformer has four taps in its secondary for connection to the four distribution wires. At full load about 400 volts pressure has to be maintained between the outside wires of the system.

The residence districts are supplied from the high-frequency alternators. At the sub-station reduction is made from 5500 to 2000 volts and also to 1000 volts for distribution. At the sub-station are also rotary converters which supply about two-thirds the railway current used in Portland and also the 500-volt power circuits. All the small motors in Portland are run from 500-volt circuits. The station also has a number of old D. 62 railway generators running as motors, each direct-connected through a flexible coupling to a 100-light Excelsior series arc dynamo.

In all the incandescent lighting circuits on the four-wire system regulators are used for varying the voltage by hand at the sub-station. Between the generating and the sub-station communication is had mainly by gong signals. A code is used whereby the number of the circuit is first struck, followed by a signal to raise or lower the voltage. This is quicker and involves less work than telephoning. The gong is operated on an iron wire circuit with 500-volt current.

Several types of compensator regulators are used, all of which depend on the principle of a boosting transformer.

Mr. J. L. Thompson, assistant superintendent, has designed a home-made regulator which is being made in the company's shop at slack times. This regulator consists of a field magnet of laminated iron, made of some old armature rings, and wound with a coil connected in shunt across the mains. One of these regulators is shown in Fig. 1. The magnet ring has a circular opening at one point to receive an armature of laminated iron, on which armature is wound a single coil connected in series in the circuit to be regulated. This armature can be turned by a hand wheel so as to bring the plane of the coil either parallel with or at a right angle with the magnetic flux through the core. When the armature coil is at right angles to the magnetic circuit there is no effect on the circuit to be regulated, save the slight reactance of the coil itself. Turning the coil one way from this position raises the voltage and turning it in the other direction lowers the voltage. The device has the advantage of requiring no switch contacts for its operation, and of being cheap and easy to make up in a hurry, when to obtain a regulator from an eastern factory might take several months.

No fuses are used in the circuits between the generators and the step-down transformers—in fact the 6000-volt lines are entirely without fuses. The secondary lines from the step-down transformers are fused.

One peculiar feature of the company's business is that of furnishing a number of isolated plants with current during the light-load hours of the station; during the heavy load periods the engines and dynamos at the various plants are used in the usual way.

The system is under the general management of H. W. Goode and T. A. W. Shock is superintendent.

A COMPARISON OF DYNAMOS WITH SURFACE-WOUND AND SLOT-WOUND ARMATURES.

BY P. M. HELDT.

American manufacturers have practically entirely abandoned the surface-wound dynamo in favor of the slot-wound dynamo. The former type is at present only constructed for special purposes, such as plating and electrolytic work. In Europe, and especially in England, the surface-wound machine is still in the lead, manufacturers there always contending that the slot-wound dynamo is much more given to sparking than is the surface-wound machine. In the experience of the writer, dynamos in the United States spark less now than they did years ago, when they had surface and hand-wound armatures. This is not saying that the slotted core improves the conditions governing sparking, but that the conditions have been thoroughly analyzed in recent years and that machines are now built along lines which reduce the sparking tendencies to a minimum. The points of superiority generally credited to the slot-wound dynamo are, first, that on account of the short air-gap there is a considerable saving of magnetizing force; and, second, that as the conductors are buried in the iron, they are not so easily damaged as when lying on the surface of the core. The writer proposes to show in the following that for small machines of given weight and angular velocity, at least 50 per cent more output can be obtained if the armature is slot wound than if it is surface wound.

A number of years ago, a manufacturer who was then still building surface-wound dynamos noticed that his machines were considerably heavier than slot-wound machines of equal output and speed, built by his competitors. A 7½-kw. dynamo, for instance, running 1200 r.p.m., weighed 1400 pounds, while machines of this size with iron-clad armatures, only weighed 1000-1100 pounds. A calculation was made and it was found that by increasing the armature diameter, reducing the length of the field cores, and making the armature of the slotted type, an output of 12½ kw. could be obtained and the speed be reduced to 940 r.p.m.

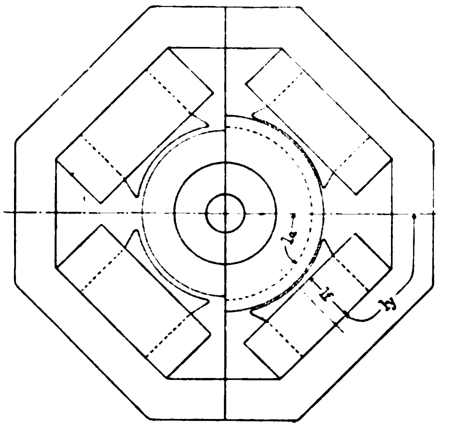

FIG. 1.—SIDE VIEW OF YOKE.

The machine referred to is of the quadripolar type, with radial internally-projecting poles. The yoke has an octagonal form, as seen in Fig. 1. The following are the data of this machine as originally constructed:

	Ins.
External diameter of armature discs...	10¼
Internal diameter of armature discs....	6⅜
Length of sheet iron core................	9
Thickness of cast iron end plates, each	½
Bore of field..................................	10[illegible]
Axial length of pole tips..................	10
Circumferential width of tips (length of arc)..	6¾
Minimum thickness of tips..............	⅜
Diameter of field cores..................	5¾
Length of field cores.....................	4
Radial depth of yoke......................	2½
Axial width of yoke........................	12

The armature has 84 sections, and for 110 volts is wound with two turns per section, of two No. 13 B. & S. wires in parallel. The winding is of the parallel or four-circuit variety. The number of effective conductors is therefore 168. The shunt field is wound with 96 pounds of No. 15 wire, B. & S. gauge. The magnetic calculation of this dynamo is as follows:

Flux (in armature) =

$$\frac{110 \times 10^8 \times 60}{1200 \times 168} = 3,274,000 \text{ lines.}$$

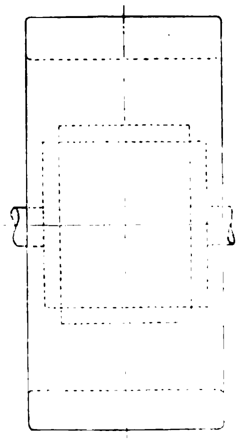

FIG. 2 —EDGE VIEW.

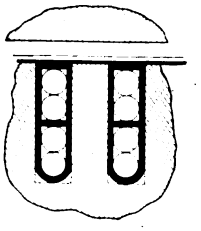

FIG. 3.—SLOT WINDING.

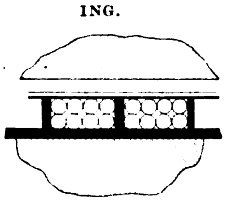

FIG. 4.—SURFACE WINDING.

The leakage coefficient is taken at 1.4, and the field flux is, therefore,

$$1.4 \times 3.274000 = 4,584,000.$$

The ampere turns to produce this flux are shown by Table I.

The total number of ampere turns for one magnetic circuit is 3263; for all four circuits, therefore, the number is 13,052 ampere turns. The shunt coils will have an internal diameter of 6 inches and an external diameter of 9¼ inches. The mean diameter is, therefore, 7⅝ inches, and the mean length per turn of wire is very nearly 2 feet. For rheostat regulation allow 15 volts, which leaves 95 volts to be applied to the field coils. Substituting now in the formula

ohms per ft. of shunt wire =

$$\frac{\text{e.m.f. (applied)}}{\left.\begin{matrix}\text{length of a turn}\\ \text{in feet}\end{matrix}\right\} \times \text{ampere turns}}$$

we find for the resistance per foot of the wire required,

$$\frac{95}{2 \times 13,052} = .00364 \text{ ohm;}$$

hence the resistance per 1000 ft. is 3.64 ohm. This is the resistance when the wire is hot. If we figure on an increase of temperature of 75 degrees Fahr., above the normal temperature, then the resistance increases in the ratio of 1.16:1. The resistance per 1000 ft. of the shunt wire, when cold, should therefore be $\frac{3.64}{1.16} = 3.14$ ohms, which is the resistance of No. 15 B. & S. wire, with which the machine is wound.

Following are the data of the slot-wound machine:

Output, 12½ kw.; voltage, 110; speed, 940 r.p.m.; number of sections in the armature, 96. The armature has a parallel or four-circuit winding, consisting of two turns No. 8 (B. & S.) wire per section.

	Ins.
External diameter of armature disc....	12⅛
Internal diameter of armature disc.....	6⅜

Width of armature slot....................	.796
Bore of field..................................	12⅜
Axial length of tips.........................	8
Radial width of tips (arc)................	6.84
Minimum thickness of tips..............	⅜
Diameter of field cores..................	5¾
Length of field cores.....................	3¼
Radial depth of yoke......................	2½
Axial width of yoke........................	12

The shunt field coils are No. 16 wire, B. & S. gauge, 80 pounds, being wound on. The magnetic lines of this machine are

N (in armature) =

$$\frac{110 \times 10^8 \times 60}{940 \times 192} = 3,660,000.$$

The leakage coefficient is here about 1.2, so that in the field frame the magnetic flux amounts to

$$1.2 \times 3,660,000 = 4,400,000 \text{ lines.}$$

TABLE II.

	Area magnetic path, sq. ins.	Length of magnetic path, ins.	Magnetic density per sq. in.	Amp.-turns required per inch length.	Amp.-turns for each section of 1 magnetic circuit.
Armature core.	16.6	3	54,000	7	21

" yoke...	30	10	37,000	46	460
Total ampere-turns................				....	2,514

Table II shows that the ampere-turns for one magnetic circuit are 2514, so that all four circuits require 10,056 ampere-turns. Allowing, as before, 15 volts for regulation, and having the same mean length of shunt turn as before, the resistance per 1000 ft. of the shunt wire is

$$\frac{95 \times 1000}{2 \times 10{,}056} = 4.721 \text{ ohms.}$$

Making the temperature correction as before, we find for the resistance of the wire, when cold,

$$\frac{4.721}{1.16} = 4.07 \text{ ohms,}$$

which is very nearly the resistance of No. 16 (B. & S.) wire. With this wire the machine was wound.

The factors which limit the output of a machine are heating and sparking. At present, machines are generally proportioned so that the limit imposed by the heating is lower than the limit prescribed by the sparking. The output of the machines under consideration was limited by heating. It might be suggested, therefore, that if there were a greater ratio of copper to iron in the smooth-core machine, it would compare more favorably with the slot-wound machine as regards output. The armature might be wound with three layers of wire of the same size of which it has two, in which case 11¼ kw. might be taken from it without causing any more heating in the armature than does the 7½-kw. output now.

But by making room for the extra layer of wire, we greatly increase the air-gap, and consequently increase the reluctance of the magnetic circuit. To force the same magnetic flux through this increased reluctance we would have to increase the size of our shunt wire, and in order to keep down the heating of the latter more wire would have to be used. In order to make room for this additional wire the field cores would have to be lengthened, which would also increase the diameter of the yoke and thus increase the weight of the machine all around. Not much, if anything, could therefore be gained in this manner. On the other hand, by making the changes described above the output of the machine was largely increased and the speed reduced, while the amount of copper in the machine and the total weight remained practically the same.

The iron-clad-armature dynamo is, therefore, lighter and more compact, and can be built at a lower cost than the surface-wound-armature dynamo of equal output and speed. The latter consideration, which concerns manufacturers and purchasers alike, certainly is responsible for the general adoption of slot-wound to the exclusion of surface-wound armatures.

◆

A NOTE ON THE USE OF THE ELECTRODYNAMOMETER.

BY FRED P. WOODBURY.

Although the electrodynamometer is large and clumsy, its suspension likely to get out of order or broken, and the mercury apt to be spilled from its cups, it possesses the almost inestimable advantage of accuracy; and when one becomes familiar with its few frailties it is more satisfactory than any other form of alternate-current ammeter, at least where accuracy is at all important. Unfortunately, the scale of the dynamometer does not read directly in amperes, but in degrees, and it is necessary to apply the formula $C = K\sqrt{D}$; where C = current, K = a certain definite constant representing the stiffness of the spring of the dynamometer and varying with each instrument, and D = deflection of the torsion head pointer in degrees of the scale.

This difficulty may be overcome in several ways. A table can be made for each instrument, giving a column of degrees, and adjacent to it a column of corresponding amperes; or, a curve may be made on cross-section paper, scaled in degrees horizontally and amperes vertically. The curve is preferable to the table in that it shows the exact current for every degree, while the table is not likely to be made with steps of less than five degrees, leaving the intermediate points to guesswork. On the other hand, it is much easier and quicker to read the table. The chief objection to both of these methods is that with even a slight change of the calibration of the instrument they become useless and must be re-calculated from the formula, using the new constant.

The ideal way of arriving at the desired result is by the use of the slide rule. By its use the constant of the instrument may be changed indefinitely and the complete table is always at hand. By simply setting the index or extreme left-hand mark of the C scale opposite the value of the constant on the D scale, the degrees of deflection may be read on the B scale, and the corresponding current will be directly below on the D scale. So, after correctly setting the slide, it is only necessary to use the runner or cursor. Thus, with a constant of 3.3, what is the current indicated by 8°? Set the left-hand end of the C scale at 3.3 on the D scale and slide the runner up to 8 on the B scale; at a glance at scale D it will be seen that the current is 9.33 amperes.

A word in regard to balancing dynamometers may not be out of place here, as the accuracy of the instrument largely depends upon the keeping of the two coils in proper relation to each other. First loosen the clamp that is always provided for holding the movable coil off the suspension when not in use. Some dynamometers are fitted with a spirit-level for balancing, but this is unnecessary. The inside terminal of the movable coil passes through a hole in a guide to keep it in proper position. By the manipulation of the three leveling screws on the bottom of the instrument the movable coil can be made to hang clear of the guide and in the center of the hole through which it passes; at the same time the pointer of the movable coil should rest on zero, when the torsion head pointer is also set on zero. At first this adjustment may cause some trouble, but after a little practice it will be easy. The object of this balancing is to bring the axes of the two coils coincident and their planes at right angles.

As the suspension locates the top of the movable coil we have the three points necessary for the location of the plane. Sometimes on account of the faulty setting of the spring, the pointer of the movable coil will not come back to zero with the bottom of the coil correctly located. In this case the torsion head pointer may be deflected forward or back until it does come to zero. After this, care must be taken to correct the reading of the torsion head pointer by the amount it was necessary to deflect it. Thus if the torsion head pointer was moved forward 4° to bring the pointer of the moving coil to zero, and on turning on the current it was necessary to move the torsion head pointer to 157° to take the reading, the correct reading would be 157° — 4° = 153°. This method does not materially affect the accuracy of the instrument.

Discovery of India Rubber on the Banks of the Amazon. — The discovery of large forests of caoutchouc or India rubber on the banks of the Niera, one of the branches of the Amazon, has lately been announced. The forests are situated about eight days' journey from the center of the great tobacco plantations. Several German houses have organized an expedition for the purpose of securing the right to gather the product of the district, the inhabitants of which are said to be so poor that it is possible to obtain the rubber at a very low cost. A special route has been projected by way of Iquitos, a town that offers the best advantages for the handling of the rubber after it has been gathered.

An Electrical Water Gauge.—An electrical indicator is employed with success by George Evans, who has charge of the electrical machinery at the big B. & M. smelter, Great Falls, Mont., for showing the height of water in a tank upon a butte several thousand feet from the works. A float is arranged so that it cuts in or out resistance in a circuit as the water rises and falls. The resistance is buried underneath the tank, so as not to be affected by the weather and changes in temperature. Down at the pumping station an ammeter is put in the circuit with its scale calibrated to correspond with the position of the float, so that the height of water in the tank is indicated directly by the ammeter needle.

RECENT TYPES OF AMERICAN AND EUROPEAN ENGINES.

NEW ENGINES FOR THE BROOKLYN EDISON PLANT.

In the leading article of our January number reference was made to the fact that two 5000-h.p. Westinghouse engines were in process of construction for the Bay Ridge station of the Brooklyn Edison Company. One of these engines has been completed and is now being erected in the station. The new engine differs considerably from engines of large output previously built by the Westinghouse Machine Works, as a glance at Fig. 4 will show. The engine is a cross-compound, with double-acting cylinders and Corliss valve-gear. The cylinders are 46 and 86 ins. in diameter, respectively, by 60 ins. stroke. The most economical rating of the engine at the normal speed of 75 r.p.m. is about 3750 horse-power, but the engine is capable of maintaining loads up to 7500 horse-power.

The valve-gear is a three-quarter cut-off Corliss gear, with straight motion on the steam side and a wrist-plate motion on the exhaust side; a heavy rocker-arm is interposed, of course, between the eccentric rod and the valve-gear proper on the steam side. The high-pressure valves have ⅝ in. lap and the low-pressure valves 1 in. lap, giving about 50° angular advance to the eccentric and obtaining thereby a comparatively quick opening of the valve. The complete gear is illustrated by Fig. 1 and a detail is shown to larger scale by Fig. 3. The designer, Mr. Cyrus Robinson, has departed from the usual construction in which the drop arm is put at the outer end of the valve stem, and has placed it inside the bonnet. This gives two bearings, one on each side, and allows the dash-pot to be located close to the cylinder, with a very short drop rod. This construction also permits the use of a long and large bearing for the hook and knock-off lever and allows the knock-off cams and governor connections to be placed at the outer position of the gear where they are more accessible. The valves are all of the double-ported Corliss type, located in the cylinder heads and as close together as possible so as to facilitate compact construction in the valve-gear. The cylinder clearances are 3 per cent in the high-pressure and 2 per cent in the low-pressure cylinders.

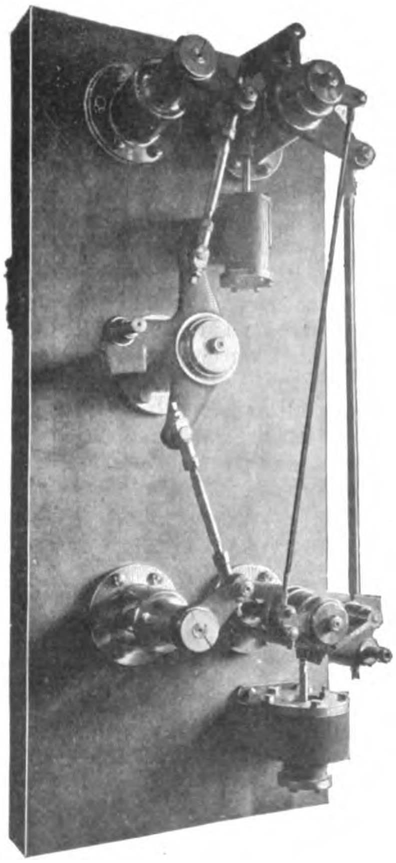

FIG. 1.—VIEW OF VALVE GEAR.

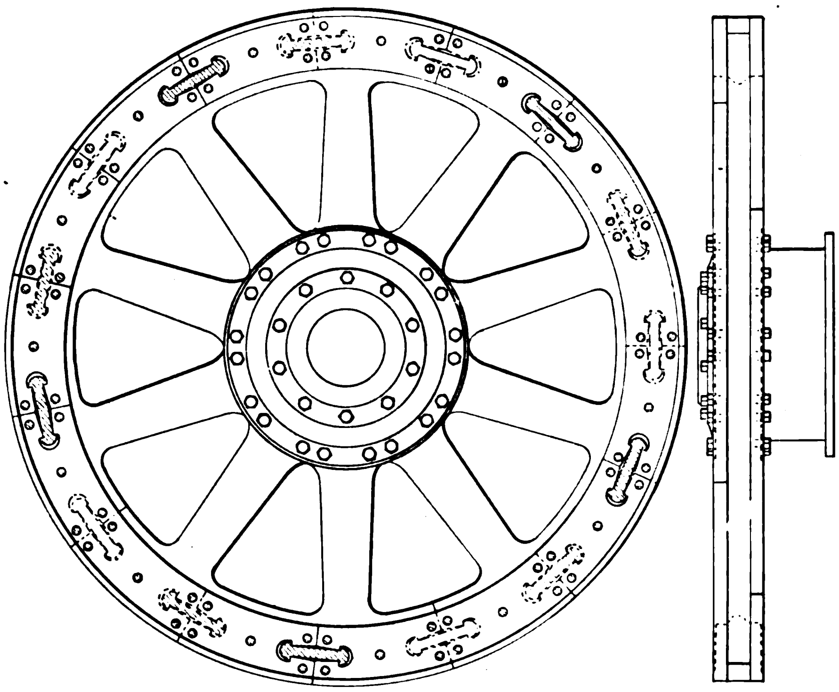

FIG. 2—THE BUILT-UP FLY-WHEEL.

Steam jackets are not used on either high-pressure or low-pressure cylinders. The Westinghouse Machine Company, builders of the engine, state that experience has convinced them that the value of a steam jacket becomes negative at about 600 ft. piston speed when the engine is in regular operation. A reheating receiver is employed; the reheater comprises 109 tubes, 12 ft. 6 ins. long and 3¼ ins. in diameter, giving a total heating surface of about 1500 sq. ft. It has been from time to time strongly advocated that reheaters proportioned to 1 sq. ft. per indicated horse-power should be used on cross-compound engines, but the builders say that their experience has shown such a reheater to have a negative value. A reheater of about the proportions used on this engine has value on light loads and in starting, and does not cut down the economy at full load. Steam at boiler pressure is used on the outside of the reheater tubes, the cylinder steam passing through them.

The connecting-rods are solid steel forgings, having solid ends and wedge-adjusted boxes; the length between box centers is 13 ft. 9 ins., which is 5½ crank lengths. The cross-head pins are 14 ins. in diameter and 14 ins. long; the crank-pins are the same size.

The shaft is a hydraulic forging of open-hearth steel, hollow throughout its length. The diameters are 39 ins. within the fly-wheel and 34 ins. in the bearings. The diameter of the hole through the center is 16 ins. The shaft weighs about 75,000 lbs., without the crank cheeks or the fly-wheel center. The cranks are of the fan-tail pattern and set 90° apart. The

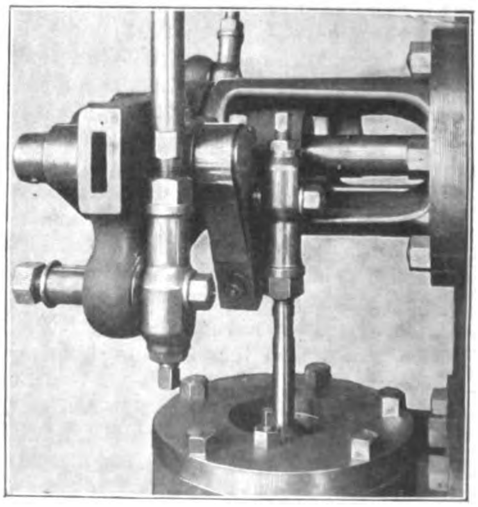

FIG. 3.—DETAIL OF VALVE GEAR.

fly-wheel is of the built-up type and is shown by Fig. 2. The construction is somewhat novel and is, we believe, original with the Westinghouse Machine Company. The fly-wheel segments and arms are made of cast-steel and the fly-wheel center is of air furnace iron. There are five center rim segments, each of which is cast integral with two of the arms; the use of five segments obviously prevents any two joints from coming diametrically opposite. The width across the face of the center rim segments is 12 ins. On each side of the center segments are disposed five plates, 6½ ins. wide, linked together and so located as to break joints with each other and with the center segments of the rim. These side plates are se-

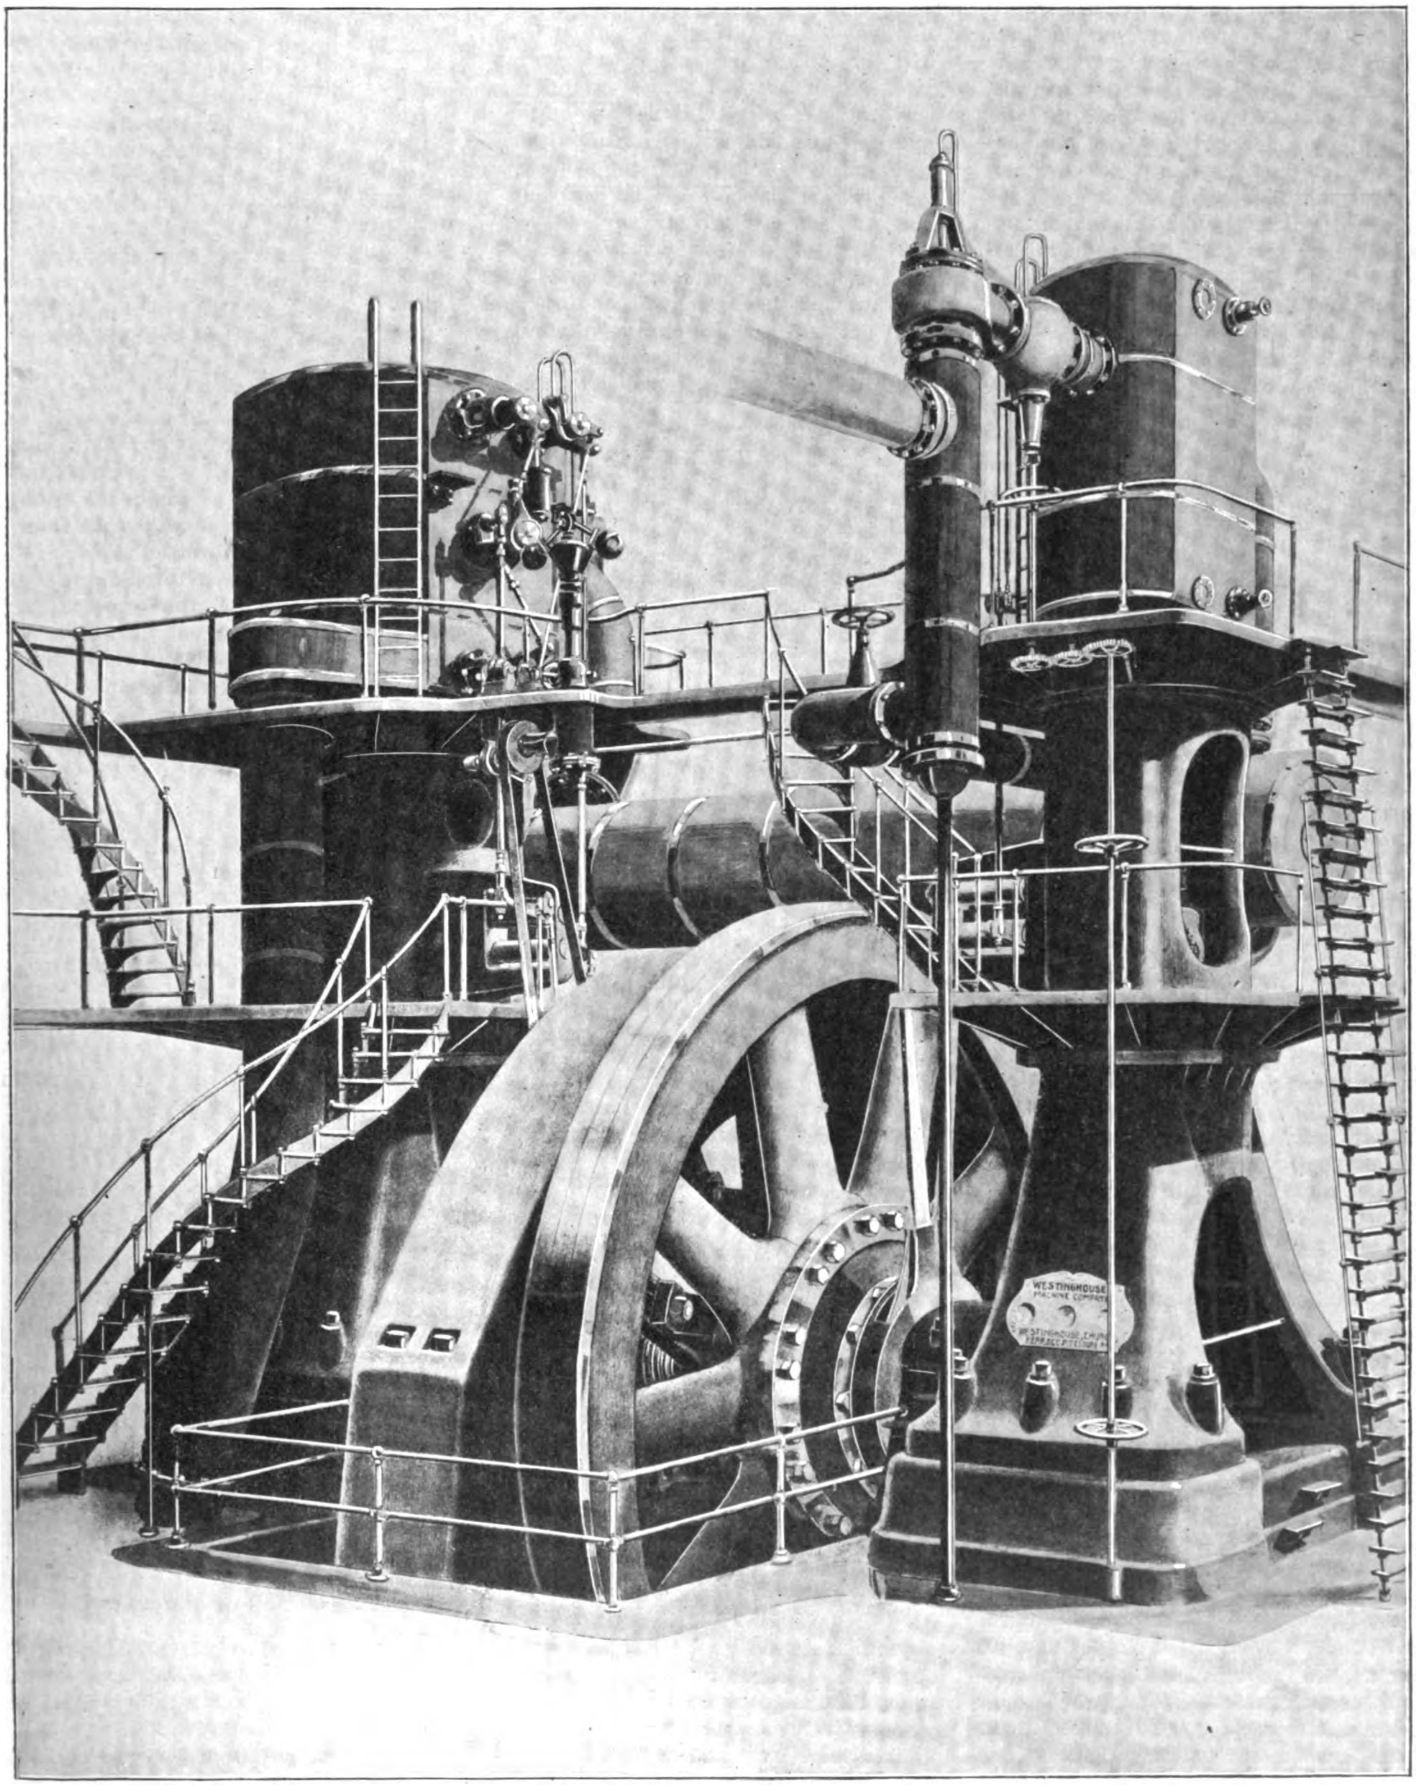

FIG. 4.—5000-H.P. CROSS-COMPOUND WESTINGHOUSE-CORLISS ENGINE FOR THE BAY RIDGE STATION, BROOKLYN.

cured to the center segments by means of 3¼-in. rivets. This construction results in practically three fly-wheels, each self-supporting as to centrifugal force. The outside segments bring no strain on the center segments, except that due to inertia effects. In the usual form of wheel embodying plate construction, the entire strain is liable to be brought on the links joining the center segments; with the construction here used this is impossible. The unshaded links in Fig. 2 are those of the center segments; the shaded ones are those which bind the side plates together. Fig. 6 is a semi-sectional edge view of the drum which is interposed between the fly-wheel and the rotating member of the alternator.

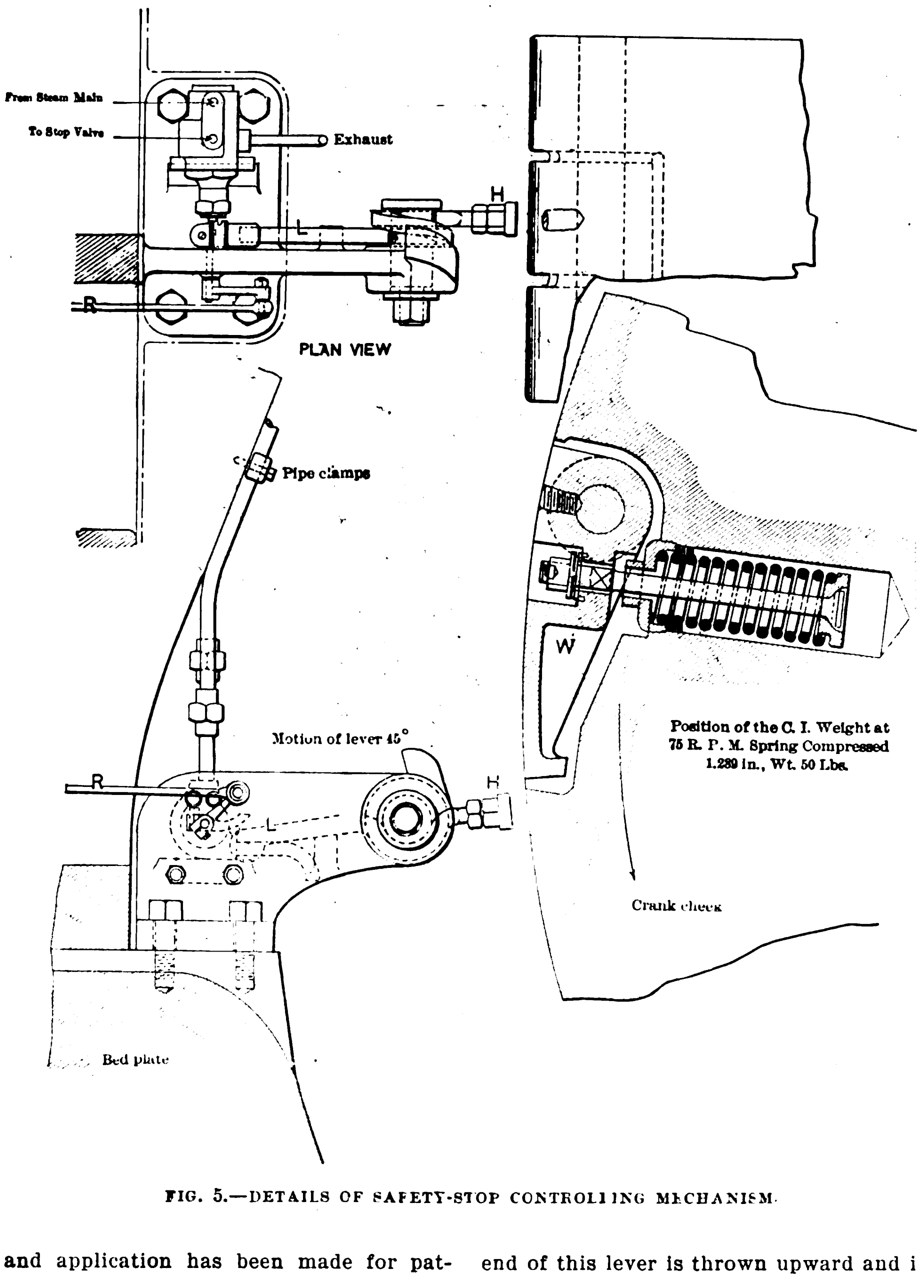

FIG. 5.—DETAILS OF SAFETY-STOP CONTROLLING MECHANISM.

Probably the most novel feature of the engine is the safety stop with which it is provided. This arrangement is original with the Westinghouse Machine Company and application has been made for patents covering it. The principal features of the safety stop are illustrated by Figs. 5 and 7, the latter illustration showing the stop valve itself, which is of the piston type. Under normal conditions the small cylinder in which the actuating piston, P, travels is open to the atmosphere so that the steam pressure in the main keeps the valve up. The pipe communicating with the upper cylinder terminates at its far end in a three-way valve which, when thrown out of the normal position, admits steam to the cylinder and closes the valve.

The controlling mechanism is shown in Fig. 6. A comparatively small weight, W, is pivoted in a recess in the face of the crank cheek and is normally held within the limits of the outline of the cheek by the helical spring shown. This spring is adjustable, of course, for any desired speed limit beyond which centrifugal force acting upon the weight overcomes the spring and throws the free end of the weight outward, when it engages the buffer head, H, on the short end of a lever pivoted on the engine frame. The long end of this lever is thrown upward and in its flight impinges upon the lever of the three-way valve above referred to, throwing this valve over and admitting steam above the actuating piston of the safety stop valve. The three-way valve is reset by means of the rod, R, which extends to the outer part of the engine frame within reach of the attendant. This also provides a means for shutting down the engine more quickly than could be done in the regular way should it be desirable to do so. When the three-way valve is reset it exhausts steam from above the piston of the stop valve and the latter is automatically reset by the steam pressure below it. It is evident that in case steam is shut off from the supply main the stop valve will drop by its own weight and close the port of the throttle valve.

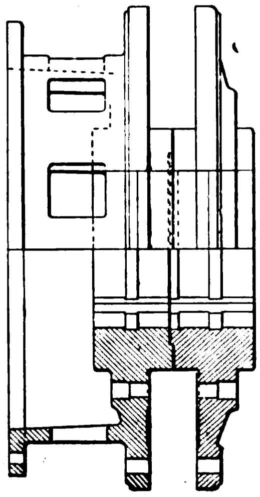

FIG. 6.—SEMI SECTIONAL EDGE VIEW OF DRUM.

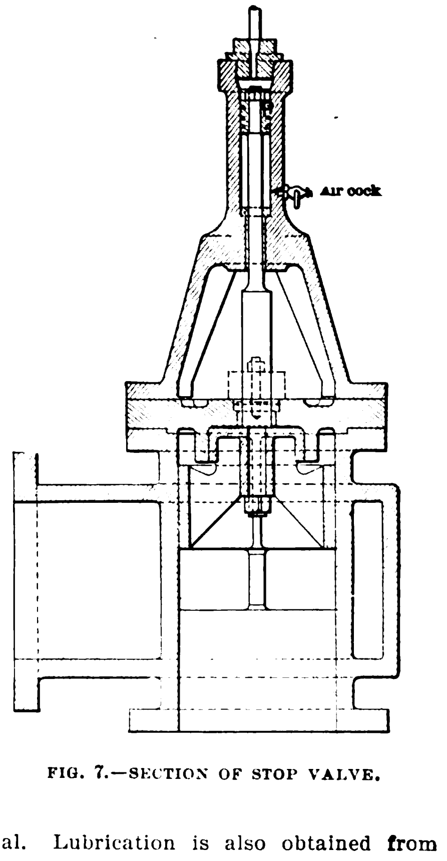

FIG. 7.—SECTION OF STOP VALVE.

The engine is arranged throughout for pressure lubrication, all the connections being brought to one point in which is placed a 1½-in. globe valve, which when closed shuts the oil off the engine. The main bearings are arranged so that a pressure of oil can be brought to bear at four points on the underside of the journal. Lubrication is also obtained from above the journal. The cylinders are lubricated by means of five feed pumps; there are three points of feed on the upper steam valve and two points of feed on the lower steam valve.

A RUSSIAN ENGINE FOR ELECTRIC LIGHTING SERVICE.

The use of variable cut-off for the regulation of speed, which has long been the universal practice of American steam-engine builders, is also becoming general among European manufacturers; this method being now used on the majority of engines designed for electric-light service excepting those built in England, many of which are still regulated by means of throttling governors. A recent type of engine in which is employed a variable cut-off mechanism of novel design is one built by Bromley Brothers, of Moscow, Russia. The accompanying engravings illustrate a triple-expansion engine of this type (together with the details of the valve gear) which was shown driving a Brown, Boveri & Co. alternator at the recent Paris Exposition. Fig. 1 is a sectional plan view from which it will be seen that the high-pressure and intermediate cylinders are mounted tandem and deliver power to a single piston rod, the low-pressure cylinder delivering power to a separate crank set 90° from the high-pressure crank. Between the two cranks the alternator is mounted. This is a revolving-field machine with the field magnet external to the stationary armature. The engine is provided with secondary valve-gear shafts mounted parallel to the cylinders and driven from the main shaft by bevel gears, which arrangement has become common practice with the builders in Continental Europe. The high-pressure cylinder is 13.386 ins. in diameter, the intermediate cylinder 21.65 ins. in diameter, and the low-pressure cylinder is 22.28 ins. in diameter. The stroke of the engine is 31.89 ins. All of the cylinders are steam jacketed; the live steam from the boiler passes through the jacket of the high-pressure cylinder before entering the steam chest, and the exhaust from this cylinder passes through the jacket of the intermediate cylinder before entering the steam chest of that cylinder; the exhaust from the intermediate cylinder in turn passes to the jacket of the low-pressure cylinder on its way to the steam chest.

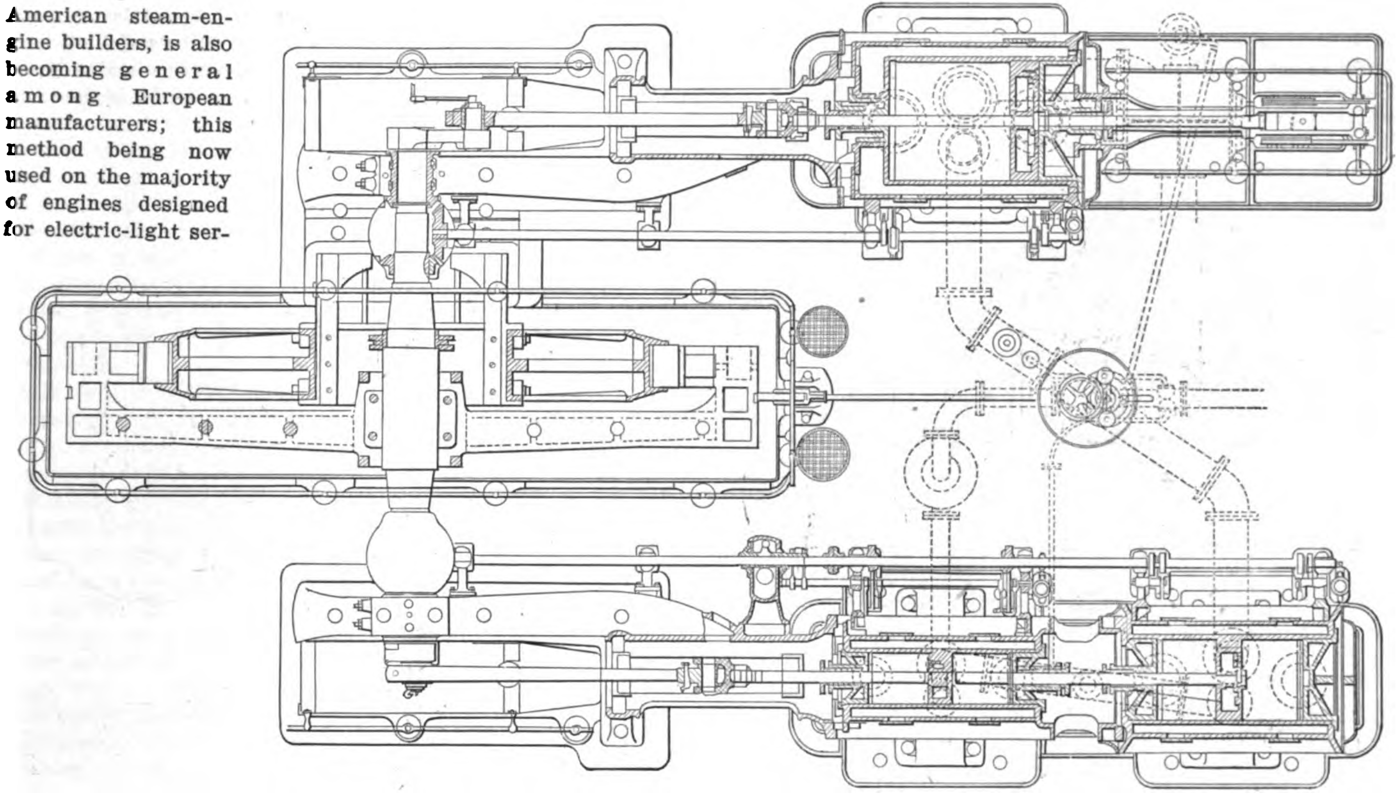

FIG. 1.—SECTIONAL PLAN VIEW OF ENGINE AND ALTERNATOR.

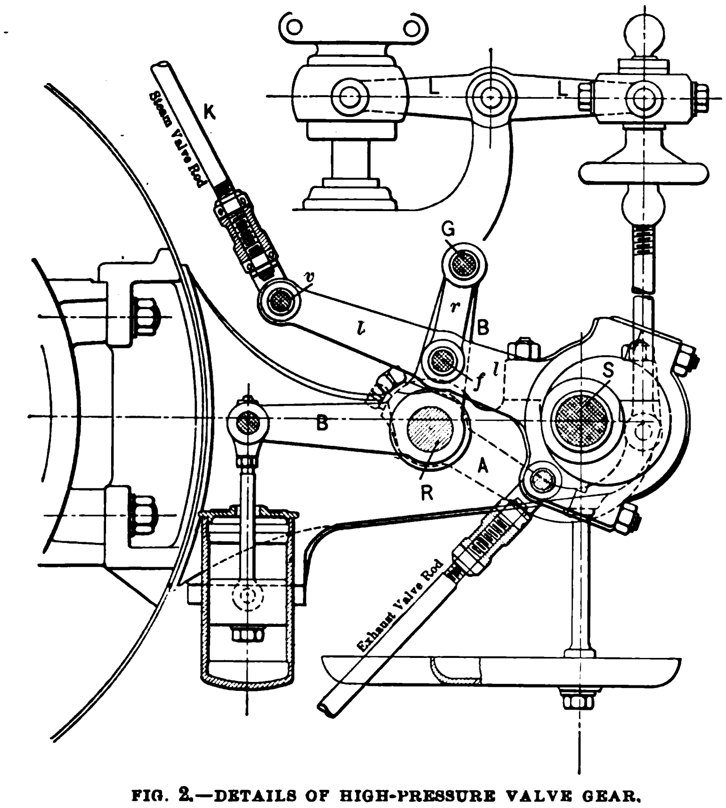

FIG. 2.—DETAILS OF HIGH-PRESSURE VALVE GEAR.

The valves are of the double-beat lift type, opened positively by the valve gear and closed by means of coiled springs applied to the valve stem, as shown in all of the engravings except Fig. 1. The steam valves of all the cylinders are on top, and the exhaust valves are beneath the cylinders. The governing is done exclusively in the high-pressure cylinder, the cut-off being fixed at the other two cylinders. Fig. 2 shows the details of the high-pressure valve gear at one end of the cylinder. The steam valve is lifted by means of a rod extending diagonally upward from the pivot, *v*, at the extreme end of the eccentric lever, or arm, *l*. The eccentric block is mounted on the secondary shaft, S, which was above referred to, and reciprocates about a fulcrum, *f*, which is a pin fixed in the end of a lever, *r*, hung from a pin, G, at the extremity of one arm of a bell-crank lever, B, B. This lever is mounted rigidly on a rock-shaft, R, and its position is controlled by the governor through the curved lever, A, attached to the same rock-shaft, and the governor rod leading up from the end of this lever to the horizontal arm, L. The right-hand end of the eccentric arm, or lever, *l*, is integral with the eccentric strap. It is obvious that the rotation of the eccentric block causes the lever, *l*, to oscillate about the fulcrum, *f*, giving the valve rod a reciprocating motion.

The point of cut-off is varied by the governor by twisting the rock-shaft and shifting the position of the pin, G. The motion of the eccentric arm, *l*, is not merely of an oscillating character; the arm reciprocates toward and away from the secondary shaft, and the movement of the pin, G, therefore varies the amount of travel given to the valve rod, which is due to the combined oscillation and endwise reciprocation of the eccentric arm, *l*.

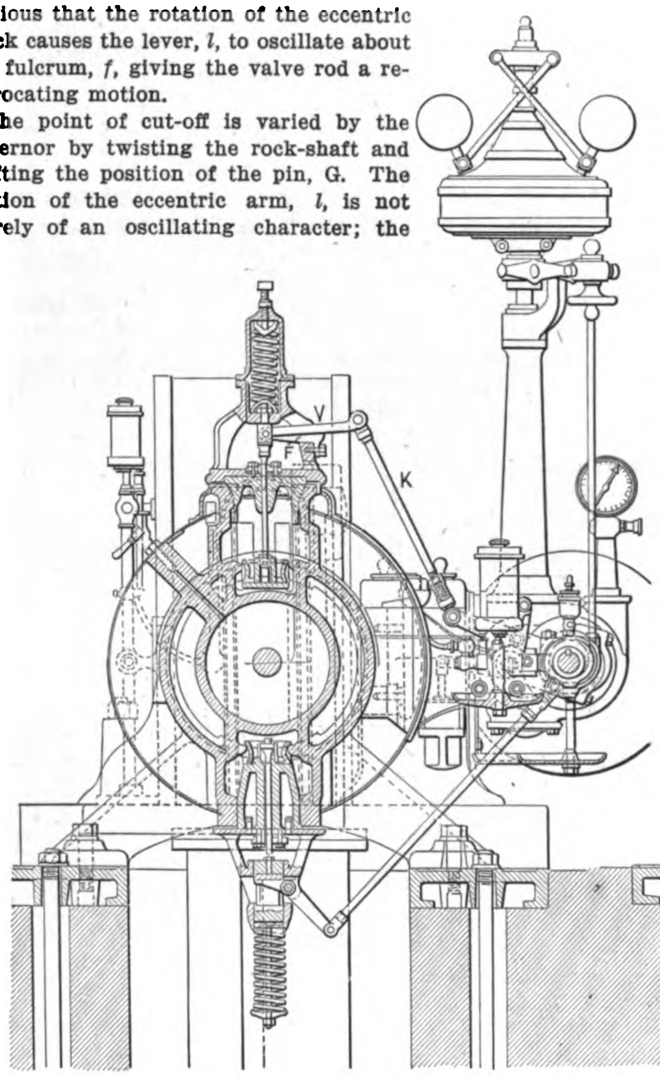

FIG. 3.—VALVE GEAR OF HIGH-PRESSURE CYLINDER.

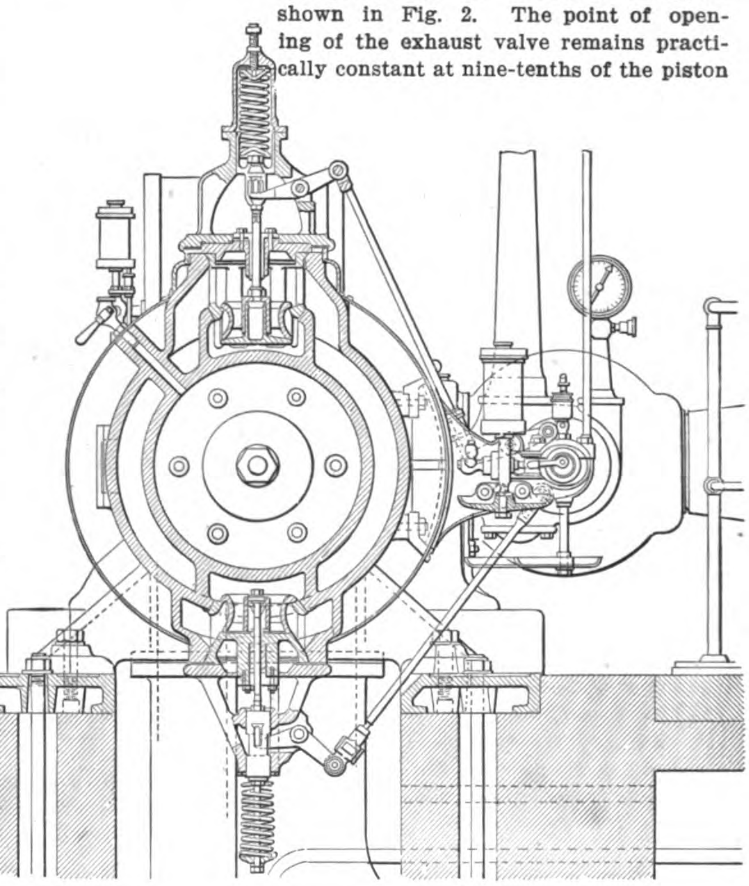

FIG. 4—VALVE GEAR OF INTERMEDIATE CYLINDER.

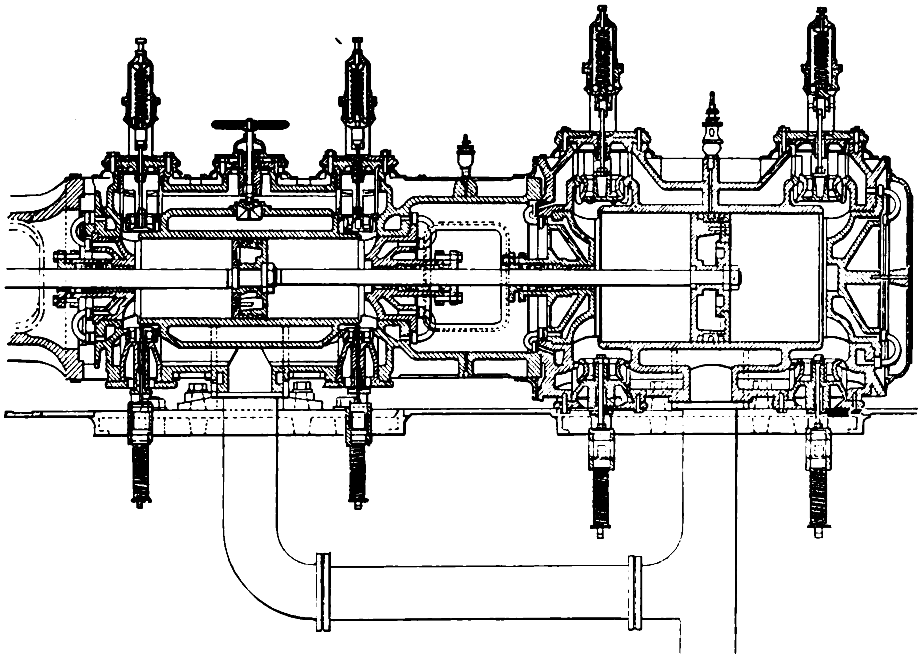

FIG. 5.—SECTIONAL VIEW OF HIGH-PRESSURE AND INTERMEDIATE CYLINDERS.

The effect of throwing the pin, G, over to the left is to give a later cut-off, as the travel of the steam-valve rod is increased. The rock-shaft, R, extends along the full length of the high-pressure cylinder and carries a duplicate mechanism at the other end of the cylinder for the operation of the steam valve at that end. The movement of the governor is damped by means of the dash pot, the piston of which is attached to the horizontal arm of the bell-crank lever, B.

The exhaust valves of the high-pressure cylinder are operated by rods extending diagonally downward from the valve gear and pivoted to the eccentric strap, as shown in Fig. 2. The point of opening of the exhaust valve remains practically constant at nine-tenths of the piston stroke, and the point of closing is fixed at 88 per cent of the succeeding stroke, so that the compression remains constant.

Fig. 3 shows the complete valve gear at one end of the high-pressure cylinder; the steam-valve rod, K, is pivoted at its upper end to a horizontal lever, V, the under surface of which is slightly convex and rolls on the flat horizontal surface of the steel fulcrum plate, F. The left-hand end of the lever, V, is pivoted to the valve stem. The effect of the arrangement described is to rapidly shift the fulcrum, which is the point of contact between the lever, V, and the plate, F, from the left-hand end of the lever over to the right as the valve is lifted. When the outer end of the lever starts downward under the pull of the rod, K, the fulcrum is at the extreme left-hand end of the plate, F. Owing to the convex under surface of the lever, V, a very small motion on the part of the lever serves to shift the fulcrum along the plate, F, until it reaches the extreme right-hand end of that plate. The ratio between the movement of the outer end of the lever and the valve stem is thus changed from a very high to a very low one; when the valve first starts to open the ratio is about 10 to 1, but is rapidly shifted to a ratio of 2 to 3, giving the valve a very rapid opening. The converse, of course, is true when the valve closes; it starts down at a comparatively high rate, which is lessened as it approaches its seat, by reason of the fulcrum being shifted along the plate, F, so that when the valve is finally seated it is done very quietly.

Fig. 4 shows the valve gear of the intermediate cylinder, which is the same as that of the low-pressure cylinder. Here the valves have a fixed travel and are operated by cams on the secondary shaft in connection with steel rollers. The steam-valve rod is attached to rocker-arms at both ends, the lower rocker-arm carrying a steel roller at one end which bears on the cam on the secondary shaft. The upper rocker-arm is bifurcated at the left-hand end and the bifurcations are provided with seats for a knife-edge on the valve spindle.

Fig. 5 is a sectional elevation of the high-pressure and intermediate cylinders, and Fig. 6 is a similar elevation of the low-pressure cylinder and the air pump. The piston rod of the low-pressure cylinder is extended through the back cylinder head and drives the air pump through the medium of a rocker-arm and links, as shown in Fig. 6. The tail-rod or rear extension of the piston rod does not depend for alignment upon the stuffing box through which it passes, but is provided with a cross-head shoe which travels along cross-head guides in the rear of the cylinder. The rocker-arm is pivoted far enough below its center to reduce the stroke of the air pump to about three-eighths of the stroke of the engine.

A peculiar feature of the air pump is that the connecting-rod which transmits the motion of the rocker-arm to the pump plunger is located within the pump piston rod. This is done, of course, in order to economize space, and also to minimize the side thrust of the pump piston rod upon the glands, the latter object being attained by the use of the unusually long connecting-rod, which is over 3 ft. long. The stroke of the air pump is 11.81 ins. and the diameter of the piston is 13 ins. The pump is double acting. The valves are rubber discs held down by conical spiral springs. The gland of each connecting-rod stuffing box is perforated in order to allow the leakage water to escape.

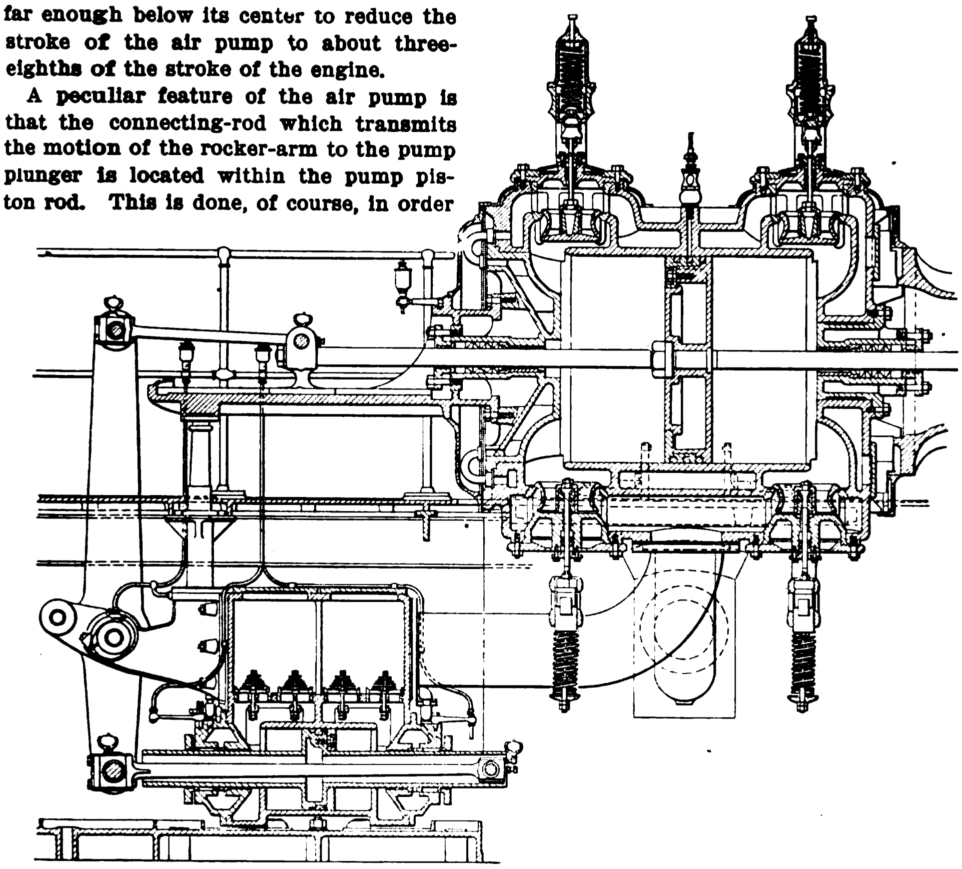

FIG. 6.—SECTIONAL VIEW OF LOW-PRESSURE CYLINDER AND AIR PUMP.

A jet condenser is used with the engine. With a condenser vacuum of 26 ins., a steam pressure of 175 lbs., and 28 per cent cut-off, the engine develops 350 horse-power; the normal speed is 92½ r.p.m. Without superheat, but with ordinarily dry steam supply, the steam consumption is said to be 13.23 lbs. per hour per horse-power.

STEAM ENGINE EFFICIENCIES.

BY A. F. NAGLE.

The engineer in charge of a plant hears a great deal about the "efficiency" of engines, but the word needs to be explained in order to be intelligently understood. "Efficiency" is a word which has come into use in engineering literature as an expression of the relation between actual results obtained in practice, and what might be expected under ideal, or theoretical, conditions. It is generally expressed in percentage, the ideal being taken at 100 per cent; the actual results obtained will be something less, of course, 50 per cent or 80 per cent, as the case may be. It is a really good word, for it gives the mind a clear idea of the relation of things and helps to suggest the probable amount of improvement one may look forward to.

Let us take a look at some of the different elements of the steam plant which are now compared by their efficiencies. To begin with, we have the furnace. It is possible to analyze coal by chemical methods, or, what is better yet, it can be burned in a coal calorimeter by means of oxygen gas, and thus the amount of potential heat which it contains can be accurately ascertained. It has been found that a pound of pure coal contains 14,500 B. T. U. (heat units). A rich bituminous coal will contain about 15,000 B. T. U., but the cheaper grades run in the neighborhood of 10,000 B. T. U. For scientific determinations it is useless.to speak of a pound of coal unless its calorific value, or heat-giving qualities, be stated. It is perfectly practical to transmit 85 per cent of the potential heat in the coal into the steam in a boiler. About eight per cent will go up the chimney, three per cent will be lost in radiation and cooling effects and four per cent will be lost by excessive air admission to the furnace. Owing to the difficulty and expense involved in ferreting out all of these various losses it is customary to group them all together and speak of the efficiency of the boiler as a whole.

The efficiency of a boiler may be accurately ascertained by testing the quality of the coal, weighing the amount burned, measuring the feed-water which goes into the boiler, and taking its temperature and the steam pressure. If, then, we can, by good design and construction, convert 85 per cent of the heat of the coal into steam, the efficiency of the boiler plant may be considered as having reached a very high state of perfection and but little, if any more, can be expected to be accomplished in the future. In general practice the results are not so good as this, 60 per cent and 65 per cent being nearer usual practice, but there is nothing in the nature of things, if we choose to pay for the talent and apparatus, to prevent us from realizing 85 per cent of the heat units contained in the coal. If the boiler can do so well as this, why cannot the engine do as well and convert, say, 85 per cent of the total heat delivered to it into power? The answer is, simply because it is a physical impossibility; the engine can do and does, however, convert almost that percentage of the available heat into power. The trouble is that the amount of heat available is only a comparatively small proportion of the total heat in the steam.

The only fair method, therefore, of considering the work done by an engine is to compare it with the maximum amount of work theoretically obtainable from the steam. Take the case, for example, of a multiple-expansion engine supplied with steam at 150 lbs. boiler pressure, working with 30 expansions and a condenser vacuum of 27.88 ins., giving a back pressure of one pound, and assume that the engine consumes 12 lbs. of steam per indicated horse-power-hour. The formula for calculating the amount of work which these 12 lbs. of steam should do is as follows:

$$W = \left[\frac{P\,(1 + \text{hyp. log. } R)}{R} - p \right] \times 144 \times R \times C \times S$$

P = absolute initial pressure = 165 lbs.
p = absolute condenser pressure = 1 lb.
R = number of expansions = 30.
C = cubic feet per pound of steam = 2.72.
S = pounds of steam used per i.h.p. per hour = 12.

Making the proper substitutions we have:

$$W = \left[\frac{165\,(1 + 3.4)}{30} - 1 \right] \times 144 \times 30 \times 2.72 \times 12 = 3{,}271{,}312 \text{ foot-pounds.}$$

As a horse-power = 1,980,000 foot-pounds per hour, the efficiency of the engine as a converter of available energy would be:

$$\frac{1{,}980{,}000 \times 100}{3{,}271{,}312} = 60 \text{ per cent.}$$

Now, here we have a fairly definite expression of how near we come to what might be done. With the use of superheated steam, which almost eliminates the loss due to condensation, and by otherwise improving the design and construction of the engine, it is claimed that engines can and do run on 9 lbs. of steam per indicated horse-power per hour. That would represent an efficiency of $\frac{12 \times 60}{9} =$ 80 per cent, which would be as near perfection as human skill and intelligence could be expected to come. Combining such an engine with a boiler of 85 per cent efficiency, the resultant would be a plant efficiency of 68 per cent, ignoring the small pipe losses.

If we should follow the custom of considering the potential energy in coal as something that may be utilized entirely, and compare this with the amount of work actually obtained, the result would be very misleading. Thus a pound of coal containing 14,500 B.T.U. has a potential energy of 14,500 × 778 = 11,281,000 foot-pounds. Assuming that the feed water was supplied to the boiler at a temperature of 198° and that 85 per cent of the heat of the coal was imparted to the water, it would require one pound of coal per hour to generate 12 lbs. of steam at a gauge pressure of 150 lbs., so that we should be obtaining a horse-power with one pound of coal an hour, which is a most excellent result. On the basis of reckoning from the total potential energy of the coal, however, the efficiency of the boiler and engine would only be

$$\frac{1{,}980{,}000 \times 100}{11{,}281{,}000} = 17.5 \text{ per cent,}$$

whereas we are entitled to claim 68 per cent, as shown by the numerical example above.

Abstracts from Foreign Contemporaries

Magnetic Blow-out for Railway Controllers.—In an article contributed to the "Elektrotechnische Zeitschrift" on the control of railway motors, Herr K. Sieber describes a magnetic blow-out designed and used by him, and attached as shown by Fig. 1. The contact arm, originally constructed as shown by Fig. 2, is replaced by a magnet, through the windings of which the current conveyed to the laminations must first pass. In order to close the magnetic circuit, iron plates are placed under the laminations. The lines of force being concentrated at the points where they are required, but a few turns are needed in order to secure a powerful action. Only part of the contact arm is arranged for spark extinguishing.

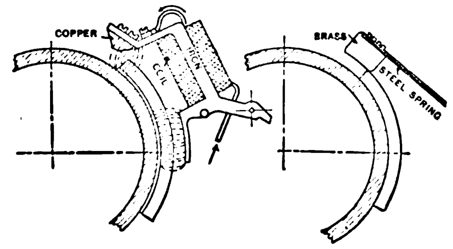

FIG. 1.—MAGNETIC BLOW-OUT--FIG. 2.

Avoiding No-Load Loss in Transformers.—The accompanying illustration taken from a recent issue of the "Zeitschrift fuer Elektrotechnik" depicts a simple method devised by M. Osnos for cutting in and out of circuit transformers supplying motors, the method being to switch out the primary winding of the transformer; the no-load loss in the transformer is consequently avoided. In Fig. 3 M is an alternating-current motor, PP, are the terminals of the high-tension supply circuit, B is a battery, U is a switch, S is a coil with an iron core, K, and R and R_1 are non-inductive resistances. To connect the motor to the circuit, the switch U is placed on contact, 2. A current from the battery traverses the solenoid, S, magnetizing the iron core, causing it to attract the iron shoulder of the lever, L. This releases the core which drops of its own weight, engaging the lever, l, which switches in the primary winding. The motor now running, the switch may be returned to its middle position. To throw the motor out of circuit, the switch is placed on contact, 1, whereupon an alternating current from the secondary of the transformer traverses the solenoid causing it to lift the iron core. This in its upward motion engages the lever, l, which opens the circuit through the primary winding. The core then drops to the position shown in the engraving, where it is held by the lever, L. It is evident that the arrangement may be also applied to a direct-current motor and that the switch, l, may be double-pole instead of single, as shown in the engraving.

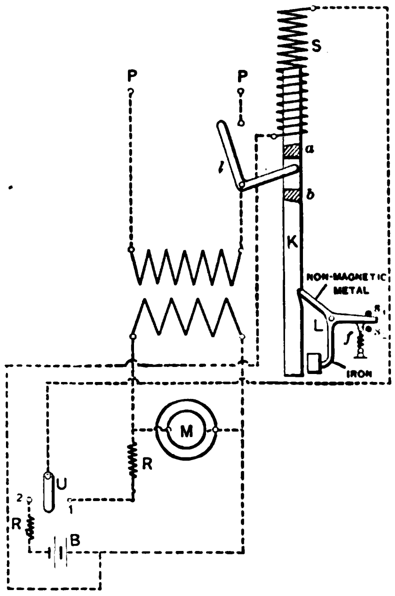

FIG. 3.—TRANSFORMER CONNECTIONS.

Testing Alternating Current Meters on Artificial Loads.—It is usually desirable when testing instruments for the measurement of large amounts of energy to do so by means of artificial loads. While this is a comparatively easy matter with direct currents, in alternating-current work there is encountered the difficulty of keeping the current and e.m.f. in phase with each other. Albert Campbell, in the London "Electrician," describes the arrangement shown by Fig. 4, which he has found convenient for this purpose. Suppose, for example, the artificial load required is 500 amperes at 100 volts. A transformer, T, with its primary supplied at 100 volts, delivers at its secondary 500 amperes at 5 or 6 volts. Connected in series on the secondary circuit are the series coil of the instrument, M, under test, an ammeter, A, and a non-inductive resistance, R, which will pass 500 amperes at about 5 volts. The low-pressure coil of a closed iron-circuit transformer, t, of a ratio of 1:20 is connected to suitable points of this resistance. The high-pressure coil of this transformer furnishes the e.m.f. required for the shunt coil of the instrument being tested. It will be found that the e.m.f. is practically in phase with the current of 500 amperes.

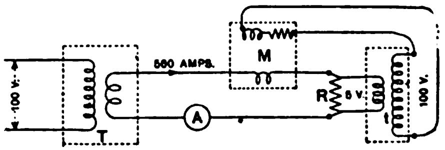

FIG. 4.—ALTERNATING-CURRENT METER TEST.

Pole Finders.—It is oftentimes necessary, especially in charging accumulators, to determine the poles of the circuit used. Aside from using deflecting electrical instruments or pocket compass, the "Elektrotechnischer Anzeiger" gives a number of other methods. Wilkes' reagent paper and the ordinary litmus paper will determine the poles when the difference of potential is as low as 1 volt; Wilkes' reagent paper giving a red spot at the negative terminal, while litmus paper gives a red spot at the positive terminal. Paper moistened with a solution of iodic arsenite of potassium yields a black color at the positive terminal. Berghausen's pole-seeker consists of a solution of phenol phthalein and chloride of sodium or sodium sulphate which gives a red color at the negative terminal; the color vanishing when the current is off. When lead electrodes are used in dilute sulphuric acid, the positive electrode becomes dark brown, owing to the formation of a peroxide, while with copper electrodes a violent evolution of gas takes place at the positive electrode. In a solution of common salt the positive copper electrode imparts a green color to the solution, the plate itself becoming somewhat reddened.

Method of Measuring Power in Alternating-Current Circuits.—The three-volt meter method of measuring power, although convenient and accurate, is not altogether free from error, especially if but one voltmeter be used; and the auxiliary non-inductive resistance is usually so large that a considerable fraction of the total available voltage is lost. In a method described by Albert Campbell in a recent number of the London "Electrician," this difficulty is entirely eliminated, not more than 1 per cent of the available voltage being lost. The connections are shown in Fig. 5. A is the circuit the power of which is to be measured. It is connected in series with a small non-inductive resistance, r, across the supply circuit. The small difference of potential between the terminals of r is raised by a small transformer, N, having a high ratio of transformation; which ratio must be sufficient to make the primary current negligible in comparison with the current in A. The power phase of the e.m.f., V., will be practically 180° behind that of U. By means of the reversing switch, H, and the electrostatic voltmeter, D, the effective resultants of e.m.f., x, and the e.m.f., V, with the latter reversed and direct, can be obtained.

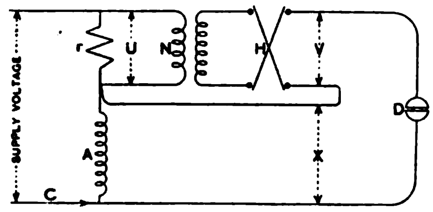

FIG. 5.—DIAGRAM OF CONNECTIONS.

Alternating Current Watt-hour Meter.—What purports to be one of the cheapest and simplest meters for alternating currents is described in a recent issue of the London "Electrical Review." It consists of a revolving disc, A (Fig. 8), subjected to the action of two alternating magnetic fields, differing in phase, which impress a driving force upon it. Potential coils, S, S_2, and a main current bobbin, H (Fig. 9), are placed at one side of the disc, their cores being connected to a single yoke, E, and the magnetic circuit completed by a single armature, R. In operation the shunt bobbins, S, S_2, impart a moderately strong turning movement to the disc which is utilized in overcoming the friction of the apparatus by adjusting the air space, L, L_2. When the main current is turned on, a mutual action takes place between the magnetic field of the main current and the vortex currents generated in the disc by the shunt bobbins on the one hand, and between the magnetic fields of the shunt bobbins and the vortex currents generated by the main current bobbin on the other hand, resulting in the rotation of the disc. To prevent the field of the main current bobbin acting upon the fields of the shunt bobbins, a part of the main current circuit is wound about one of the shunt cores as shown in Fig. 9. The speed of rotation imparted to the disc is directly proportional to the product of the current and the pressure, and is transmitted to a counting mechanism by worm gearing, the magnet, M, acting as a brake to the disc. The reading is in kilowatt-hours and is shown in a single row of figures on the face of the meter. No reduction is necessary, since the constant of the instrument is always unity.

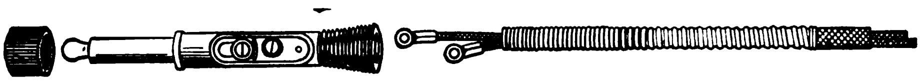

FIG. 6.—TELEPHONE CIRCUIT PLUG.—FIG. 7.

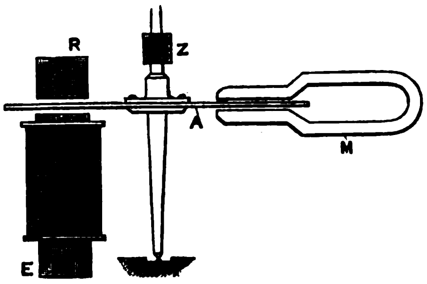

FIG. 8.—DISC AND MAGNETS.

A New Circuit Plug.—A recent number of the "Elektrotechnischer Anzeiger" contains a description of a new circuit plug illustrated herewith. The wires are double cotton covered each wound separately with different colored silk in order to differentiate the poles. Both are then wound with glazed yarn and are further strengthened by a winding of thin whipcord, or gut-string. Contacts are soldered on the ends as shown in Fig. 7. The cord is then passed into the circuit plug and the terminals securely fastened by screws as shown in Fig. 6. The small chuck at the right firmly clamps the cord for some distance, and together with the screwed contacts renders less liable ruptured plugs resulting from rough usage.

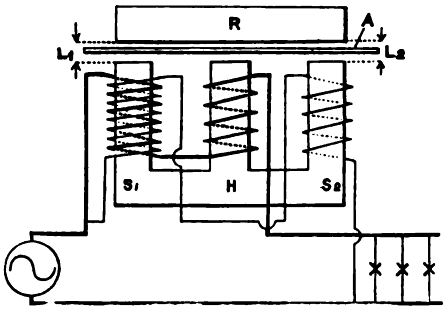

FIG. 9.—DIAGRAM OF WINDINGS.

Commercial Nernst Lamps.—The London "Electrical Review" has described some commercial forms of Nernst lamps as they are being made by the Nernst Electric Light Company, Ltd., of Great Britain. Fig. 10 shows a 16-c.p. lamp designed to be lighted by heat applied from the outside through a hole in the bottom of the globe, and Fig. 11 shows the interior parts of this lamp. The top of the lamp consists of a brass cap with a bayonet lock for holding the globe in position. This cap contains two metal hooks to which the leading-in wires are attached. The glow rod or burner is suspended from a porcelain block by means of nickel connecting wires. The series-resistance coil which is used to compensate for the negative-temperature coefficient of the glow rod, consists of a very fine platinum wire wound on a triangular piece of porcelain and suspended just below the porcelain block. The two contact strips projecting above the upper side of the block constitute the terminals of the arrangement, and these hang from the hook terminals within the brass cap. Fig. 12 shows an automatic 16-c.p. lamp, and Fig. 13 shows diagrammatically the arrangement of the parts of this lamp. A heating coil is em-

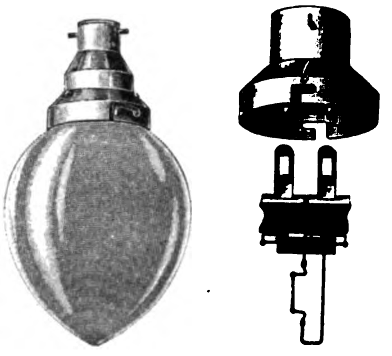

FIG. 10.—16-C.P. NERNST LAMP.—FIG. 11.

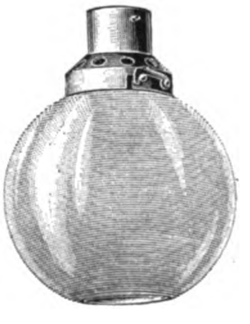

FIG. 12.

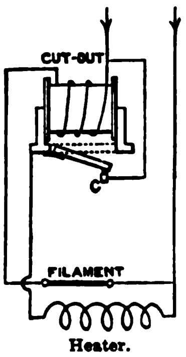

FIG. 13.

ployed, which is mounted below the glow rod, and is cut out of circuit by the relay as soon as current begins to flow through the glow rod. The relay is mounted in the top of the lamp or socket. The life of the glow rod is said to be about 500 hours, and the efficiency slowly falls from 1.7 to 2 watts per candle. When used on direct-current circuits, the positive end of the glow rod tends to get excessively hot, and in order to prevent this the platinum connections at each end of the glow rod have been made with a little star-shaped piece which provides a radiating surface and keeps down the temperature. These lamps are standardized for 8, 16, 32 and other candle-powers, to operate on circuits of 100 volts and upward.

Test of a Large Gas Engine Using Producer Glass.—An elaborate paper which was read recently by Mr. Herbert A. Humphrey before the British Institution of Mechanical Engineers included some important records of gas-engine trials using producer gas made from cheap fuel by the Mond process. The fuel used in the manufacture of the gas was bituminous slack containing 62.69 per cent of carbon and having a calorific value of 12,215 B. T. U. per pound of dry fuel. This coal produced 59.2 cu. ft. of dry gas (at 32° Fahr.) per pound of fuel, and the calorific value of the gas was 158.8 B. T. U. per cubic foot at that temperature. Fig. 14 is a diagram of the apparatus. The Mond process consists broadly of feeding the bituminous slack into a bell or retort at the top of the producer, where it is first heated. The products of distillation pass downward into the hot zone of fuel before joining the bulk of the gas leaving the producer; this destroys the tar and converts it into a fixed gas, and also prepares the slack for its descent into the body of the producer, where it is acted upon by an air blast saturated with steam at 185° Fahr., and is thus superheated before coming into actual contact with the fuel. The quantity of steam introduced into the air blast is relatively large, amounting to 2½ lbs. for each pound of fuel gasified. Half a pound of steam is decomposed in the producer for each pound of fuel burnt, thereby yielding free hydrogen to the extent of 29 per cent (by volume) in the fuel gas.

The hot gas and undecomposed steam leaving the producer, pass first through a regenerator in the opposite direction to the incoming blast, thereby delivering heat to the air blast. The blast is still further heated by passing down an annular space between the two shells of the producer on its way to the grate. The hot products from the producer are passed through a washer which cools the steam and gas down to about 194° Fahr., and by the formation of more steam, tending to saturate the gas with water vapor at this time, the bulk of the sensible heat is converted into latent heat. The producer gas then passes upward through a lead-lined tower filled with tiles, in which it meets a downward flow of acid liquor containing sulphate of ammonia, with about 4 per cent excess of free sulphuric acid. Combination of the ammonia of the gas with the free acid takes place, furnishing still more sulphate of ammonia, so that in order to make the process continuous some sulphate liquor is constantly withdrawn from circulation and evaporated to yield solid sulphate of ammonia, and some free acid is constantly added to the liquor, which is circulated through the tower by means of pumps. The gas having delivered this ammonia, is conducted to a cooling tower, where it meets a downward flow of cold water which cools and cleans it before it passes to the various furnaces and engines in which it is used. The cooling of the gas and steam results in the condensation of the latter, and in the elevation of the temperature of the cooling water, of course, so that the latter leaves the tower as hot water. It is utilized in a third tower, called the air-heating tower, through which the air blast for the producer passes. It is stated that utilizing the heat of the gas in this manner adds nearly a pound of steam to the producer blast for each pound of fuel gasified, and forms one of the distinctive features in the economy of the plant. This water which performs the double duty of cooling the gas and heating the air blast is circulated constantly through the two towers by pumps. Both towers are filled with tiles in order to give large areas of contact surface.

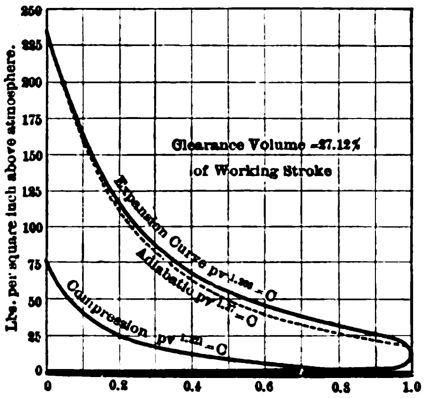

FIG. 15.—INDICATOR DIAGRAM.

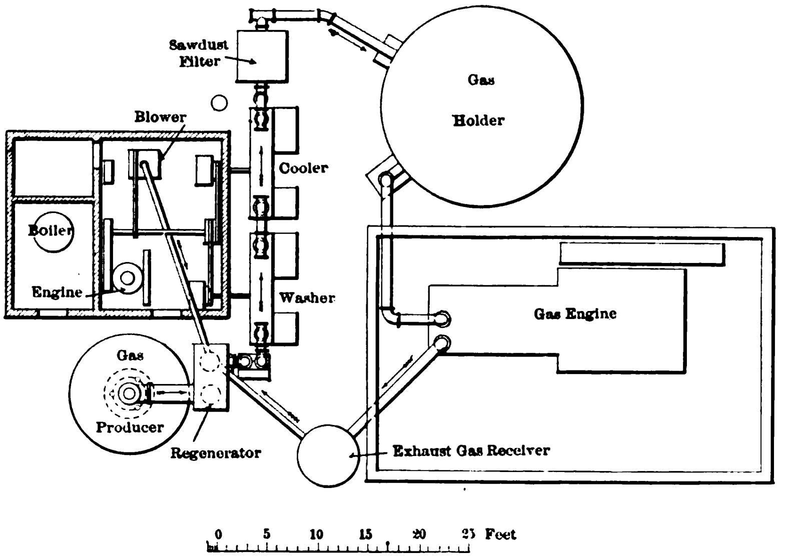

FIG. 14.—DIAGRAM OF PRODUCER GAS PLANT.

Producer gas made by the Mond process just outlined requires 1.15 volumes of air for perfect combustion. The gas has a specific gravity of 0.7882; a specific heat at constant pressure of 0.3201, and a specific heat at constant volume of 0.2321. The specific heat at constant pressure of the products of combustion is 0.2622, and the specific heat at constant volume of the product is 0.1922. A test of a 400-h.p. Crossley double-cylinder engine driving a dynamo and using gas made by this process having a calorific value of only 90 B. T. U. per cubic foot, showed a consumption of 60 cu. ft. per hour per indicated horse-power. The mechanical efficiency of the engine was 83 per cent, and the overall efficiency of the dynamo was 93 per cent, so that the gas used per kilowatt-hour was 104.3 cu. ft. reduced to the basis of 32° Fahr. The thermal efficiency of the engine was 26.23 per cent, calculated on the basis of indicated horse-power, or 21.78 per cent on the basis of the horse-power delivered to the dynamo. Fig. 15 herewith shows an average of the indicator diagrams taken from this engine during a test of six hours. As the diagram plainly shows, the expansion curve actually obtained was slightly higher than the theoretical adiabatic curve, but in the main did not depart greatly from the theoretical curve. The author stated that the cost of fuel per unit of power developed by the use of the Mond gas process in large gas engines was approximately 23 per cent of the cost of fuel per unit of power for a steam plant, based on ideal conditions of economy, and slightly less than 12½ per cent of the cost of fuel for steam plants based on data taken from 83 principal electrical stations in Great Britain for the year 1898.

The Measurement of Steam Delivery—A discussion of a direct system measuring both the quality of steam delivered in a given time and the rate of delivery at any instant by means of a Gehre steam meter is the subject of an article by Herr L. C. Wolff in a recent issue of the "Zeitschrift des Vereines Deutscher Ingenieure." The Gehre meter, it might be said by way of explanation, has for its principle the drop in pressure caused by a flow of steam through a contracted aperture. The simplest means of computing the velocity of flow under these conditions heretofore was by Napier's law from which the weight of steam discharged per second through a given opening may be found. To obviate any arithmetical operations the meter has a mechanical device by means of which the weight of steam can be determined by examining a recorded diagram. The position of the recording point gives the rate of flow at the moment of observation, while the total delivery of steam in an extended period is obtained by measuring the area of the recorded diagram, the same as one would measure the area of a steam indicator diagram. The accuracy of the readings were tested by repeated measurements of volumes of steam, condensed and weighed, and the error of the apparatus was found to be less than 1 per cent.

Some Recent Electrical Patents

Motor-Starting Rheostat.—In almost all modern motor-starting rheostats there are provided two distinct automatic devices, the function of one being to release the rheostat arm in case the current supply fails, and allow the arm to be returned to zero by its spring, and the function of the other being that of an ordinary circuit-breaker, namely, to open the circuit in case the motor becomes seriously overloaded. Fig. 1 represents a rheostat devised by E. M. Hewlett in which both of these functions are discharged by a single mechanism. The no-load release magnet, E, is provided with the usual pole pieces, which hold the armature, E², of the rheostat arm as long as the current passes through the winding. The core of the magnet, however, instead of being of the ordinary fixed type is divided into two parts, a stationary plug, e¹, and a plunger core, F, which has a limited range of movement. This latter core, in conjunction with the winding, constitutes the overload relay; on its outer end is carried a contact strip, I, which, when the current becomes too heavy, is drawn up against the contact posts, G, G. Connections from these posts lead to the terminals of the winding, E, so that the strip, I, short-circuits that winding, the result being the release of the armature, E², allowing the rheostat arm to be thrown to the "off" position. The winding, E, of the magnet, instead of being connected in series with the field winding of the motor as is usually the case, is connected in series with the armature. At first thought this might seem to be a defect as it seemingly fails to provide for the release of the rheostat arm in case the field circuit of the motor is broken while the armature circuit remains intact. In such a case, however, it is plain that the breaking of the field magnet circuit would result in overloading the armature, so that the plunger, F, would be immediately drawn in, short-circuiting the magnet winding and releasing the rheostat arm. Patent No. 664,087.

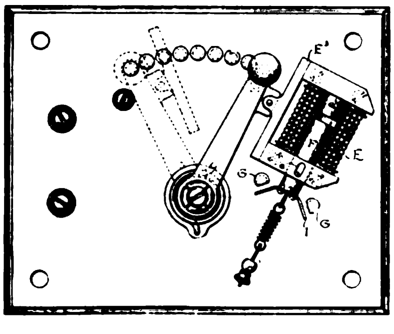

FIG. 1.—RHEOSTAT.

Telephone Transmitter.—Fig. 2 illustrates a peculiar form of carbon contact for use in a telephone transmitter which has been patented by August H. Skold, the object of the inventor being to eliminate the induction coil used for intensifying the action of the ordinary transmitter. The carbon contacts are in two pieces, a circular central plug, C^1, constituting one terminal, and the segment, C^6, of the surrounding block constituting the other terminal of the circuit. The ring of granular carbon surrounding the central plug is cut entirely through between the segments, C^3 and C^4, but is only slit down about two-thirds of its thickness between C^4 and C^5, C^2 and C^6, and C^2 and C^3. The transmitter diaphragm carries three connecting strips of tinfoil, as shown in Fig. 2. The relation between the carbon contacts and the diaphragm is such that the piece of tinfoil, p^1, which is insulated from the diaphragm, connects the face of the central button, C^1, with the carbon segment, C^2. The tinfoil segment, p^2, which is also insulated from the diaphragm, connects the faces of the segments, C^3 and C^4, and the tinfoil segment, p^3, which is not insulated from the diaphragm, forms a connection between the latter and the face of the segment, C^5. This arrangement gives five points of contact, all in series, and the claim is that the effect of the transmitter diaphragm is intensified fivefold by this arrangement. The path of the current is from the button, C^1, to the tinfoil segment, p^1; thence to the segment, C^2; down through the lower part of the carbon ring to the segment, C^3; thence by way of the tinfoil segment, p^2, over to the carbon segment, C^4; thence down through the lower part of the carbon ring again to the segment, C^5, and from the face of that segment to the tinfoil segment, p^3, which is electrically connected with the other terminal of the battery through the diaphragm, D. Patent No. 664,904.

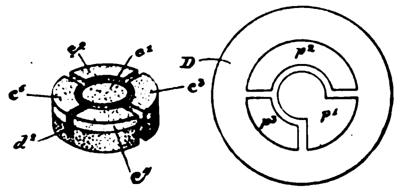

FIG. 2.—CARBON CONTACTS.

Enclosed Fuse.—When safety fuses are entirely enclosed by an insulating casing, it is usually impossible to tell by an inspection of the exterior of the casing whether the fuse has blown or not. This has led to the practice of providing auxiliary fuses of a smaller carrying capacity than the main fuse and connected in parallel with it. Fig. 3 herewith illustrates an arrangement of this sort which has been patented by Otto Feuerlein. The feature of this arrangement is that the two fuses are mounted in one cylindrical casing but are separated by a partition wall of insulating material, so that the main fuse, *d*, is entirely enclosed while the supplementary fuse, *f*, is visible through the opening, *c*. Another feature of the arrangement is that the fuse, *f*, is so proportioned that a current flowing from one terminal plate, *e*, to the other over the parallel path supplied by the two fuses will divide between the two fuses in such proportion as that the limiting capacity of the main fuse will be reached before that of the auxiliary fuse, thus insuring the melting of the main fuse. If the characteristics of the two fuses were identical, one would be just as likely to go first as the other, as the current would divide between them approximately in proportion to their carrying capacities, and the condition of the main fuse would not necessarily be indicated by that of the auxiliary fuse. Patent No. 661,241.

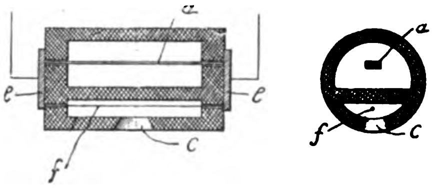

FIG. 3.—ENCLOSED FUSE.

Brush-Holder.—Much effort has been devoted toward the production of a holder for carbon brushes which shall fulfill the requirements of compactness, reliable contact and positive feeding. A recent form of brush-holder devised with these requirements in view has been patented by Christian W. Kragh, and is illustrated by Fig. 4 herewith. The brush-holder, B, consists of a slotted block through which the brush, A, slides in the ordinary manner. Permanent contact between the brush and the holder is obtained by the use of the flexible strip, D.

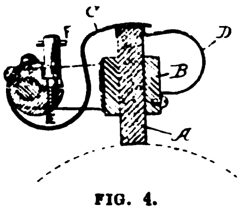

FIG. 4.

The brush is forced toward the commutator by means of flat springs, C, the tension of which is adjustable by twisting the collar, E, about the brush-holder rod. The collar is clamped by means of the screw, F. Patent No. 664,649.

Commutator.—One of the drawbacks inherent in the operation of modern commutators is the wearing away of the copper commutator segments at a greater rate than the mica insulating strips are worn away, the result being that the strips eventually project slightly beyond the level of the copper segments and cause the brushes to chatter and spark. A method for eliminating this trouble has been patented by E. D. Priest and George L. Schermerhorn, and consists of using strips of mica which are not quite as wide as the copper segments, so that the edges of the mica strips are not quite flush with the brush tread of the copper segments. Patent No. 662,465.

NEW BOOKS.

Twenty-Third Convention of the National Electric Light Association. Published by the Association. Cloth; 460 pages, 6 x 9 ins.

This book contains the complete proceedings of the twenty-third convention of the association which was held in Chicago last May, including all of the extremely interesting papers which were read at that convention.

Report of the Fifth Annual Convention of the International Association of Municipal Electricians. Published by the Association. Flexible leather; 204 pages, 6 x 9 ins.

This is a well-executed record of the proceedings of the convention held in Pittsburg last September, and opens a brief history of the association. The proceedings of the fifth annual convention are given in full, and contain much information of practical value to municipal electricians, and operating engineers also.

Design and Construction of Oil Engines. By A. H. Goldingham. New York: Spon & Chamberlain. Cloth; 196 pages 5 x 7½ ins.; 79 illustrations. Price, $2.

This book has all the ear marks of a compilation at the hands of a smatterer. Among the bits of definite wisdom in the chapter on design is this: "The circulating-water space around the cylinder is made ¾ in. to 1½ ins. deep, the water inlet and outer pipes being so arranged as to allow free and efficient circulation of the cooling water around the cylinder." That's all. Again: "The cylinder clearance allowed will depend upon the pressure of compression as determined by experiment and by the indicator diagram, producing properly timed ignition and combustion." One naturally pauses to ask how on earth one is to get an indicator diagram from an engine not yet designed. And that sciolistic gibberish about ignition and combustion—what purpose it serves is difficult to conceive. On the subject of shafts the author waxes prolific in data, having stumbled upon William Norris' formula (which he has the nauseating impudence to "recommend"!) and table of dimensions. The book is puerile and amateurish, the small amount of definite data which it contains having been apparently copied from various sources available to everyone.

Machinists' and Draftsmen's Handbook. By P. Lobben. New York: D. Van Nostrand Company. Cloth; 438 pages 5 x 7½ ins. Price, $2.50.

This is a most convenient reference book, containing formulas, tables and rules applying to mechanical engineering generally. Among the many commendable features are trigonometrical formulas of a practical value and not usually found in handbooks; an excellent and comprehensive chapter on Strength of Materials, and one on power transmitting mediums—shafting, belting, gears, etc. The hydraulic formulas are rather empirical and are not reduced to their simplest form, but they serve well enough for approximate calculations. The book is of value not only to machinists and draftsmen but to all classes of engineers.

NOTES.

Sparking Dynamo Winding. — In the description of the small sparking dynamo for gas engine service which was published last month, it was stated that the armature winding for 32 volts consisted of "16 coils of No. 22 wire"; this should have read "16 coils of No. 28 wire."

Atlanta Independent Telephone Exchange.—In the article descriptive of this interesting exchange published in our January number credit should have been given to Col. John W. Rutherfoord and H. A. Douglass, of the Atlanta Standard Construction Company, who had charge of the line construction of the plant.

Telephone Extensions in Italy.—The Italian Board of Public Works has approved of an important project for placing the various railway stations of the Mediterranean, Adriatic and Sicilian companies in touch with one another by means of the telephone. The exchange will be in Rome, and the project is to be put in execution this year.

National Electric Light Convention. — The twenty-fourth convention of the National Electric Light Association will be held May 21 to 23 inclusive at Niagara Falls. The headquarters of the delegates will be at the International Hotel. Full information regarding train schedules, special rates, etc., may be had from Mr. Geo. F. Porter, secretary of the Association. The secretary's office is at 136 Liberty Street, New York.

Water Power Development in Spain.—The Sociedad di Approvechamiento del Rio Gallego is the name of a company that has been formed at Saragossa, Spain, for the utilization of two waterfalls situated on the River Gallego. The first is in the Province of Puendeluno and is calculated to develop 3200 horse-power, the second is in Murillo, and is estimated to yield 2600 horse-power. Both courses are within 30 miles of Saragossa.

Lowering Arc Lamps in a Public Street.—A recent decision of the Second Appellate Division of the Supreme Court of New York vindicated the practice by electric light companies of lowering arc lamps in the streets for trimming. A suit was brought by a bicycle rider who came into collision with an arc lamp on one of the streets of Yonkers just as the lamp was lowered for the purpose of trimming. Judgment was given to the plaintiff in a lower court, and this judgment was reversed by the supreme court, which in its opinion stated that there was no presumption of negligence on the part of the electric light company by reason of an employee having lowered a lamp for giving it attention.

Electric Traction in Australia.—The old steam-tramway lines in Sydney are being rapidly displaced by an overhead-trolley system. The opening of the latest section of these railways was recently celebrated by the Electrical Association of New South Wales in a characteristically colonial fashion by a trolley-car party. A line, backed by private capital, has also been established between Rockdale and Lady Robinson's Beach. The plant for this line is thoroughly modern, consisting of Willans high-speed engines direct-connected to Siemens generators; Babcock & Wilcox boilers fed by motor-driven pumps, and an auxiliary battery of Chloride accumulators. In Melbourne, notwithstanding the success of the cable system, the suburban authorities are urging the construction of a trolley line to connect the suburbs with each other direct, the cable system being entirely a radial one. Messrs. Callender and the Westinghouse Company have a bill before Parliament asking for the power to convert some 50 miles of present horse-car lines into electric lines, and the suburban authorities are also working with the same end in view.

An Important Patent Decision. —The suit brought by the American Bell Telephone Company against the National Telephone Manufacturing Company, the Century Telephone Company and others, to restrain the respondents from the manufacture, sale or use of telephone apparatus including a microphone form of transmitter, was decided against the Bell Company on February 27 by Judge Brown of the United States Circuit Court, sitting in Boston. The patent involved is the one issued in 1891 to Berliner, which was considered one of the most important of the fundamental patents held by the Bell Company. The decision of the court holds that the Berliner patent is invalid; first, because at the date of the application for the patent Berliner had not made the invention covered by the patent; second, because the invention described in the patent is radically different from that described in the application; third, because the invention was previously patented by Berliner in 1880; and fourth, because Edison was the prior inventor. The rescript compares the work of Berliner with that of Edison at considerable length, the argument being that the world owes the modern transmitter to Edison and not to Berliner. The case will doubtless be appealed.

An American Institute Conversazione.—Encouraged by what has been accomplished by other technical societies, and what they have recently seen abroad, the Council and Committee on Meetings of the American Institute of Electrical Engineers have arranged for a conversazione to be given by that body some time in April. Through the courtesy of Columbia University, the conversazione will be held in the Electrical Engineering Department, with the co-operation of Prof. Crocker, Dr. Pupin, Mr. G. F. Sever and others of the staff there, and so much interest has already been shown in the matter that a brilliant success is forecast. While the conversazione will be largely social in character, a special feature will be the exhibition of latest electrical apparatus, inventions, etc., in working condition. Mr. Edison, Prof. Elihu Thomson, Dr. Pupin and others have promised personal assistance in this respect. Secretary Pope and Mr. W. S. Barstow, chairman of the Papers and Meetings Committee, extend through the press an invitation to all members to contribute features of scientific interest and to give an early notification of what they will do in this respect.

A Mysterious Current.—A very peculiar phenomenon has been observed in connection with the 1500-kw. alternators at the big Snoqualmie Falls plant, near Seattle, Wash. The generators are three-phase machines of the revolving armature type, giving 1000 volts and 1500 amperes, and running at 300 r.p.m. They are direct-connected to impact water wheels. There is a difference of potential between the end of the armature shaft and the journal box sufficient to maintain a short arc between the shaft and the free end of a wire connected to the journal box at its other end. There is evidently a heavy flow of current from the shaft to the box, and the thin film of oil between the shaft and bearing offers some resistance to this flow, so that there is an appreciable difference of potential between the shaft and the bearing. The effect is not only curious, but sometimes troublesome. There is enough sparking around the oil ring at times to burn and blacken the oil, and the bearing spits oil all over the surroundings. A contact brush bearing on the shaft obviates this, but it frequently becomes very hot from the passage of current through it. The flow of current seems to be proportional to the load on the machine. The armature and fields are perfectly free from grounds and of high insulation resistance.

Electric Light Plant Projected in Bucharest.—The "Compagnie du Gaz de Bucharest," whose headquarters are at Paris (Boulevard Haussmann) are at present in treaty with the communal administration of the Roumanian capital for a 40 years' concession for the lighting of the city. The municipal council propose to replace the gas lamps in the town by electricity and the oil lamps of the suburbs by gas. The concessionaires would be granted an exclusive right for the laying of electric cables in the town for lighting and motive power. Exception is made, however, in the case of conduits for electric traction. The offers of the gas company have received favorable consideration but still await the approbation of the Chamber. In case of acceptance, which seems probable, the construction of an important electric-power station would be immediately commenced.

M. Zenobe Theophile Gramme, who is known the world over by reason of his invention of the well-known ring armature winding, died at his residence in Bois Colombes, near Paris, on January 20. M. Gramme was born at Jehay-Bodignée, near Liege, Belgium, in 1826, and was in his youth a carpenter. Having a natural predilection, however, for mechanical and scientific subjects, he attended a course of lectures at Liege and afterward went to Paris, where he obtained employment as a pattern-maker in the factory where the old Alliance dynamo was made. Later on he worked under Ruhmkorff, and up to the time of his invention of the ring winding he followed the occupation of a machinist. The rapid commercial success of the Gramme dynamo is ascribed by Prof. Silvanus P. Thompson to the fact that it was the first practical machine in which were combined the features of continuity of commutation, self-excited fields, proper lamination of the armature core and reasonably good proportions in the magnetic circuit. Gramme exhibited his machine at every exposition that was held up to about 1881, and received many honors on account of his invention. The French Government awarded him a prize of 20,000 francs, and the Academy of Sciences gave him the Volta prize, which carried with it the same amount of money. He was also decorated by the French and several other European governments.

THE LATE Z. T. GRAMME.

In 1877-78 he designed and built a number of alternating-current machines for supplying current to Jablochkoff candles. The field magnet of these machines rotated; the armature was stationary and was so wound that a different number of circuits could be led from it, according to the manner in which it was connected up. Gramme retained his connection with the company originally organized to manufacture his apparatus, the Société Gramme, up to the end of his life, although recently this connection was merely a nominal one. M. Bollinckx, the well-known Belgian engine builder, informs us that Gramme was often asked to take out naturalization papers in France, but steadfastly refused, preferring to remain a Belgian subject. There is a street in Liege which bears his name.

Wiring for the Pan-American Exposition.—Mr. Henry Rustin, chief of the Mechanical and Electrical Bureau of the Pan-American Exposition to be held this summer at Buffalo, states that the wiring of the grounds and various buildings of the Exposition has progressed satisfactorily. The two restaurants are complete in their wiring and are ready for the lamps. Machinery Building is complete, so far as the wiring is concerned, and half of the lamps are in place. A test of the illumination of this building has been made, and is reported as highly satisfactory. The group of three buildings, Mines, Horticulture and Graphic Arts, is complete with the exception of the upper portion of the main dome. The three buildings of the Government group are also complete with the exception of the center dome of the main building. Electricity Building and Agricultural Building have been completed and are ready to light up. The Ethnology Building, the Temple of Music and the Manufacturers' Building have been completed so far as the staff work will allow attachment of lamp sockets. At every point, the electricians are following the staff workers as rapidly as possible. On the Electric Tower a large force of men is keeping up with the construction work, and the structure is being brought rapidly to a state of completion.

In the courts and canals, in fact all the open areas, a vast amount of underground wire is being laid to serve the lighting posts, each of which will have from 26 to 100 incandescent lamps. The number of incandescent lamps to be used in the exterior lighting effects has been estimated at 200,000, but the fact is that the number will be over 500,000.

ESTABLISHED 1889.

American Electrician,

WITH WHICH IS INCORPORATED
Electrical Industries.

CECIL P. POOLE, Editor.

The Berliner Patent.

The decision handed down a few days ago by Judge Brown, of the United States Circuit Court, in the Berliner patent suit appears to bring up one or two new points. Hitherto, the points at issue affecting the validity of the patent were whether the Berliner transmitter patent of 1891 was void by reason of the Berliner receiver patent of 1880 describing precisely the same apparatus, and whether the invention described in the 1891 patent was the invention described in the application or an entirely different invention introduced by an amendment more than two years after the patented invention had been in public use. Judge Brown declares the Berliner patent invalid on both of these points, and in addition maintains that it is invalid because at the date of his application, June 4, 1877, Berliner had not made the invention described in his patent and because he was antedated in actual discovery by Edison, although the date of Edison's application was later than that of Berliner's. If the present decision be sustained, there will remain only switchboard details as an important source of legal contention between the Bell and the independent companies.

Steam Engine Efficiency.

Much has been said and written on the subject of steam engine efficiency, and the fallacy of considering engine efficiency as identical with the efficiency of heat utilization has been pointed out in these columns more than once. Notwithstanding the frequency with which engine efficiency proper has been explained, however, there arises a calamity howler from time to time, burdened with a sense of the sinful inefficiency of the steam engine and feeling it incumbent upon him to enlighten the balance of the world as to the "one converter of energy that has remained practically unimproved," etc., so that it is scarcely possible to give too much explanation of the right sort.

On another page will be found set forth a method of considering steam engine efficiency which is different from the one usually employed, and which has the partial advantage of including in its formula an expression that is more familiar to the average steam engineer than are the thermodynamic formulas. Unfortunately, the method is inaccurate for the reason that it is based upon isothermal expansion, or, if you please, the hyperbolic curve corresponding to isothermal expansion, which is not by any means the ideal curve and therefore cannot rationally be considered a standard. If it is desirable at all to use the formula of any curve as the criterion of what steam should do in a cylinder, the adiabatic curve would be the one to use, as it represents ideal thermal conditions. This would convert Mr. Nagle's formula for the work theoretically obtainable from the steam into

$$W = 144 \left[\frac{10\,P}{R} - \frac{9\,P}{R^{1.111}} - p \right] R\,C\,S$$

which is not attractive to contemplate.

However, with all respect to Mr. Nagle's well-known and high ability, there seems to be no particular need to seek anything better than the comparatively simple method of figuring efficiency on the basis of temperature range. In order to extract all of the heat energy from a pound of steam it would have to be expanded until its temperature fell to 461° below zero, which would mean a range of T + 461°, T representing the temperature of the steam when expansion begins. This is, of course, impossible; steam ceases to expand when its temperature reaches that of the medium into which it is discharged—the condenser, in the case of a condensing engine, and the atmosphere, in that of a non-condensing engine. Indicating the temperature of the ultimate receptacle by *t*, the range of expansion will be $T - t$, instead of $T + 461$, which would be necessary in order to utilize all of the heat. Consequently, the proportion of the heat units in the steam actually available for work is $\frac{T - t}{461 + T}$, and if the engine converts 60 per cent of this proportion into work it has an efficiency of 60 per cent, even though $\frac{T - t}{461 + T}$ may be only one-tenth of the heat range.

If the heat units contained in a pound of steam at boiler pressure be represented by H, then there will be available for conversion into mechanical work $H \frac{T - t}{461 + T}$ heat units per pound of steam delivered to the engine. If the engine consumes S pounds of steam per horse-power-hour, the available heat units contained in that steam will evidently be $H\,S \frac{T - t}{461 + T}$. Now, a horse-power-hour is equal to 2545 B. T. U. (heat units); therefore the efficiency of an engine using S pounds of steam per horse-power-hour will be given by the formula

$$\frac{254{,}500\,(461 + T)}{H\,S\,(T - t)} = \text{Per cent efficiency,}$$

which is simpler of solution than the less accurate formula advocated by Mr. Nagle. In his article is given a numerical example based on an engine taking 12 pounds of steam at 150 pounds gauge pressure, expanding it 30 times and exhausting against 1 pound condenser back pressure. The temperature, T, of steam at 150 pounds is 365.6°, and a pound of it contains 1193.5 B. T. U. The condenser temperature, t, would be 102°; S = 12 and H = 1193.5; substituting these values in the above formula gives

$$\frac{254{,}500\ (461 + 365.6)}{1193.5 \times 12\ (365.6 - 102)} = 55.7 \text{ per cent}$$

instead of 60 per cent, as given by Mr. Nagle's formula.

Line Construction.

In the reading and discussion of one of the papers presented before the recent convention of the Northwestern Electrical Association there were brought out several points regarding pole-line construction which should be noted by all superintendents of moderate-sized central stations. Prominent among these was the importance of electrically separating the upper from the lower portions of guy-wires and arc-lamp hoisting cables by means of circuit-breaks, and positively grounding the lower portions. Had Mr. Burch felt disposed to go farther into details it is highly probable that he would have recommended the location of the guy-wire circuit-breaks or insulators in a horizontal plane 5 or 6 ft. below the bottom cross-arm of a pole. Locating the insulators below the level of the lowest cross-arm gives assurance that the portion of the guy-wire between the insulator and the ground will not be liable to accidental contact with any of the line wires; placing these insulators as far as 5 or 6 ft. below the cross-arm puts the grounded portion of the guy-wire out of reach of a lineman's legs while his body is hemmed in by live wires. Another point that is very frequently ignored, and which should always be observed, is that the upper end of a guy-wire should never be made fast to the pole above the lowest cross-arm or insulator bracket. The progress of a climber is sufficiently impeded by the line wires and cross-arm braces without carrying the guy-wires up into the same plane.

The recommendation to put cross-arms on the side of the pole opposite the direction of strain might reasonably have been accompanied by a hint as to the direction from which the heaviest strain comes. In "pulling up" a line the strain is in the direction of pull so far as the last arm to which the line was tied is concerned, and this arm bears the brunt of the pull. The way the cross-arm should go on the pole depends upon how the running part of the line is made fast for tying; if it is temporarily "hitched" to a pole while the taut part is being tied to the insulators, which should be the practice, then the worst strain is that due to the "pulling up," and each cross-arm should go on the side of the pole away from the pulling-up tackle. All terminal poles and corner poles should be double cross-armed, and where very heavy wires are carried, every pole should be so treated. In the case of high-tension lines from which taps are made, it should be the practice either to leave the two pins next to the pole free of wires or to use special cross-arms having a spacing of at least 24 ins., and preferably 30, between the two pins next to the pole on each side. The increased space thus provided for the lineman's body gives him vastly better working speed because of both the decreased risk of electrical injury and the greater freedom from mechanical interference by the inner line wires. Of course this consideration does not apply to feeder or other lines from which branches do not have to be tapped from time to time while the circuit is alive.

Magnet Windings.

It is probably safe to say that nine persons out of ten labor under the delusion that the individual convolutions of wire in each layer of a magnet coil "bed" themselves in the slight trough between the convolutions of the next layer beneath. An eminent English authority, in discussing dynamo field magnet coils, suggests an allowance of 10 per cent for this bedding of wires! Now, unless all layers are started from the same end of the coil, which is obviously impracticable, the crease or groove formed by the convexity of surface presented by individual convolutions of a layer is a right-handed spiral in one layer and a left-handed spiral in the next, and so on. It will be evident upon a little reflection that the convolutions of a right-handed spiral cannot bed between those of a left-handed spiral to any considerable extent—certainly not to such an extent as to affect the calculated depth of the winding, as the bedding will take place at irregular points and merely affect the circularity of the layer.

There is, of course, some difference between the depth in inches of a given number of layers and the length of coil in inches given by the same number of turns side by side. The adjacent turns, no matter how accurately they may be wound, are not forced into such intimate contact as are contiguous layers, which are drawn down hard by the tension on the wire. This results in compressing the insulation between layers while that between adjacent turns is about normal or a trifle thicker than normal, so that ten turns of wire will take up more space along the core than ten layers will occupy measured outward from the core. The difference between the calculated depth of a coil and its actual depth, assuming that the gross diameter of the insulated wire is accurately measured, rarely exceeds 2 per cent of the total calculated thickness or depth when the wire is of a substantial size, say any size larger than No. 18, B. & S. gauge. For smaller sizes of wire, especially those above No. 30, the work of calculating the coil depth is scarcely justified, as the wire is usually put on so irregularly and the co-efficient of insulation compression is so uncertain that the relation between the calculated and the actual depth of a large number of layers is variable, and therefore problematical.

The relation between the dimensions of a coil and its magnetizing power is also not so well understood as it might be by general readers. The length of a coil parallel with its core affects its magnetizing power practically not at all if the applied e.m.f. is constant; the magnetic effect of the coil upon its core depends entirely upon the size of the wire, the terminal e.m.f. and the mean length per turn of wire (total length of wire divided by the total number of turns). With a constant difference of potential at its terminals, the magnetizing power (ampere-turns) of a coil varies inversely as the mean length per turn is varied, the size of wire being unchanged. Thus, a given size of wire made into a coil having an average length of 24 ins. per turn will have only seven-eighths the magnetizing power of the same wire made into a coil having an average length per turn of 21 ins., the voltage being the same in both cases. The reason for this becomes clear upon a little analysis. A given total length of wire wound into a coil of a given mean diameter will make more convolutions than if wound to a larger diameter. The voltage being the same, the current will be the same, and the ampere-turns of the smaller coil will, therefore, be greater than those of the larger one. It may be stated, therefore, as a general proposition, that thin coils are more efficient than thick ones.

THE CONSTRUCTION OF AN INTERCOMMUNICATING TELEPHONE SET.

The accompanying sketches illustrate more or less diagrammatically the essential features of a simple intercommunicating telephone outfit which may be constructed by any student of average mechanical and electrical ability. It will be impossible, however, for an amateur, no matter how skilled, to obtain the same results in the construction of the transmitter and receiver as are obtained by manufacturers with full facilities for this class of work, for two reasons; first, because the proper quality of carbon and steel will be difficult to obtain; and second, because an amateur cannot have adequate facilities for properly treating the steel of the receiver magnet. The set here described, however, will give good results in interior service, constructed from materials which are available to any reader.

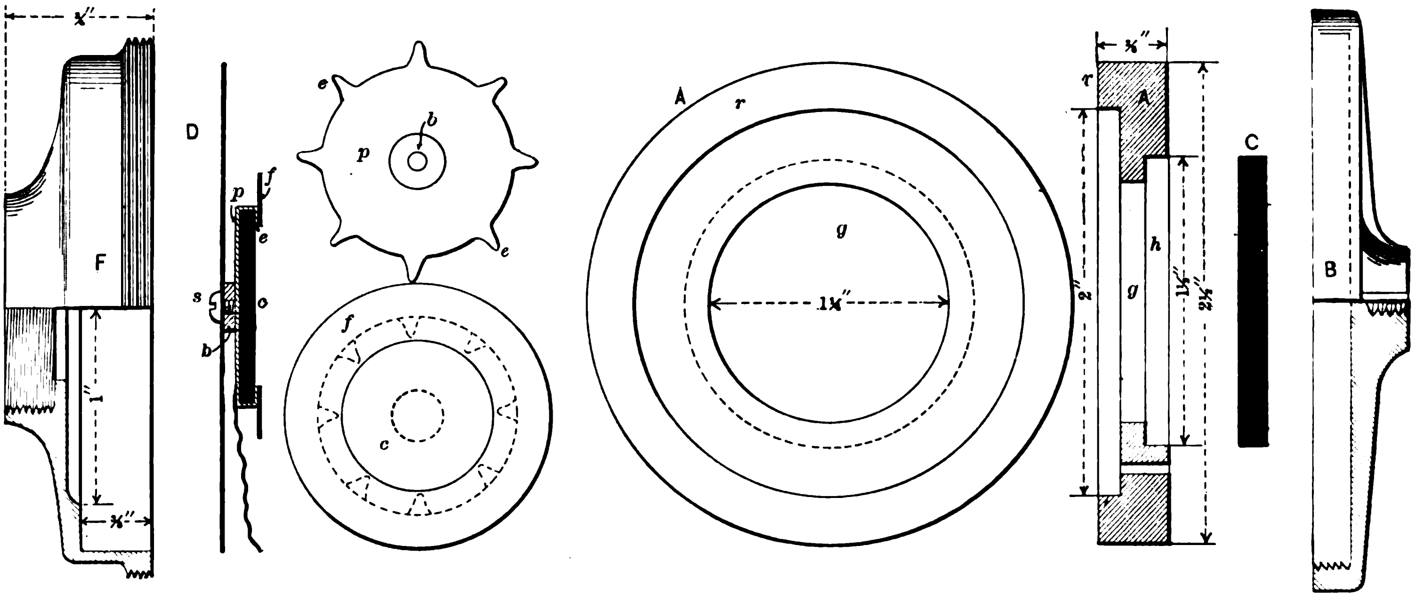

FIG. 1. FIG. 2. FIG. 3. FIG. 4. FIG. 5. FIG. 6.

DETAILS OF TELEPHONE TRANSMITTER.

The transmitter is illustrated by Figs. 1 to 9, inclusive. Fig. 1 is a semi-sectional view of the front cap or shell of the transmitter, which may be made of brass or any other metal. The outside diameter of the body portion is 2⅝ ins., and the diameter of the threaded portion is 2¾ ins.; the wall of the shell is 1/16 in. thick. The diameter of the mouth into which a rubber mouthpiece should be screwed, is ⅞ in., and the depth of the mouth-piece thread is ¼ in. The other important dimensions are marked on the sketch. The diaphragm and front electrode are shown in cross-section by Fig. 2. The diaphragm, D, consists of a disc of tin 2⅛ ins. in diameter and 0.012 in. thick. To the center of the diaphragm is secured the front electrode by means of the small brass screw, *s*, and a round nut, *b*. The electrode, *c*, is a disc of carbon 1 in. in diameter and 1/16 in. thick, mounted on a very thin brass plate, *p*, a front view of which is shown in the upper part of Fig. 3 with the retaining clips or ears, *e*, straightened out. These ears are bent over the rim of the carbon disc to hold it in place. The plate, *p*, is soldered to the nut, *b*. After mounting the carbon disc, *c*, on the plate and bending the ears over its edge, a ring of felt, *f*, 1½ ins. in diameter, with a ¾-in. hole through the center, should be glued to the electrode by means of shellac varnish, so that the metal ears or clips which lap over the carbon disc will be covered by the felt and prevented from coming into contact with the carbon granules when the transmitter is assembled. This felt ring also serves to hold the granules in the chamber, as shown in Fig. 9.

Fig. 4 is a front view of a hard-wood ring which serves to hold the rear electrode and carbon granules; Fig. 5 is a cross-section of this ring. The hole, *g*, in the center of the ring, forms the chamber to hold carbon granules, and is 1¼ ins. in diameter. The circular recess, *h*, on the rear side of the disc, forms a pocket for the back electrode, C, which is a carbon disc 1½ ins. in diameter and ⅛ in. thick. The recess, *h*, should be just a shade less than one-eighth of an inch in

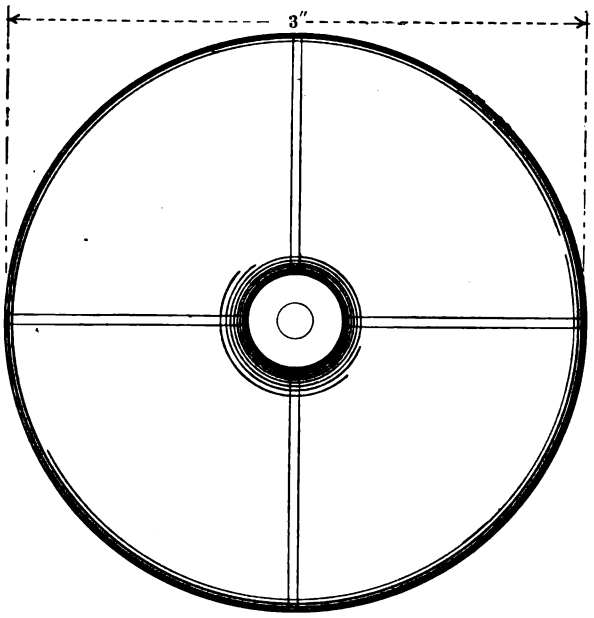

FIG. 7.—VIEW OF REAR CAP.

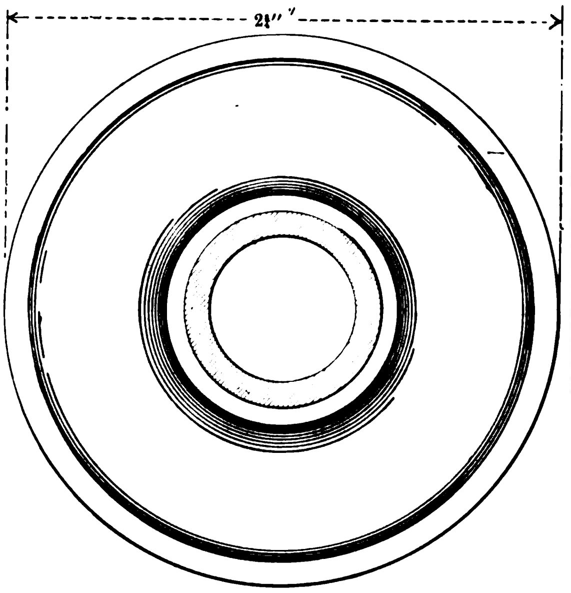

FIG. 8.—VIEW OF FRONT CAP.

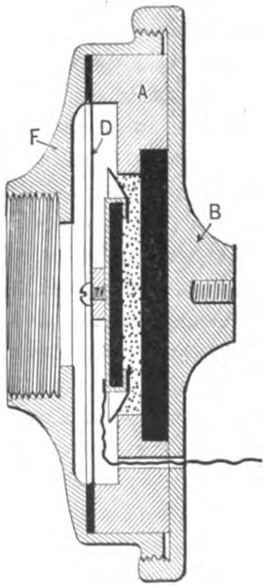

FIG. 9.—SECTION OF COMPLETE TRANSMITTER.

depth, so that the exposed surface of the carbon disc will not be exactly flush with the rear surface of the insulating ring, A. Reference to Fig. 9 will show the object of this arrangement.

When the rear cap, B, a semi-sectional view of which is shown by Fig. 6, is screwed upon the shell, F, of the transmitter, it should come into intimate contact with the back face of the carbon disc, C, so that one terminal of the transmitter can be led from the rear cap. (See Fig. 9.) Fig. 7 is a face view of this cap, from which it will be seen that there are four stiffening ribs extending from the central boss out to the rim. These ribs are 1/16 in. thick, and are provided in order to make the cap rigid and prevent its buckling away from the back electrode. Fig. 8 is a face view of the case or front cap of the transmitter.

The cross-sectional view of the complete transmitter, Fig. 9, shows the carbon chamber nearly filled with granules, and also indicates how the felt ring, *f*, Figs. 2 and 3, serves to keep these granules in the chamber. This ring also acts as a damper to the motion of the diaphragm, D. Connection is made to the front electrode by means of an insulated wire led into the transmitter from the rear through a hole in the cap, B, and the insulating ring, A. This wire is soldered to the thin brass plate on which the front electrode is mounted. In assembling the transmitter a rubber ring should be set in front of the diaphragm so as to be clamped between the diaphragm and the front cap, F. This rubber ring serves to prevent the entrance of moisture to the carbon chamber through the mouth piece.

The receiver is of the Ader bipolar type. A cross-sectional view is given by Fig. 10, and Fig. 11 is a plan view of the receiver case and magnet with the rubber ear-piece removed. Referring to Fig. 10, M is a permanent magnet made of tool steel 3/16 in. thick and ½ in. wide, bent to a circle of 2 ins. inner diameter. The tips of the magnet are shaped as shown by the detail sketch in the center of the ring, and to these are bolted soft-iron pole-pieces, P, P. The screws which hold the pole-pieces to the magnet poles also hold the receiver cup, K, in position. This cup is made of brass or any other non-magnetic material, and is circular, as shown by Fig. 11. The pole-pieces, P, P, are merely right-angle pieces of soft iron, preferably wrought iron, of the dimensions and shape shown by Fig. 12. It will be noticed that the upper ends of the pole-pieces are rounded off instead of being perfectly square. The cup, K, is 15/32 in. deep over all, and its wall is 1/16 in. thick.

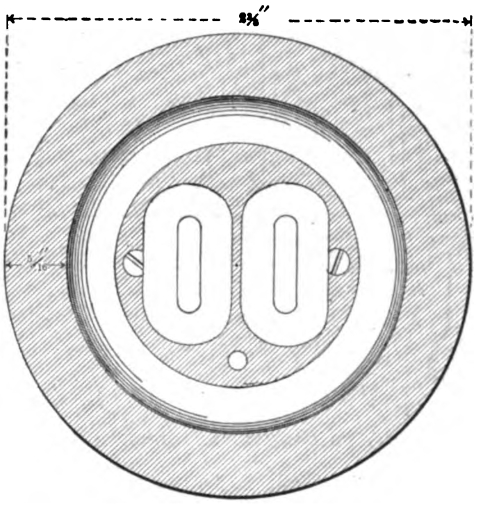

FIG. 11.—PLAN VIEW OF RECEIVER CASE.

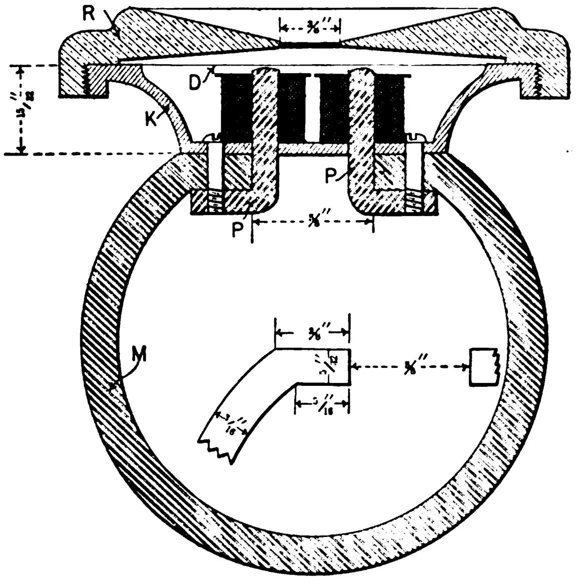

FIG. 10.—SECTION OF BIPOLAR RECEIVER.

The diaphragm, D, is a tin disc 2¼ ins. in diameter and 0.01 in. thick. It is held on the rim of the cup by the rubber ear-piece, R, which is screwed to the outer edge of the rim in the usual manner. Should the reader make the wall of the receiver cup of any other thickness than 1/16 in., care must be observed to have the bottom of the cup exactly accurate, as any variation will effect the dimensions of the magnet coils and, consequently, the working of the receiver.

The receiver coils consist of No. 36 silk-covered wire, each coil containing exactly 125 ft. of wire. The coils should be wound on bobbins made of thin vulcanized fiber, and the terminals may be soldered to the ends of a length of silk-covered lamp cord, say, No. 22. Before making this connection a knot should be tied near the end of the lamp cord, and when the magnets and coils are assembled the free portion of the cord should be threaded through a hole in the bottom of the receiver cup, located as shown in Fig. 11. Part of the heads of the screws which hold the structure together will have to be cut away after the magnet and cup are bolted together in order to allow the magnet coils to go down flat on bottom of the cup. The coils may be held in place by using shellac varnish applied to the bottom of the cup and to the heads of the coils next to it.

A sectional view of the induction coil is given by Fig. 13. The primary coil consists of two layers of No. 20 silk-covered wire wound on a bobbin measuring 2½ ins. between heads and having a ⅜-in. hole through its center. The bobbin tube may be made of thin fiber and the heads of hard wood. The secondary coil consists of 2000 ft. of No. 33 silk-covered wire wound over the top of the primary coil after wrapping three or four layers of oiled paper over the primary. Both terminals of the primary coil should be led out at one head and those of the secondary coil out through the opposite head. The core of the induction coil consists of fine soft-iron wires, about No. 24 gauge; as many of these should be used as can be packed into the hole through the center of the bobbin.

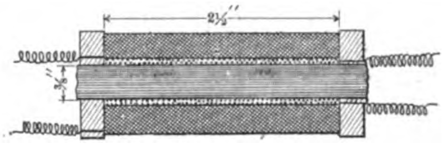

FIG 13.—SECTION OF INDUCTION COIL.

The hook switch is shown by Fig. 14, and consists of a simple strip of metal 6½ ins. long and ⅛ in. thick, having a hook formed at its outer end and being pivoted at its inner end to a brass bracket. The width of the switch at the pivot is ½ in., and this is tapered uniformly to ¼ in. near the hook. The thickness of ⅛ in. is the same throughout its length. The details of the bracket are shown in the upper part of the engraving. The bracket itself is merely a right-angle casting ⅛ in. thick everywhere except at its upper end, where it is 3/16 in. thick in order to give a good hold to the thread of the flat-head screw on which the lever is pivoted. The head of this screw should be of the same

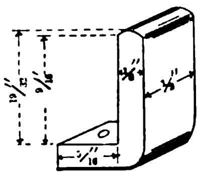

FIG. 12.

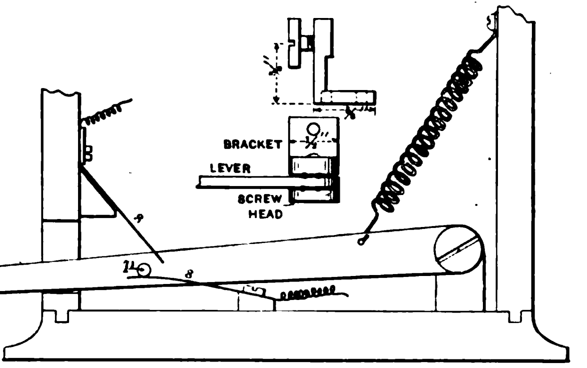

FIG. 14.—DETAILS OF THE HOOK SWITCH.

diameter as the width of the vertical lug of the bracket in order to prevent any tendency on the part of the lever to wabble sidewise. The contact springs, *s*, *s*, may be made of phosphor bronze or thin German silver. A brass pin, *p*, ⅛ in. in diameter and 1 in. long, is mounted in the center of the lever 3¼ ins. from the pivot hole. This pin serves as a contact for the switch springs, *s*, *s*. The lower spring is mounted on a wood block 3/16 in. high at its front edge, ⅛ in. high at the back edge, and ⅝ in. wide between these edges.

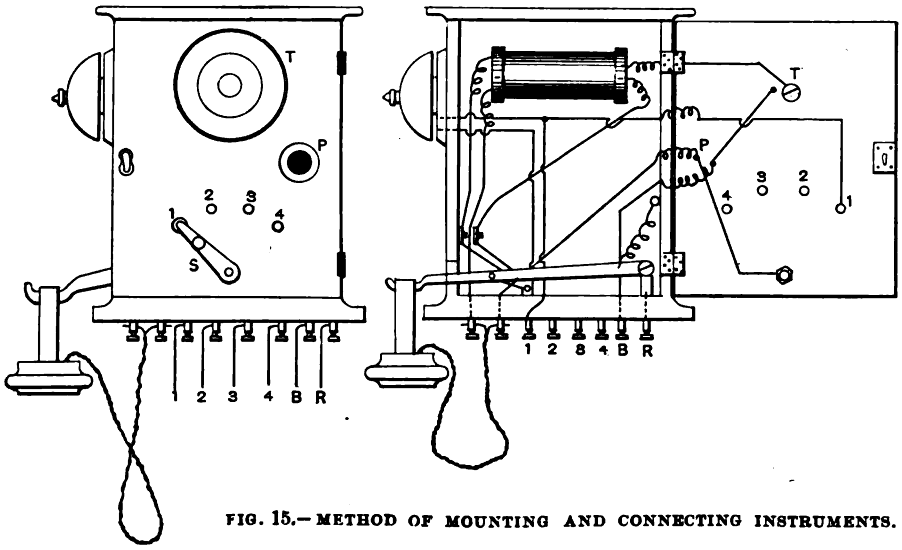

FIG. 15.—METHOD OF MOUNTING AND CONNECTING INSTRUMENTS.

The screw which holds the spring on this block may be an ordinary wood screw sunk into the floor of the box, but it is preferable to have the block either glued to the floor of the box or fastened to it separately, using the screw only to hold the contact spring down. The wire leading to this spring should be soldered to its back end, so that the contact will be permanent regardless of the condition of the screw. There are two of the upper springs, but as they are in line with each other only one shows in the drawing. These are held to the side of the box by means of thin brass plates screwed down with ordinary wood screws. A triangular block of wood should be provided immediately beneath the springs in order to prevent them from following the pin, *p*, too far when the hook is pulled downward. This sketch is exactly one-half size, so that any dimensions which are not marked may be taken from it by a rule.

Although the reader may mount his apparatus in any way he pleases, it is suggested that it be mounted as shown by Fig. 15, in which, T, is the transmitter bolted to the front of the box; P is an ordinary push-button; and S is the selective switch, consisting of an ordinary strap switch with as many contact buttons as there are stations. The connections within the box are shown in the right-hand part of the engraving. In this sketch one of the two upper springs of the hook switch is shown detached from the side of the box in order to clearly indicate the connection between it and the primary of the inductive coil. The upper hinge of the door is shown as forming the connection between the other end of the inductive coil primary and the transmitter, but the hinge need not necessarily be used. The wire can be carried across from the stationary part of the box to the door by coiling it into a long spiral, as indicated in the other three connections, and tacking it down at each end of the spiral. The connections between binding posts, 2, 3 and 4, and the nuts, 2, 3 and 4, on the inside of the door are not shown.

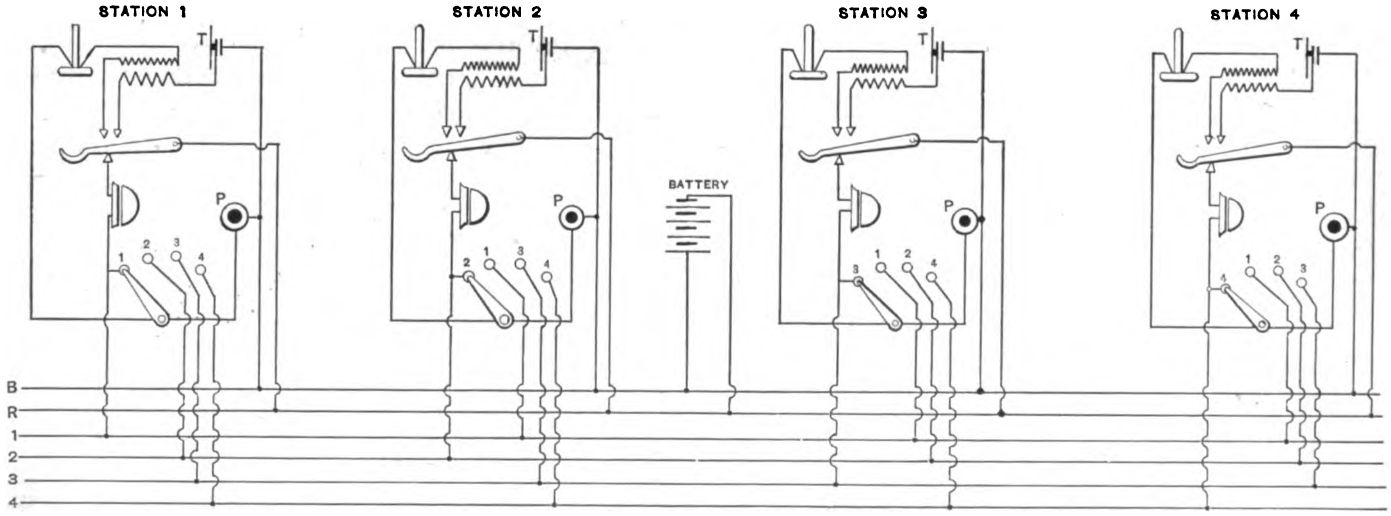

FIG. 16—DIAGRAM OF CONNECTIONS FOR FOUR INTERCOMMUNICATING TELEPHONE STATIONS

As the sketch is a small one and the lines are necessarily very close, it may be advisable to enumerate the connections; these are as follows: From the left-hand receiver post to one end of the induction coil secondary; from the right-hand receiver post to one side of the push-button and also to the lever of the selective switch; from binding post No. 1 to one terminal of the bell and also to button No. 1 of the selective switch; from binding posts Nos. 2, 3 and 4 to buttons Nos. 2, 3 and 4, respectively, of the switch; from binding post, B, to the secondary terminal of the push-button and also to one terminal of the transmitter; from binding post, R, to the lever of the hook switch; from the lower spring of the hook switch to the second terminal of the bell; from one of the upper springs of the hook switch to the unconnected secondary terminal of the induction coil (one terminal having been already connected to the left-hand receiver binding post); from the other upper spring to one primary terminal of the induction coil; and from the other primary terminal to the unconnected terminal of the transmitter (one terminal having been connected to the push-button and binding post, B).

The connections of the system are shown by the diagram, Fig. 16. In this diagram only four stations are indicated, but it will be evident that any desired number may be put in by simply adding one individual line and one selective switch button for each additional station. The arrangement used is a common-battery system, only one battery being required for both signalling and talking. It is recommended that the reader use a bell of what is known as the King type, as indicated in Fig. 15, but, of course, any ordinary vibrating bell will answer. It will be evident from an inspection of the diagram, Fig. 16, that no magnetos are necessary. It should be noted that the left-hand button of the selective switch at every station is connected to one terminal of the bell and to the individual wire the number of which corresponds with the number of that station. The battery is shown located midway between the extreme ends of the main circuits, and this should be the practice if possible.

In operation the procedure is to move the switch, S, to the button corresponding to the station desired and press the push button, P. This rings the bell at the desired station and conversation may be carried on by removing the receiver from the hook switch, allowing the latter to be drawn up in the usual manner. After the conversation is finished the selective switch, S, should always be returned to the home button. Should this be neglected conversation cannot be carried on with the station at which the switch has not been returned.

REPAIR SHOP NOTES.

BY ARTHUR B. WEEKS.

When removing an armature for truing up the commutator, the nuts at the end of the commutator should always be tightened, as they are frequently the cause of the truing being required.

Current should never be turned on an armature until it has been thoroughly dried. Should a set of car heaters be available, and no oven, a temporary one can be rigged up in a few minutes by placing the armature in a convenient spot with the heaters around it, and having boxes so arranged that a canvas thrown over them will cover the whole. The best place for an electric oven is below the shop floor, covered by a hinged lid; in this way no valuable floor space is used. Line the box with sheet iron, and have it only large enough to accommodate the largest apparatus that may be put into it. Arrange some sort of hoist above it, if it be only a span wire thrown over a beam and let down the proper distance, with a loop in the lower end for a chain-block. Fig. 1 shows a simple and useful type of crane for such a purpose or for general use.

In tearing a commutator apart to repair it, if carefully dismantled, it may not be necessary to true the commutator afterward. If the mica rings have been disturbed, replace them as you found them, or a truing cut will be required. A highly discolored bar, due to excessive current and usually occurring when the armature becomes grounded, should be replaced when other repairs are being made; otherwise, a flat place will appear after truing and continue to cause sparking and fusing until the commutator is worn out, which will not be long.

It is always a good plan to mark with a prick-punch the end of a flat or burnt spot that requires truing, so that it may be known if the trouble reappears in the same place, as is often the case. A record should also be made in a book kept for that purpose. Such a record will be found a great help in following up the work.

If your armature shafts are not numbered, stencil them at your earliest opportunity.

The question has been asked often, how thin can a commutator become before replacing it? That will depend to a great extent upon the make of motor. If the commutator is straight across its face, for motors rated at 25 horse-power or under, 3/16 inch is a safe limit. Then again the brush-holders may limit such thicknesses, for it may not be possible to adjust them to get this amount of wear; however, the commutator should be removed before there is any danger of its wearing through.

Whenever you have an armature out to be repaired, and there are one or more dark bars on the commutator, re-solder the leads to such bars, for frequently the cause is a poor contact which has made the machine spark more or less. The writer has seen connections in such condition that a little pressure would push the wires out of the slot.

The commutator connections on a generator armature sometimes break off, especially if such connectors are thin, flat copper strips and extend straight up radially to meet the armature conductors. They break off close to the commutator, and if a steady white spark is noticed all along the row of brushes, when just before there was practically no spark, it is pretty certain to be caused by a loose or broken connection. The longer it runs in this condition the worse it becomes, and the greater the amount that will be required to be taken off the commutator to true it.

Some plants shut down machines only on certain days for cleaning, so one must be able to detect such trouble immediately and have the dynamo shut down as soon as possible, to save time and expense in turning. Do not try to make yourself believe it is due only to a poor brush, or that it will soon stop, for it will not. Only by the study of the different kinds of sparks can you tell their meaning, and it is a study well worth one's while.

It is often impossible to detect a broken bar connection with the eye, but a pine stick pried gently between connections will locate it. To repair it requires considerable skill and sound judgment. First, disconnect the broken connector from the armature conductor. In some cases they are fastened with stove bolts and are also soldered.

Before using a blow-lamp protect the adjacent bars with sheet asbestos pushed between bars. When the broken connector is disconnected, cut a slot in the commutator bar with a cape chisel a little narrower than the connector which is to be fitted into it. Some connectors are fastened to the side of the commutator bar, others in the center. If at the side, great care must be exercised that the mica be uninjured, since injury easily occurs, should the chisel slip or a copper sliver pierce it. Next fit the new connector into its place and pack asbestos back of the connection to prevent short circuit from the solder. Have at least two blow-lamps in case one gives out, lest the joint get cold and cause a delay. Use solder and acid cautiously. Being satisfied that the joint is all right, remove all loose solder and asbestos. Turn the armature over by hand and blow it out, as pieces of metal are apt to drop in between the connectors and wedge themselves there. If the instruments are available (as they should always be) test the commutator for short circuits. Then, being satisfied that everything is all right, paint the new connection and others near it with an insulating paint.

FIG. 1.—CRANE FOR REPAIR SHOP USE.

INTERIOR WIRING.

BY CHARLES E. KNOX.

THE LIGHTING OF A DEPARTMENT STORE.

Although the lighting of a store building is apparently quite simple, there are several points in connection therewith which require considerable thought and attention in order to obtain the best results. It will be the object of this article to discuss these few points. The first problem to be considered is the system of general lighting (that is, arc or incandescent) that is best adapted for the case in hand. It is quite safe to say that in the large majority of cases the arc system is best adapted for the general lighting of a department store. This is true because of a number of reasons, probably the chief of which is that the light from an arc lamp possesses more nearly the characteristic properties of the sunlight than does that from an incandescent light. This feature of the arc light is particularly valuable in a department store, where color values and matching of colors is such an important consideration. The modern arc light also makes a store more attractive and brilliant in appearance than does an incandescent lighting system.

The arc system having been determined upon, the question of the kind of arc lamp to be used is disposed of quite readily; there is little room for doubt that the long-burning constant-potential enclosed-arc lamp is best adapted for indoor purposes. This lamp will burn on an average 125 hours without having to be retrimmed, although the globe must usually be cleaned oftener than the lamp has to be retrimmed. It has also the important advantages (over the series open-arc lamp) of reducing the danger to life and property, and also reducing the risk of fire and consequently the fire insurance premium. The constant-potential arc lamp also admits of being wired on the same circuits as the incandescent lamps, which simplifies and reduces the cost of wiring.

The next point to be determined is the arrangement and location of the arc lamps themselves. This problem is one that admits of unlimited discussion and a number of solutions. It must be solved to suit the particular case and conditions, and no general law will apply to it. As a rule, the lamps are placed (on the ceiling) over the main aisles. The distance between the lamps depends upon circumstances; sometimes the distance between lamps is determined by architectural conditions, such as columns, ceiling panels, etc. The writer has seen arc lamps in a department store as close together as 10 ft. and as far apart as 30 ft. For ordinary cases they should be arranged so that the distance between centers would be somewhat between the figures mentioned above.

The first point to be determined in wiring a constant-potential arc-light system is the number of arc lamps to be wired on each branch circuit. If it be decided to wire but one lamp on a circuit, the wiring is simplicity itself. If more than one lamp be wired on a branch circuit, the grouping of the lamps on the various circuits should be carefully considered. If the potential is from 100 to 115 volts (and for a department store no other need be considered) it is unwise to put more than two arc lamps on a circuit. As a rule, wiring two lamps on a circuit gives good satisfaction and the cost of wiring is quite a little less than when only one lamp is wired on each circuit. The latter method has the advantage of simplifying the control, and of allowing all the fuses to be placed at the distributing centers. When two arc lamps are placed on a circuit the rules of the National Board of Fire Underwriters require that a fuse cut-out be placed at or near each lamp. If one lamp only be connected to a circuit, No. 14 B. & S. wire may be used for the branch circuits; when two lamps are placed on a circuit it is preferable to use No. 12 B. & S. gauge. Under ordinary circumstances the best results are obtained (where two lamps are grouped on a single circuit) by wiring the lamps in alternation. This method is in some cases undesirable, and the question must be decided on the merits of the case. As a rule, it is desirable to provide a switch in the cut-out cabinet to control each branch circuit, though in some cases it is better to control each lamp by the switch located on the lamp itself.

In regard to the feeders for constant-potential arc-lamp systems, it might be well to add that a slightly greater loss may be allowed than for an incandescent lighting system, for the reason that the regulation need not be as close as in the latter system, and also because a portion of this loss may take the place of the resistance forming a part of the lamp itself.

Having considered the question of general lighting, it may be advisable to speak briefly of special lighting. Under this head would come window lighting, show-case lighting, office lighting, etc. Such lighting is of course best obtained by means of incandescent lamps. Remarkably fine results in window lighting are now obtained by placing a row of incandescent lamps in a suitable silvered glass reflector having the proper curvature or angle and arranged along the upper front edge of the window. If the reflector be properly placed and of the proper form the light will be diffused over the entire window without allowing the lamps them-

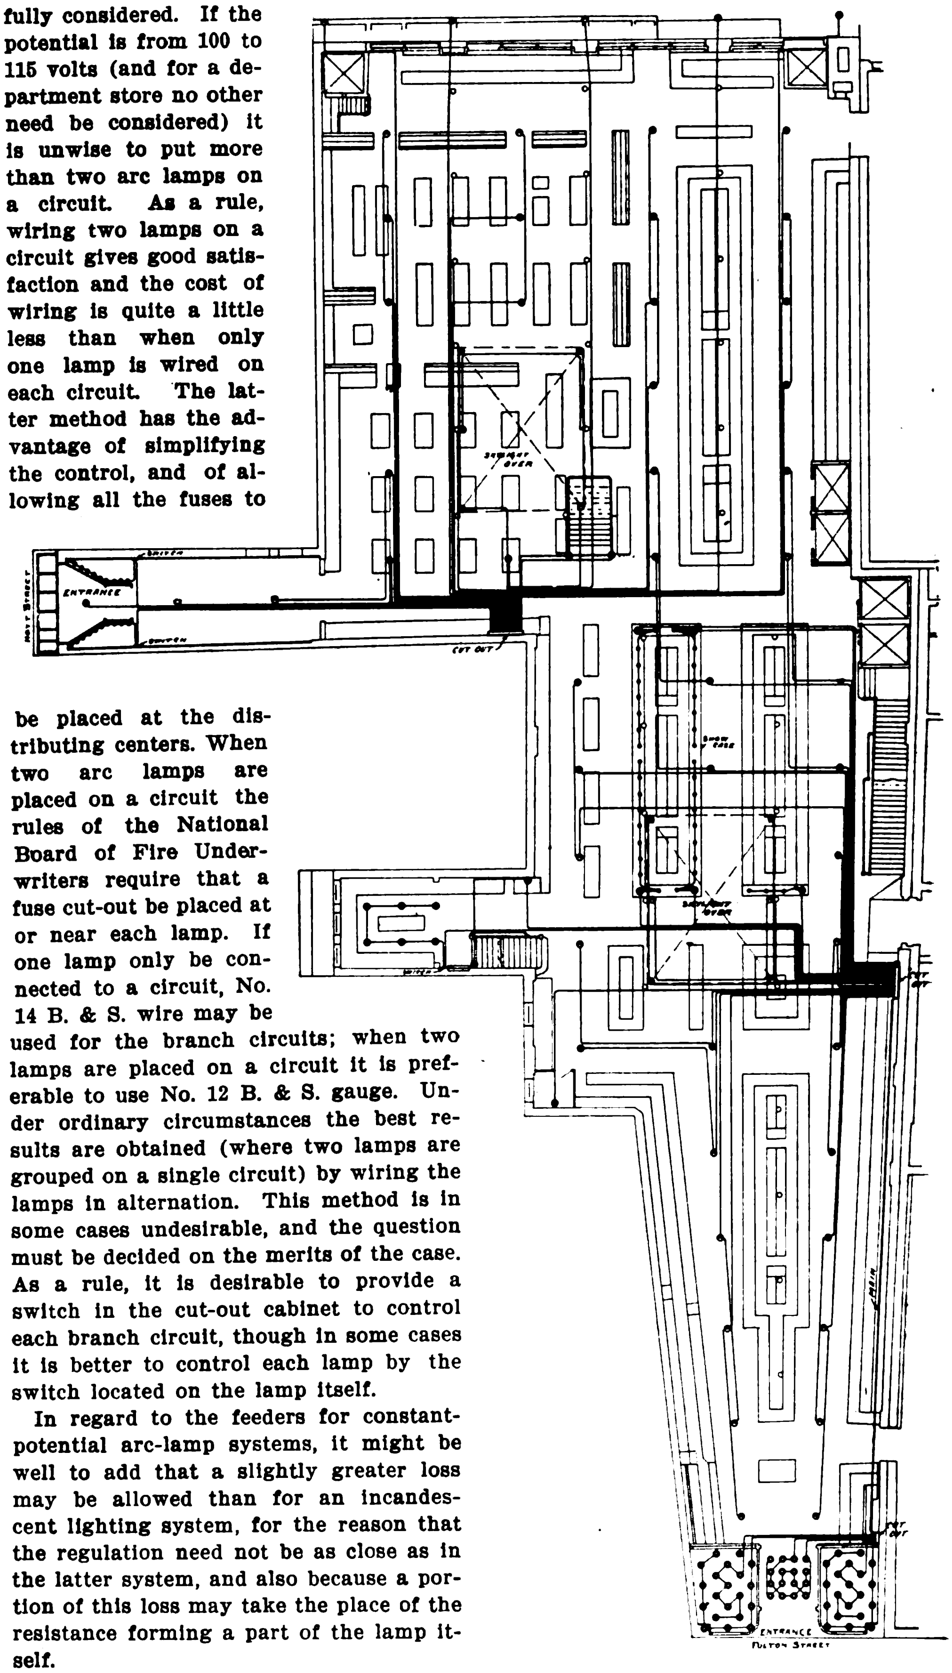

FIG. 1.—WIRING PLAN OF THE FIRST FLOOR.

selves or their direct rays to be visible to the observer from the outside. The same results may be obtained by similar means in certain forms of showcases. In some instances, however, it is better to use individual reflectors for both window and showcase lighting. The lighting of the offices of a department store does not differ materially from ordinary office lighting, and as this has been described in previous articles it need not be dwelt upon here.

As an example of department store lighting, a typical case has been selected and a floor plan showing the number, arrangement and wiring of the lamps is shown in Fig. 1. This diagram shows the first floor plan of one of a group of buildings which form the principal department store in Brooklyn, N. Y. The building is irregular in shape, faces Fulton street and has entrances on two other streets. It consists of a basement and four stories. As the general lighting of all the stores is more or less similar it has been deemed sufficient to show but one floor, as this floor will show the peculiar features of all the others. It will be seen from the plan that arc lamps have been used entirely for general lighting, except at the Fulton street entrance, and in the small extension near the Hoyt street entrance. In the former case incandescent lamps were used because the ceiling was divided in small squares or panels and was therefore well adapted for such lamps, and also because they would interfere less with the lighting of the windows, where incandescent lamps were used. In the case of the short extension, the head room did not admit of the use of arc lamps.

It will be noticed from the plan that the arc lamps are, as a rule, located over the main aisles, except the 12 lights located around the two skylights, where for obvious reasons it was impossible to follow this rule. The distance between the centers of the lamps (in the other direction) varies from 16 to 20 ft. This distance is governed by the columns, the lamps being placed midway between the columns in all cases, with the exception noted above. The six lamps around each skylight are placed at the four corners, with two midway between the corners on the longer sides. These lamps were suspended beneath the skylight by means of long iron brackets. In all other cases the lamps were suspended from screw hooks. Owing to the great height of the first story it was necessary to use extension tubes for supporting the lamps. In this case the screw hooks were screwed into hollow extension tubes, which were fastened to the ceiling, the hook being screwed to the lower end of the tube. At the other floors (the height of stories being less) the hooks were fastened directly to the ceiling. The lamps used were constant-potential enclosed-arc 150-hour lamps. Their resistances were adjusted for, and the lamps are used on circuits having a potential from 95 to 100 volts. Opal inside and outside globes are used. Each lamp is equipped with a switch located at the top of the lamp.

The lamps are mostly wired two on a circuit, and in alternation. The circuits are supplied from two distributing centers, located at the points shown on the plan. Each branch circuit is controlled by a push-button switch located at the cut-out cabinet. Each distributing center is also provided with a knife switch to control the entire group of circuits supplied from that distributing center. No. 12 B. & S. wire is used for the branch circuits. A double-pole fuse cut-out is placed near and connected in circuit with each lamp.

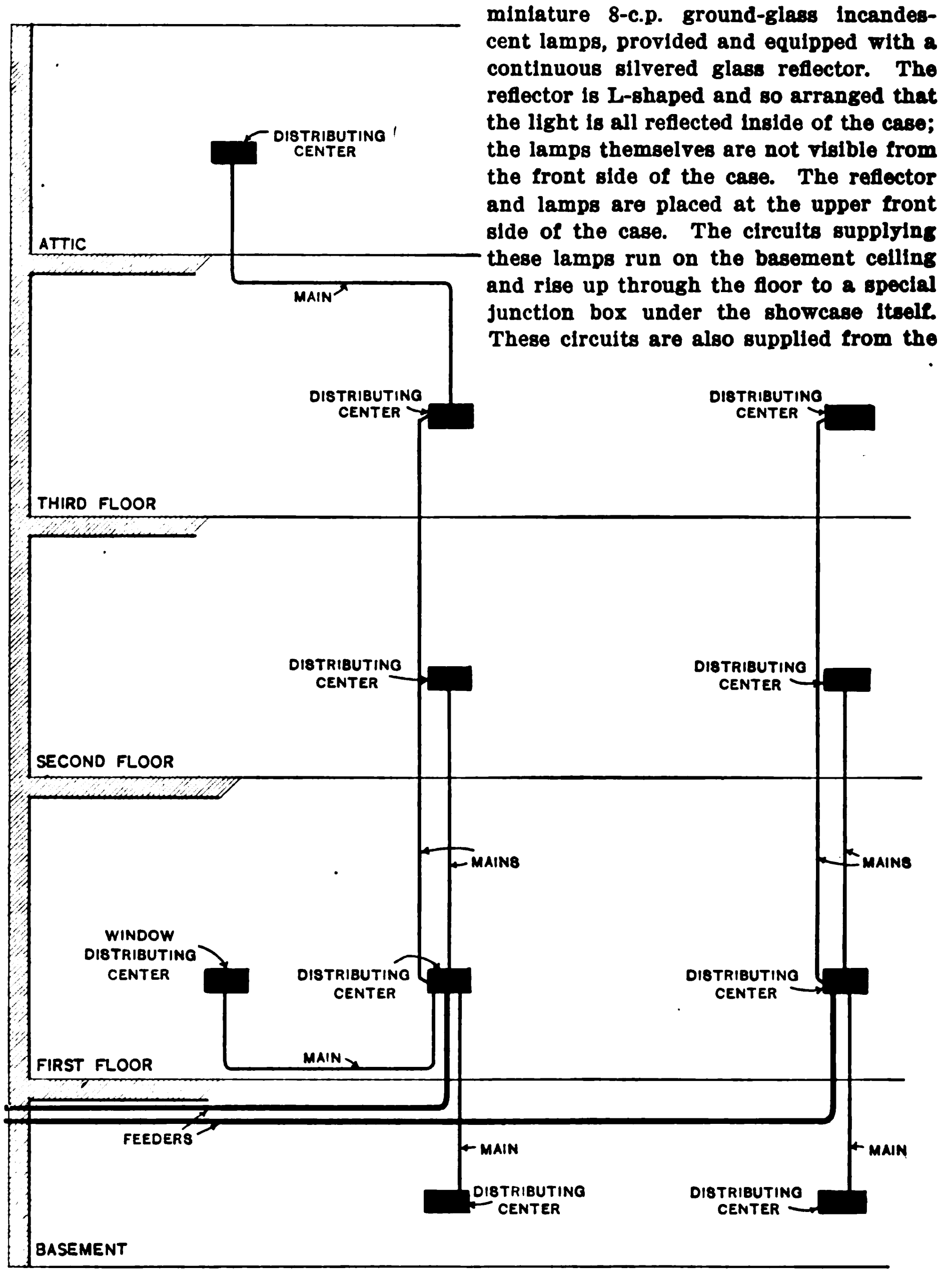

FIG. 2.—LAYOUT OF THE FEEDERS AND MAINS.

The arrangement of feeders and mains is shown in Fig. 2. For the purposes of current supply the building may be considered to be divided into two symmetrical vertical sections, each section being supplied by a separate feeder from an electric plant located in an adjoining building. Each feeder terminates at the first floor; the distributing centers at the basement and upper floors being supplied by mains extending from the first floor. Each feeder is two-wire and of 1,500,000 circular mils sectional area.

The special lighting in the windows is effected by means of incandescent lamps arranged as shown on the plans. Each lamp is set in a ceiling receptacle secured to the ceiling and equipped with a silvered glass reflector. The group of lamps in each window is wired on two special branch circuits originating at a special (window) distributing center, as shown in Fig. 1. This center also supplies the lights at the Fulton street entrance. It is supplied from the same system of feeders and mains that supplies the arc lamps.

The lighting of the showcase near the center of the store is effected by means of miniature 8-c.p. ground-glass incandescent lamps, provided and equipped with a continuous silvered glass reflector. The reflector is L-shaped and so arranged that the light is all reflected inside of the case; the lamps themselves are not visible from the front side of the case. The reflector and lamps are placed at the upper front side of the case. The circuits supplying these lamps run on the basement ceiling and rise up through the floor to a special junction box under the showcase itself. These circuits are also supplied from the arc-light system of feeders and mains. The arrangement of lights in the two showcases at the Hoyt street entrance is the same as in the showcase in the middle of the store. Two special circuits supply two outlets in the newel posts at the head of the basement stairs.

Wireless Telegraphy for French Warships.—A cable dispatch states that the French Government has decided to provide its entire Mediterranean squadron with wireless telegraph apparatus.

COMMON BATTERY TELEPHONE SWITCHBOARD SYSTEMS.

BY W. S. HENRY.

In many switchboards with combination listening and ringing keys arranged to normally ring only through the calling plug, there is an extra push-button by means of which the generator may be connected to the answering plug. This avoids the necessity of interchanging the plugs in case it is necessary to ring up the original calling subscriber, and gives what is sometimes called the ring back. This remark applies to the type of switchboard described in the last article.

A common battery or central-energy system is generally understood to mean one in which all batteries and generators, not only those for ringing up a subscriber, but also those for calling up the switchboard operator, and for supplying current to the subscribers' transmitters, are located at or near the switchboard. Moreover, it is desirable to make one battery supply current for all the subscribers' telephones. Even if located at one central point, a separate battery for each two subscribers that were talking together through the switchboard would be very inconvenient and troublesome, to say nothing of the cost of so many cells.

Before describing a common-battery switchboard system it will be well to consider the principle of some methods that may be employed. In any case it is necessary that the variable resistance of the microphone shall be relatively large in order to alter by an appreciable amount the total resistance of the circuit in which it is connected. The larger the constant resistance in the microphone circuit the less will a given change in the microphone resistance vary the current. By using a transmitter in a local circuit with the primary of an induction coil a current varying between wide limits can easily be obtained in the local circuit, because then the variable resistance of the microphone is an appreciable part of the total resistance of the local circuit. This current causes an alternating electromotive force to be induced in the secondary coil of such a high value that sufficient current is sent through the relatively high resistance secondary circuit to operate the receivers satisfactorily. In the simplest common-battery system where the receivers, transmitters and battery are in series in the same circuit, it is not so easy to make the microphone vary the total resistance of the circuit enough to give satisfactory results. Consequently this simple method is seldom used.

Improvements in the construction of microphone transmitters have, however, helped to make common-battery systems successful. Microphones as now made for common-battery systems have resistances anywhere from 30 to 90 ohms; formerly the resistance of a good microphone only amounted to a few ohms. Of course merely a high resistance in the microphone is not desirable, but if two microphones vary in resistance by the same per cent then the high-resistance one is the more desirable, because it produces the greatest percentage change in the total resistance of the circuit. A good microphone should also be able to carry the necessary current without excessive heating. Microphones for common-battery systems require from .15 to .17 ampere.

There is a considerable number of common-battery systems that differ in principle as well as in details of construction. The Bell companies' systems depend upon a plan devised by H. V. Hayes and represented diagrammatically by Fig. 1. In this diagram two subscribers' stations, S and N, are shown connected together through the apparatus at the central exchange, D, where the common battery, B, and two repeating coils, *o*, *o'*, and *c*, *c'*, are located. These repeating coils are merely induction coils having two coils of equal resistance and the same number of turns. They are wound upon a soft-iron wire core, so constructed that it forms a closed magnetic circuit, and in practice the four coils, *o*, *o'*, *c*, and *c'*, are wound upon the same iron core. The repeating coil used by the Bell Telephone Company is made about as follows: The iron core is ½ in. in diameter by 6 ins. long. The two ends are ¼ in. thick and the center division ⅛ in. thick. The two winding spaces are about 2 11/16 ins. long, each space containing room for two windings. Each winding has 16 layers of No. 26 single silk-covered wire. The two inner windings have a resistance of about 20 ohms each, and the outer windings about 34 ohms each. One inner and the opposite outer winding having a resistance of about 54 ohms, form one-half of the repeating coil, the remaining two windings form the other half.

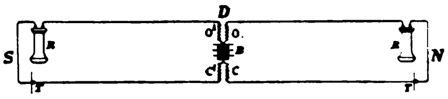

FIG. 1.—THE HAYES SYSTEM.

At the subscribers' stations the transmitters and receivers are shown connected simply in series for the sake of simplicity, but, as a matter of fact, the arrangement is usually quite different, as will be shown later. When the two subscribers' stations are joined together through the switchboard connections, the current from the positive pole of the common battery, B, will divide and pass through the separate windings, *o* and *o'*, of the repeating coil to the live wires leading to subscribers' stations, N and S. The two portions of the current will then flow through the apparatus at the subscribers' stations and return to the central office through the windings, *c* and *c'*, to the negative pole of the common battery, B.

The action of one circuit upon another is as follows: The two circuits may be considered as entirely separate, connected inductively only through the windings of the repeating coil. If the transmitter at station N varies its resistance, the current flowing from the battery through that circuit will vary correspondingly. These variations, passing through the windings, *o* and *c*, will induce electromotive forces in the windings, *o'* and *c'*, producing in the circuit through station S fluctuating currents similar to those in the circuit through station N. When station S is transmitting this action will be merely reversed.

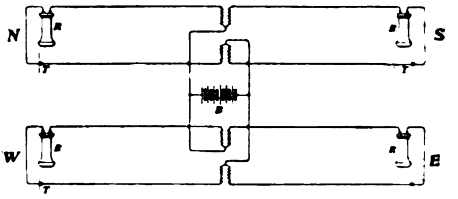

FIG. 2.—ONE BATTERY ARRANGEMENT ON TWO CIRCUITS.

A separate repeating coil must be used at the switchboard in each pair of cord circuits, but the same battery may be employed to serve all the subscribers. Such an arrangement for supplying current from one battery through two separate repeating coils to two separate pairs of subscribers' telephone circuits is shown in Fig. 2. The battery, B, should have a low internal resistance in order to avoid danger of cross talk. Where storage batteries are used there is not the least bit of trouble from cross talk. Low internal resistance primary cells may also be used.

The principle of the system devised by J. S. Stone, also of the Bell Telephone Company, is shown in Fig. 3, where I and I' are two impedance or choke coils that consist of a large number of turns of insulated copper wire wound on a soft-iron wire core; the core being so constructed as to form a complete iron circuit for the magnetic lines of force. The actual shape of the coils is not shown in the figure. The impedance coils are wound with rather large copper wire so that their ohmic resistance may be small and their impedance very large. Hence they will allow steady currents to flow through them quite readily, but will form a practical barrier to rapidly-fluctuating currents such as are produced when telephoning.

The current from the positive pole of the battery, B, will flow through the impedance coil, I', to a point, *b*, where it will divide and pass through each subscriber's station and back to the point, *a*. At this point the two currents will reunite and pass through the impedance coil, I, to the negative pole of the battery. If the two circuits have the same resistance the total current from the battery will divide equally between the two stations. Suppose the resistance of the microphone at E increases, then the resistance of the two circuits will no longer have the same

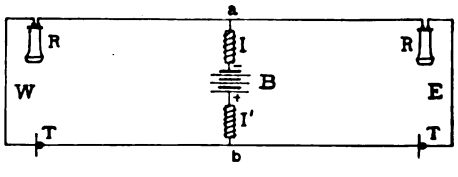

FIG. 3—THE STONE SYSTEM.

relation to each other as before. Moreover, the impedance coils in the bridged circuit with the batteries prevent any appreciable fluctuation in the total current from the battery, and hence it is evident that there will be quite an appreciable decrease in the current through W and a corresponding increase in the current through E. If the resistance of the transmitter at W decreases there will be an increase in the current through W and a corresponding decrease in the current through E. Consequently a rapidly-fluctuating current will flow through E when one speaks into the transmitter at W. In a similar manner the receiver at W will respond when one speaks into the transmitter at E.

By arranging the circuits as shown in Fig. 4 a single battery may serve for a large number of cord circuits. Each cord circuit must be connected through a separate pair of impedance coils with the common battery. Fluctuating currents produced by the operation of the transmitter at E will be confined to the line circuit containing E and W because the impedance coils, I and I', form, as already stated, a practical barrier against the passage of such currents. Even if a small portion of the fluctuations did pass through the coils, I and I', and produce fluctuations in the current through the battery, B, no cross talk would be produced in the other circuit because the battery, if the proper kind is used, has such a low internal resistance that the fluctuating current through it does not produce a fluctuating electromotive force at the battery terminals. Hence there will be little or no tendency for the circulation of a fluctuating current through the impedance coils, J and J', and the subscribers' stations, S and N. Moreover, if there was set up a fluctuating electromotive force at the terminals of the battery, the impedance coils, J and J', would offer such a high impedance that very little or no fluctuating current could get through them. Hence, for the two reasons stated there would be very little or no cross talk produced.

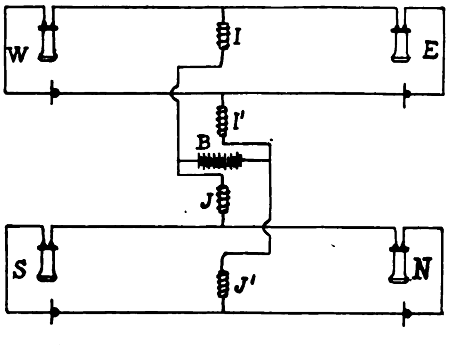

FIG. 4.—COMMON-BATTERY ARRANGEMENT FOR A NUMBER OF CIRCUITS.

The Dean system, shown in Fig. 5, employs an induction coil at the subscribers' station, thereby retaining the advantage due to the use of induction coils. The two subscribers' telephones, N and S, are connected with the central station, D, by means of two line wires and the ground. There are similar impedance coils, I, I' and J, at each station and at the central office. A battery, B, is connected between the ground and the center of the central impedance coil, J. The center, 3, of the subscriber's impedance coil is connected through the primary, p, of the induction coil and the transmitter, T, in parallel, and to the ground, G. The secondary coil, s, and the receiver, R, are joined in series across the terminals, 1 and 2, of the impedance coil.

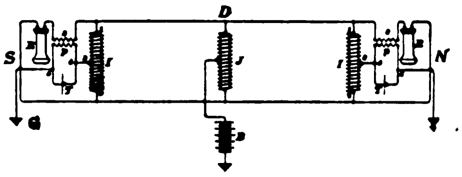

FIG. 5.—THE DEAN SYSTEM.

The current from the positive pole of the battery, B, divides at the center of the impedance coil, J, flowing toward both line wires. Hence this current will not even magnetize the iron core of the impedance coil, J, since it flows around it in opposite directions in the two halves. Hence the iron is in a neutral state, which is its most sensitive condition to repel the passage through the coils of a fluctuating current.

The current flows over the two line wires and the two halves of the impedance coil, I', in multiple to the center point, 3, where the two portions unite and pass to the point, 4. As in the case of the impedance coil J, the current from the battery through the two halves of the impedance coil I' will not even magnetize the iron core, since these currents flow around the core in opposite directions. Hence the iron core remains neutral, and ready to repel the passage through it of rapidly fluctuating currents through the two halves in series. At the point 4 the current again divides, one part passing through the primary coil, p, and the other through the transmitter, T, finally reuniting again at 5 and passing to the ground, G, and back to the battery, B. In an exactly similar manner current from the same battery, B, flows through the lines to station N, and returns by the ground to the battery, B.

Suppose that subscriber, N, is talking. Whenever the resistance of the transmitter at N decreases, a larger portion of the current will pass through the transmitter and a smaller portion through the primary, p, of the induction coil. When the resistance of the transmitter increases a smaller portion of the current will flow through the transmitter and a larger portion through the primary, p. The fluctuating current thus produced in the primary coil, p, will induce an alternating-electromotive force in the secondary coil, s, which will cause the current to flow over the line wires and through station S, operating the receiver there in the usual manner. These fluctuating currents will not pass through any of the coils, I, I' or J', on account of their high impedance to such rapidly varying currents. The voice currents would have to pass through the two halves of the coils in series, and hence, in this case, the two halves would not tend to neutralize one another, but both would tend to magnetize the iron in the same direction. Consequently they offer a very high impedance to the voice currents, but only half the resistance of one coil and line to the current for the transmitter circuit.

AN UNUSUAL CONDITION.

BY E. C. PARHAM.

On a trolley line there is a chance for the line loss or the "drop" to become very great, not only on account of the trolley wire being too small and inadequately supplied with feeders; but on account of the disarrangement, breakage or theft of some of the 350 bond wires to be found in each mile of single track. Each bond wire has two contacts, making 700 joints to the mile, and an imperfection in either contact impairs the usefulness of the bond. The bonds may, to the eye, be in good shape, but each one does not need to have very much of a fault in its contacts in order for the total effect to cause a line loss of 50 or 100 volts. There are many roads where the line loss at a far end of the line amounts to 250 volts. There are other roads on which the loss in places exceeds this, all on account of poor ground returns. In many cases, enough copper could be profitably taken away from the overhead work to properly bond the rails. It is of no use to add more feed wires when the ground return is poor; one might as well poke one part of a water pipe full of sponges and then sand paper and oil the part next to it to make the water flow more freely.

The "unusual condition" forming the particular subject of this article occurred on a 6-mile road where the voltage at the end of the line was so low that a motor car would run up a 5 per cent grade faster with the motors in series than with the controller thrown around to the multiple position. In order to understand the situation, note the following points: In Fig. 1 the motors are shown diagrammatically connected in series in the upper part and in multiple in the lower part of the sketch. The dotted line, x, x, merely indicates corresponding points in the two diagrams. Now, in order for a motor to have a certain pulling power it must have a certain amount of current go through it at a certain voltage. When the motors are in

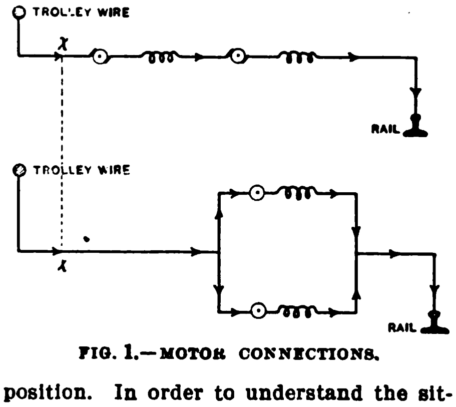

FIG. 1.—MOTOR CONNECTIONS.

series, as shown in the upper sketch, the same current goes through both motors and each one, therefore, gets all of the current that flows in the main line and in any part of the car circuit, as at the point, *x*. But when the motors are in multiple the main line current splits between the two of them, so that in order for each motor to get as much current as it did when they were in series, the main line or total current must be twice as great.

When the motors are in series their counter e.m.fs. are added, of course, and help each other to check the flow of current. As soon as they are thrown into multiple the counter e.m.fs. are no longer added and the ability of the motors to limit the value of the current is much less (practically, about one-half what it was before) so the current taken by the car increases. With the motors in series and the smaller main line current flowing, the line losses amount to a certain value; as soon as the motors are thrown into multiple the main line current increases and the line drop increases at the same rate, because for a given resistance the drop in any line is proportional to the current flowing through it.

Now, the ability of a motor to do work depends upon the amount of power supplied to it, and the amount of work done by a street railway motor is directly proportional to the speed of the car; consequently, if the resistance of the line is so high that the increase of current flowing through the motors when they are connected in multiple pulls down the voltage at their terminals until the current multiplied by the volts is less than the product of amperes and volts when the motors are in series, less power will be delivered to the motors and they will do less work; that is to say, they will not drive the car at as great a speed as before. This was exactly the condition in the case described. With the motors connected in series the number of watts at the motor terminals was greater than when the motors were connected in multiple, on account of the excessive loss; consequently, the speed was higher in series than in multiple.

As intimated in the first part of this article, the greater part of the line loss may be, and usually is, in the ground return through the rails and bonds; consequently, in order to avoid any such contingency as that here described it behooves railway superintendents to make sure that their rail bonds are always in first-class condition.

GLOBE VALVES AND TRAPPED WATER.

BY R. A. DOUGLASS.

There are many little things about a steam plant that for one reason or another do not receive the attention that they deserve. One of these little things, which is really quite essential to the smooth working of a system of piping, is the way in which globe valves ought to set on horizontal pipes. It is just as easy to put them on right as to have them wrong; and yet it is very common to see them put on wrongly. They are shown wrongly, too, in many of the mechanical journals whose editors ought to know better, and even in the trade catalogues that are issued by firms that do know better. These remarks do not relate to the old question of whether the valve ought to shut against the pressure or not, but to the far simpler one of whether the stem of the valve should be upright or horizontal.

A glance at the accompanying engraving will make the point clear. It shows a sectional view of a globe valve that is in position on a line of pipe, with its stem sticking straight upward, instead of off to one side, as it should be. The engraving shows that when a valve is put on in this way, the seat of the valve acts as a sort of dam. Water cannot run through a valve that is set in this position, until it stands as high in the pipe as the edge of the valve seat. When this level has been reached, any further supply of water that may enter the pipe can run over the edge of the valve seat and escape; but the water below the level of that shown in the engraving cannot flow out of its own accord, but must remain in the pipe all the time, unless removed by some cause other than its own natural tendency to run down hill.

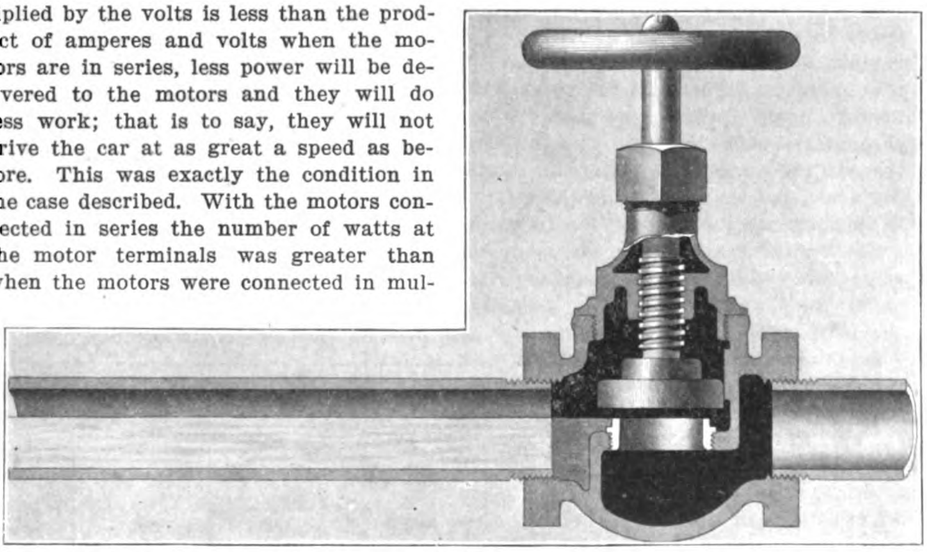

FIG. 1.—SECTION OF GLOBE VALVE SHOWING TRAPPED WATER.

The presence of such trapped water is always objectionable, because under any circumstances it chokes the pipe and lessens its steam-carrying capacity, by diminishing its effective sectional area. This choking effect is hardly worth mentioning, however, in comparison with the trouble that so often follows from turning live steam into a cold pipe half filled with water. Under such conditions, the current of steam causes the water to surge back and forth in the pipe with rapidly increasing violence, until presently the piping begins to "pound" badly, and there is more or less likelihood of a break in the fittings, which may be followed by the most serious consequences if the pipe is carrying steam of high pressure. In heating systems, where the pipes are small and the pressure does not exceed a few pounds to the square inch, there is, of course, no great danger from the water, and yet even in these cases the loud rattling and snapping to which it gives rise are exceedingly annoying. When the pipes are larger, however, and the pressure runs up, perhaps to 75 or 100 lbs., the danger of a rupture becomes correspondingly imminent and grave, and it should be realized and guarded against; for the breaking of a fitting on a large pipe containing steam at a high pressure may do a great deal of damage to property, besides inflicting personal injuries and causing loss of life.

The writer recalls an instance in which an 8-in. globe valve on a high-pressure line of piping burst, apparently on account of the accumulation of trapped water in the pipe; and he was very deeply impressed by this experience with the importance of attending to the drainage of such pipe lines. The valve in question was on a main steam pipe, and every time it was opened the accumulated water in the pipe would be thrown violently about, so that a loud "pounding" was produced, which lasted until the water finally found its way down into the boiler or somewhere else. Things went on in this way until one day the valve gave out. It may be that a crack had been started gradually somewhere by the violent hammering that the casting had received from the water; or it may be simply that the valve was opened quicker than usual on this particular occasion, so that the water-hammer action was unusually severe. At any rate, at the time of the accident steam had hardly been turned into the pipe when a large piece of the valve casing broke away, and a vicious blast of steam blew out into the boiler room, fatally scalding one man and inflicting dangerous and very painful injuries on two others.

Troubles of this kind may be due to incorrect design of a pipe line, for it is by no means uncommon to see a line of pipe put in so that it cannot drain itself under any circumstances, whether the valves are put on correctly or not; but it should be noted that so far as they are attributable to the water-trapping action of a globe valve, they may be entirely avoided by putting the valve in so that its stem lies horizontal. When this is done the valve seat will stand up edgewise (that is, vertically) and cannot act as a dam. The opening in the valve seat is supposed to be equal in diameter to the full diameter of the pipe; hence when the valve seat stands vertically the bottom of the opening in it will be on a level with the bottom of the inside surface of the pipe, so that all the water in the pipe can run through the valve and none of it will be trapped in the manner illustrated in the engraving. As has already been said, it is just as easy to put valves on in this way as to put them on in the wrong way; and, therefore, there is no excuse for making the error under discussion after attention has once been called to it.

FLY WHEEL ACCIDENTS.

BY C. W. OBERT.

There is no part of the steam engine which is more given to accidents than the fly wheel. In spite of careful design, both in the fly wheel and in the engine's governing devices, some component in either is liable at any time to fail and cause a costly, if not fatal, accident. It is a matter of common knowledge that there are many engines that are being run at higher speeds and higher pressures than normal in order to obtain greater power therefrom without the expenditure of an addition to the plant. But this is almost criminal carelessness, as a slight increase of speed in such a case, caused perchance by a slip of the governor belt or the sticking of the governor parts, can set up centrifugal strains in the wheel sufficient to rupture it, and it is certain that many accidents have happened in this way.

The object sought in placing the fly wheel upon an engine's shaft is to "balance up" the unevenness of the engine's working and to tend to keep the shaft revolving at a constant speed regardless of the conditions imposed upon it. When the load on the engine varies suddenly, the fly wheel must either absorb or give out energy, according as the load increases or diminishes, until the governor has had time to regulate the piston effort to the necessary amount. But besides these variations of speed due to outside causes, which it is the function of the governor to check, there are variations from causes within, over which the governor has no control. These internal causes are the varying rate at which the engine does its work, on account of the changes of steam pressure in the cylinder during a stroke and the different leverages that the connecting-rod has on the crank pin in its different positions. As is shown by any indicator card, the greatest steam pressure acting on the piston, does not continue further than from about one-third to one-half stroke in the cylinder of an engine working expansively, after which the piston pressure decreases very rapidly owing to expansion of the steam. And then the connecting-rod does not have nearly as great a leverage to turn the crank when the crank pin is near the dead centers as when it is at the top and bottom quarters.

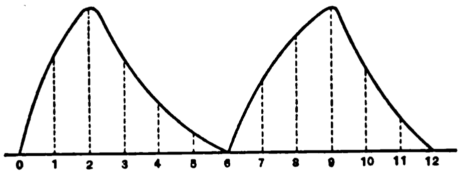

FIG. 2.—DIAGRAM OF CRANK EFFORT.

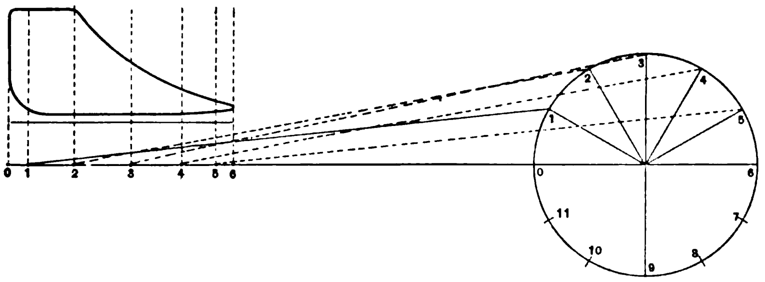

FIG. 1.—METHOD OF FINDING CRANK EFFORT FROM INDICATOR CARD.

As illustrated by Fig. 1, at the beginning of a stroke, just after the crank has passed the inner center, the steam pressure acting on and tending to drive the piston is highest, but the connecting-rod has such a short leverage over the crank that the resulting "crank-effort" is very small. As the crank moves around toward the quarter, the leverage becomes greater and greater, and consequently the crank effort increases until the cut-off takes place. Then the steam begins to expand, causing its pressure on the piston to diminish, and shortly thereafter the crank passes the quarter, and the leverage begins to diminish. The combined result of these variations is that the greatest turning effort delivered to the shaft is exerted at or near the cut-off point of the stroke, while at the other parts of the stroke the turning effort is very small.

The varying value of the turning effort at different positions of the crank pin is shown by the curves in Fig. 2. Now it is the province of the fly wheel to serve as a storage reservoir to receive these extreme turning efforts, and then give them out later in the stroke when the piston is doing less and less work, besides acting as a supply reservoir in general when the load on the engine changes. Therefore, in the design, much care has to be given to properly proportioning the spokes, as well as to the weight of the rim, as the entire effect of the shock of these sudden and repeated changes of effort and load has to be borne by the spokes.

It would seem that a carefully-proportioned wheel should easily withstand the strains due to its intended speed, but there is always the uncertainty of hidden defects in construction over which the designer has no control. If the fly wheel is to be made of cast iron, as most of them are, it is almost impossible to avoid having internal strains come upon it in the cooling after casting, which weakens it. If the spokes are made straight, as is usual, the massive circular rim will, in shrinking, tend to press inwardly upon them, sometimes with almost crushing pressure. Skilled designing and careful handling in the foundry will generally eliminate the evils of unequal shrinkage; nevertheless, if a flaw should exist, it could not be seen, and the fly wheel would operate as a menace to everyone near. Even in the laminated rim and various anti-bursting types of fly wheels there is a possibility of the endangering flaw.

The most common apparent cause of fly-wheel accidents is the slipping of the governor belt or some disarrangement of the governor's mechanism. The cause of the bursting of a fly-wheel in Peoria, Ill., was said to have been the slipping of the governor belt. The fragments of the wheel in this accident destroyed three dynamos and did considerable damage to the structure of the building, crushing massive floor beams, while portions went through the roof and landed a block away.

In the case of the bursting of a 20-ft. fly-wheel in a large steel works it was claimed that one of the governor balls became detached, allowing the engine to race. Although this wheel is said to have been especially well designed and carefully constructed, it flew into fragments, tearing out the entire end of its building and roof.

Sometimes, on the other hand, the engineer becomes confused from excitement and does not choose the wisest course. At the Hoboken electric light station an engineer became "rattled" during the replacing of some burnt-out fuses, and attempted to slow down the engine by raising the governor balls. But he moved the governor mechanism in the wrong direction, as a result of which the engine raced until the fly-wheel burst, tearing out the walls and roof of the station. The unfortunate engineer paid with his life the penalty of his confusion.

One of the most remarkable of these accidents took place at Lynn, Mass., during a slight fire in the wire tower. A general short-circuiting was claimed to have taken place at which the pulleys on the jack shaft crushed, allowing the engine to run away. It was presumed that a flying fragment from a jack pulley deranged the governor mechanism, although the true cause of the engine's running away remains shrouded in mystery. The fragments of the fly-wheel cut a swath through both sides and the roof of the building, one large piece being carried fully 150 ft. and wrecking the corner of a neighboring house.

One of the most recent fly-wheel accidents occurred at South Bend, Ind., Jan. 19. The engine was a 300-h.p. slow-speed, of the Corliss type. The fly wheel was 24 feet in diameter, with a 4-ft. face, and was driven at 65 r.p.m. A nut dropped off in the cylinder, which jammed the piston and threw the crank shaft out of its bearings. The engineer heard the noise in the cylinder and just had time to shut off steam from the cylinder when the fly-wheel flew into pieces. Fortunately no one was hurt. The flying fragments tore a large hole through the engine-room roof and wrecked the engine completely.

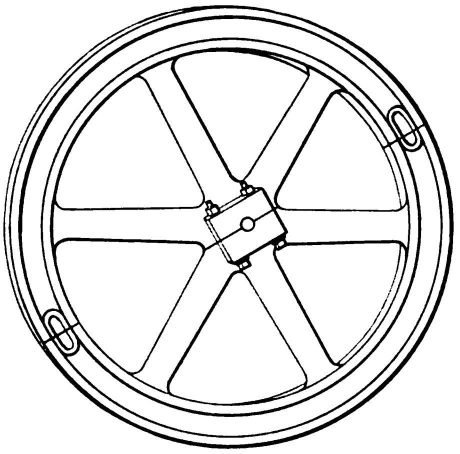

FIG. 3.—LINKED JOINT FLY WHEEL.

A series of experiments has been conducted recently at the Case School of Applied Science, Cleveland, Ohio, to determine the strengths of different kinds of fly-wheels by deliberately running them at sufficiently high speeds to burst them. A great many important points were learned in connection with these tests. It was found, in a comparison of solid and segmental wheels, that none of the segmental wheels were as strong as the solid wheels. These tests revealed the unknown difficulty of properly securing together the two halves of a "split" fly-wheel. Of all the prevailing methods of joining, the linked joints, such as are common in very heavy direct-connected railway generator work, were found to be the best; these proved to be two-thirds as strong as the solid rim which they connected. Joints made in the ordinary manner, with internal flanges bolted together, are probably the worst that could be used for this purpose, as they were found to have only one-fourth the strength of their rim.

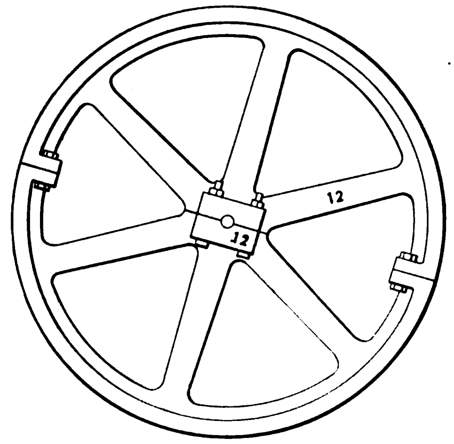

FIG. 4.—INTERNAL FLANGED FLY WHEEL.

It seems rather strange that notwithstanding the availability of several efficient safety stops, fly-wheel accidents due to excessive speed continue to occur right along. There are several devices on the market which are designed to shut off steam from the engine in case its speed should rise beyond a certain predetermined value, wnile others have been attempted which should at least give a signal, electrically or otherwise, in case of such excessive speed. Safety stops of the former types, especially those independent of the governor mechanism, have proven very successful in actual service, and a more general use of them would do much to protect life and property.

If for any reason the use of a safety stop is impractical, some means should certainly be provided for the control of the engine without jeopardizing the safety of the engineer. It should be possible to shut off steam at a moment's warning from a point distant from the engine, or, in the absence of an arrangement of this kind, the throttle valve should be located on the side of the cylinder opposite from the fly-wheel side of the engine instead of on the same side with it, where it is almost always put. This would enable the engineer to handle his throttle without the absolute certainty of being killed in the event of the disintegration of the fly-wheel.

Lessons in Practical Electricity

THE ROTARY MAGNETIC FIELD.

Like the current which produces them, magnetic fluxes due to alternating current have phase relations. If two coils of wire be mounted on a single core and traversed by alternating currents which differ in phase, the magnetic flux produced will be the resultant of the two fluxes which would be produced by the coils separately. Thus, if the currents were equal but differed in phase by a quarter of a cycle (commonly termed 90°), they would be represented by two vectors of equal length, 90° apart, as in Fig. 1. The fluxes produced could be represented by the same vectors, as the magnetic lines rise and fall in the same fashion as the current that produces them; the resultant of the two fluxes, therefore, may be plotted by combining the vectors, as shown in Fig. 2, and explained in the February Lesson.

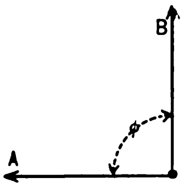

FIG. 1.

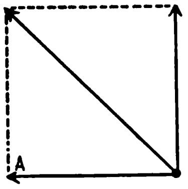

FIG. 2.

Suppose two coils be wound on an armature core as indicated in Fig. 3; the coils being arranged at right angles with each other, the individual fluxes which they produce will also be at right angles with each other, the flux produced by the coil, A, being parallel with the wires of the coil, B, and the flux produced by the winding, B, being parallel with the wires of the coil, A. If the two coils be connected in series, as shown in the diagram, and a current, alternating or otherwise, be passed through them, the two fluxes produced by the coils will combine into a single resultant flux, the direction of which will be midway between the two, as indicated by the dotted lines in the sketch. (For the sake of simplicity the dotted lines are not carried all the way across the core but the lines of force, of course, extend across from side to side.) The strength of this resultant flux is measurable by the parallelogram method, just as the resultant of any other two forces. For example, referring to Figs. 1 and 2 again, if each individual flux has a strength of 100,000 lines then the resultant flux will have a strength of 141,421 lines, the ratio of the diagonal of a square to one of its sides being 1.41421.

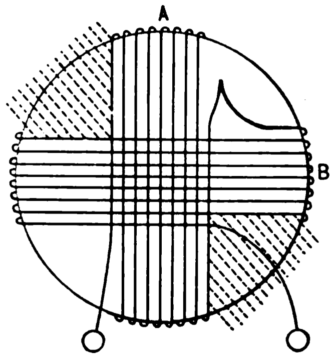

FIG. 3.—COILS 90 DEGREES APART.

Now, if the windings be separated and each winding supplied with a separate alternating current, the two currents differing in phase by a quarter of a cycle, the resultant magnetic field will not remain stationary midway between the two coils, as shown in Fig. 3, but it will rotate just as though it were supplied from a permanent bar magnet pivoted at its center and rotated by some external force. Inspection of Figs. 4 and 5 in connection with Fig. 3 will make this clear. Referring to Fig. 3, it will be evident that the flux produced by the coil, A, alone would have a

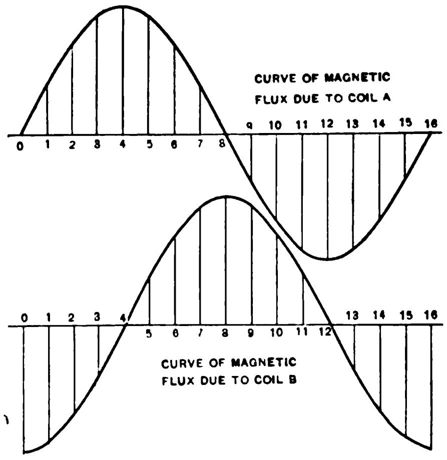

FIG. 4.—TWO-PHASE CURVES.

horizontal direction and would simply vary in strength and alternate in polarity. This flux may be represented, therefore, by a horizontal vector, the length of which represents the strength of the flux at a given instant and the direction its polarity. The flux created by the coil, B, would also vary in strength and alternate in polarity, but its direction would be vertical. This flux may, therefore, be represented by a vertical vector, making the length of the vector indicate the strength of the flux at any given instant and the direction its polarity. Fig. 4 gives a comparison of the strengths of the two fluxes at 16 equidistant instants during one complete cycle. The strength of the flux at each instant is indicated by the length of the vertical lines between the horizontal zero line and the sine curve, in the usual manner.

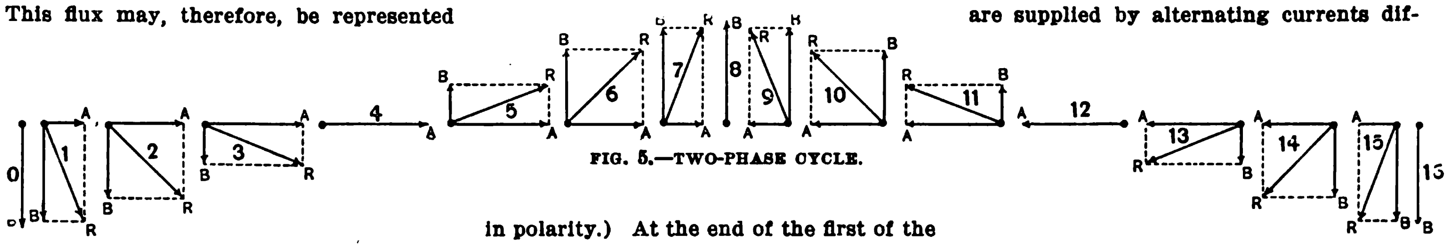

FIG. 5.—TWO-PHASE CYCLE.

In Fig. 5 the strength and polarity of the two fluxes are plotted for each of these 16 intervals of a cycle, and their resultant is also plotted. At the beginning of the cycle the strength of the flux from the coil, A, is zero, and that from the coil, B, is maximum (say, 100,000 lines) in the negative direction. (Assume that in Fig. 3 when the vertical flux passes from the bottom to the top of the core through the coil, B, its polarity is "positive," and when the horizontal flux passes from left to right through the coil, A, it is positive in polarity.) At the end of the first of the 16 intervals of the cycle (Figs. 4 and 5) the flux through A has risen to 38,268 lines, and the flux through B has diminished to 92,388 lines. These fluxes are indicated in Fig. 5 by the vectors, A and B, the resultant of which is the vector, R; if the vectors, A and B, are plotted to scale, the length of R on the same scale will indicate a resultant flux of 100,000 lines; its position, it will be noted, has shifted just 1/16 of a circle from the position of the vector, B, which at the commencement of the cycle was the only flux and therefore identical with R. At the end of the second interval the flux through A has risen to 70,711 lines, and the flux through B has decreased to the same figure. The resultant of these is still 100,000 lines, but the resultant flux has shifted through another 1/16 of the circle. The rotation of this resultant field may be traced throughout Fig. 5, the individual diagrams of which represent the combination of the two fluxes at the sixteen intervals of the cycles; these intervals are indicated by numerals in both Figs. 4 and 5.

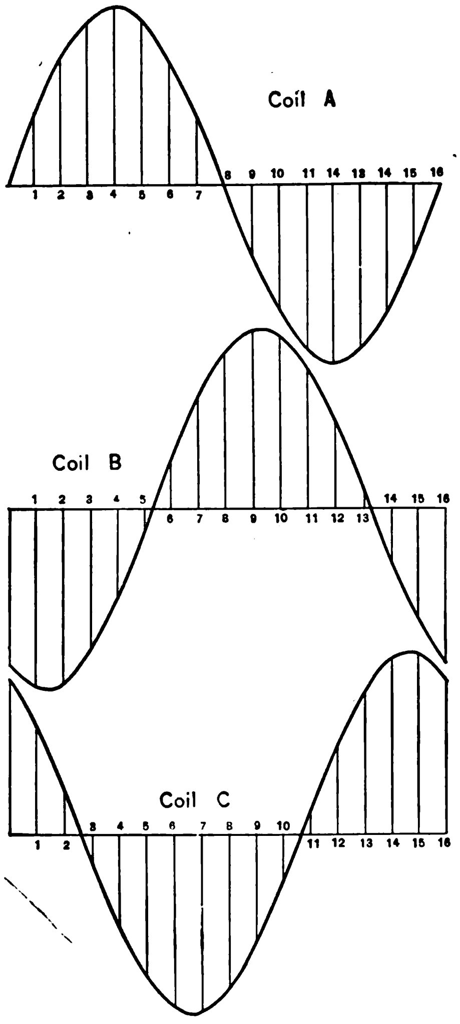

FIG. 6.—THREE-PHASE CURVES.

It will be evident that the length of the vector, R, remains constant throughout, and its position shifts around the circle by intervals corresponding with the intervals of a cycle, so that at the end of one cycle the plane of the result flux, represented by the vector, R, will have made one complete revolution. It will be understood that the rotation of the field will be uniform as to rate, and will not occur in jumps from one position to another, as a too literal interpretation of the diagram might lead a beginner to suppose. The cycle has been divided into 16 steps merely for convenience; but the shifting of the field will be continuous, just as though one divided the cycle into an infinite number of steps.

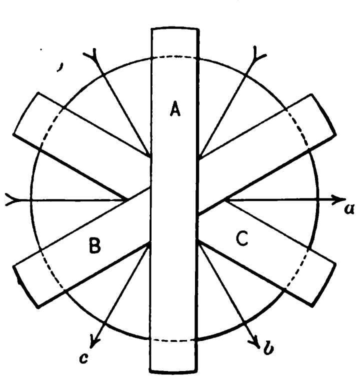

FIG. 7.

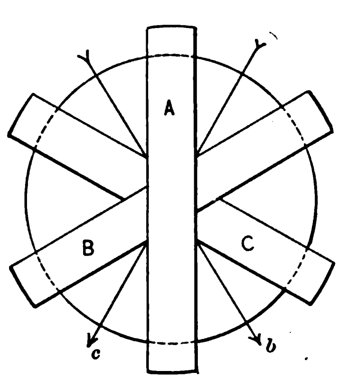

FIG. 8.

The case of a three-phase rotating field is similar but not quite so simple. Fig. 6 shows three curves, representing the rise and fall through one cycle of three magnetic fluxes produced by three coils which are supplied by alternating currents differing in phase by 120°. As in the previous case, the cycle has been divided into 16 equal intervals indicated by numerals. If these three coils be mounted on a single core and displaced angularly 120°, as indicated in Fig. 8, the three-phase currents supplied to them will produce a rotating field just as the two-phase currents did in the two coils previously considered. It will not be necessary to follow through a complete cycle in order to demonstrate this; one-quarter of a cycle will be sufficient.

At the beginning of the cycle the coil, A, produces no flux; we will assume that the current through the coil, B, is in such direction as to produce a flux in the direction of the arrow, *b*, and that the current through the coil, C, produces a flux in the direction indicated by the arrow, *c*. We will also assume that the strength of the flux is proportional to the strength of the current and that the maximum strength of the flux produced by any one coil is 100,000 lines, as before. At the beginning of the cycle all of the flux is due to the coils B and C, which produce each a flux of 86,603 lines. It will be evident upon inspection that the mechanical phase difference (angular displacement) between these two fluxes is only 60°. The combination of the two fluxes is indicated by the extreme left-hand diagram of Fig. 9 (which is marked 0 to correspond with the numbering of the intervals in Fig. 6), where B and C represent the two individual fluxes and R the resultant. This resultant is 150,000 lines.

At the expiration of the first interval of the cycle, the coil, A, produces a magnetic flux from left to right, as indicated by the arrow, *a*, Fig. 7. This flux is indicated in Fig. 9 by the vector, A, and its strength at the end of the first interval is 38,268 lines. The strength of the flux from coil B has increased to 99,144 lines and the strength of the flux from coil C has diminished to 60,876 lines. The resultant of the fluxes, B and C, is indicated by the broken line, *r*. Combining this vector with the vector, A, by the parallelogram law gives the resultant, R, the length of which indicates the flux of 150,000 lines; the direction of the resultant has been shifted 1/16 of a circle. The diagrams marked 2, 3 and 4, in Fig. 9, show the combinations of the three fluxes at the expiration of the second, third and fourth intervals of the cycle, the fourth interval completing a quarter revolution of the field. In each case the resultant of the fluxes, B and C, is indicated by the broken line, *r*, and this is combined with the vector, A, to form the resultant, R, which invariably indicates 150,000 lines of force. Between the second and third intervals the flux from coil C comes to zero and reverses (see lowest curve in Fig. 6); at the expiration of the third interval, therefore, the polarity of this flux will be opposite to its former sign, so that the vector, C, is plotted on the opposite side of the point of origin in diagram No. 3 of Fig. 9. The angular displacement of the two fluxes, B and C, is now 120° instead of 60. At the expiration of the fourth interval the resultant of the fluxes, B and C, is in line with the flux, A, so that it is added directly to it, giving the vector, R. Applying a scale to the diagram will show that the length of the vector, R, has remained constant, the only effect being to shift its position around through one-quarter of a circle.

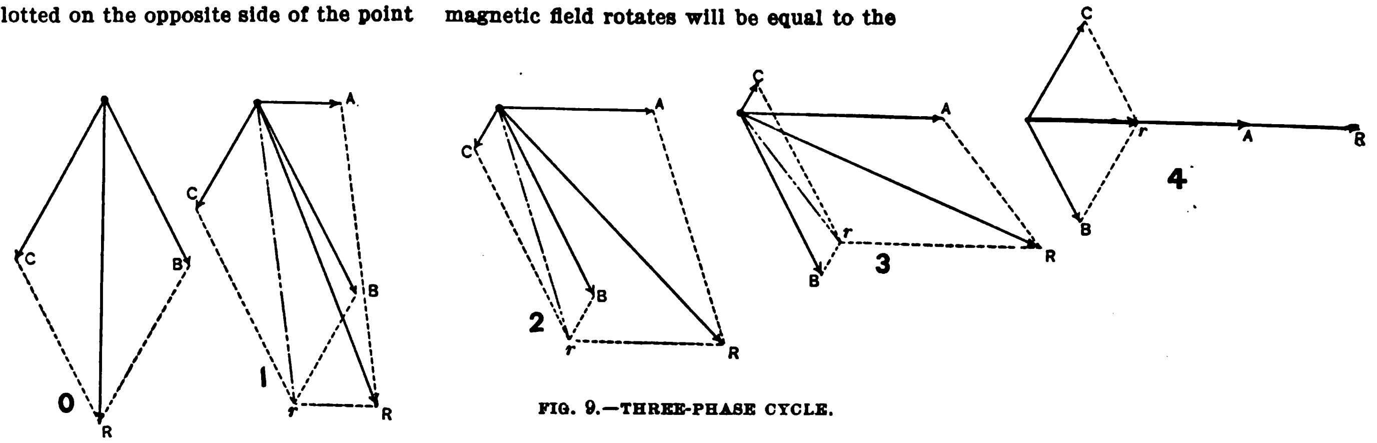

FIG. 9.—THREE-PHASE CYCLE.

The accompanying table gives the instantaneous values of each of the three fluxes through one complete cycle at intervals of 1/16 cycle, together with their polarities, calling the horizontal flux of Fig. 8 positive when its direction is from left to right and the other two fluxes positive when their direction is upward.

Parts of a cycle.	Flux A	Flux B	Flux C	Resultant Flux, 150,000 Lines.
Start	0	86,603 N	86,603 N	Vertical; downward
1/16	38,268 P	99,144 N	60,876 N	22½° from vertical.
2/16	70,711 P	96,593 N	25,882 N	45° from vertical.
3/16	92,388 P	79,335 N	13,053 P	67½° from vertical.
4/16	100,000 P	50,000 N	50,000 P	Horizontal; right
5/16	92,388 P	13,053 N	79,335 P	22½° above horizontal.
6/16	70,711 P	25,882 P	96,593 P	45° above horizontal.
7/16	38,268 P	60,876 P	99,144 P	67½° above horizontal.
8/16	0	86,603 P	86,603 P	Vertical; upward
9/16	38,368 N	99,144 P	60,876 P	22½° from vertical.
10/16	70,711 N	96,593 P	25,882 P	45° from vertical.
11/16	92,388 N	79,335 P	13,053 N	67½° from vertical.
12/16	100,000 N	50,000 P	50,000 N	Horizontal; left
13/16	92,388 N	13,053 P	79,335 N	22½° below horizontal.
14/16	70,711 N	25,882 N	96,593 N	45° below horizontal.
15/16	38,268 N	60,876 N	99,144 N	67½° below horizontal.
End	0	86,603 N	86,603 N	Vertical; downward.

From the foregoing it will be evident that:

(1). If two or more coils, arranged with their centers coincident and their planes displaced until the included angles are all equal, be excited by individual and equal alternating currents which follow the sine law and differ in phase by $\frac{1}{x}$ of a cycle, x being the number of coils, the magnetic fluxes produced by the coils will combine to form a resultant field which will revolve uniformly about the center of the coils in a plane of rotation at right angles with the planes of the coils.

(2). The resultant flux will not be alternating but will remain constant at a magnitude equal to $\frac{x}{2}$ times the *maximum* value of the alternating flux produced by any one coil.

(3). The rate at which the resultant magnetic field rotates will be equal to the frequency of the exciting currents. Thus, 60-cycle currents will cause the field to make 60 revolutions per second (in the elementary case under consideration).

Should the currents not follow the same law or should they be unequal in value, the resultant magnetic flux will not be constant, but will vary between $\frac{x}{2}a$ and $\frac{x}{2}z$, a and z representing the maximum values of the strongest and weakest fluxes respectively, and x, the number of coils. The rotation of the field will also be irregular, being more rapid during some parts of a cycle than during other parts of the same cycle; the average rate, however, will remain identical with the frequency of the exciting currents.

Letters on Practical Subjects

Starting Up Steam Engines.

To the Editor, American Electrician:

Sir:—It is customary with many engineers in starting up an engine, after opening the drip cocks and clearing the water out of the cylinder, to run the engine up to speed with the drip cocks still open. If the drip is delivered into the open air this practice is all right, but where the drips are delivered to a trap or are connected so that their ultimate opening into the atmosphere can be plugged up with the water of condensation, the practice of bringing the engine up to speed with the drip cocks open has been known to cause serious accidents, especially in the case of small high-speed engines. In one case within the writer's observation water was drawn into the front end of the cylinder from the drips and pushed the piston partly off the rod, breaking off the threaded end of the rod on which the piston-head nut was screwed. This broken end consequently fell down between the piston and the back cylinder head and on the return stroke it jammed the piston forward to such an extent that the piston rod buckled inside the cylinder; when the crank went forward the next time, the piston rod followed until the bent portion struck the inner edge of the stuffing box, when, of course, it could go no further, and the engine was brought to a sudden halt. The cylinder head was knocked off by the force of the blow from the piston when the rod was buckled.

The explanation of the origin of the trouble is, that when the engine is turning over slowly with the drips open, if the throttle is opened at all quickly the piston gives a sudden leap, throwing the governor weights out beyond their normal position and entirely closing the valve. The consequence is that on the return stroke the engine takes no steam and the piston forms a partial vacuum in the cylinder, drawing back the water from the drips. With large slow-speed engines, of course, this trouble is not so likely to occur, as the inertia of the moving parts will usually prevent such sudden motion on the part of the piston as to make the governor close the valve entirely, but on medium-size and small engines with shaft governors, the drip cocks should be invariably closed after the cylinder has been cleared of water and before the engine is speeded up. W. C. Townsend.

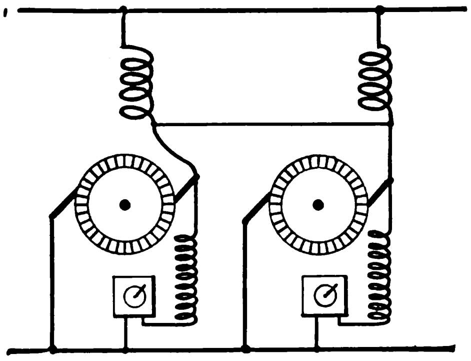
Compound Dynamos in Parallel.

To the Editor, American Electrician;

Sir:—In the latter part of Mr. Parham's article on "Bucking of Railway Generators" last month, the statement is made that if one machine tends to overpower its mate and drive it as a motor, and the two are highly compounded, "the series field of the motored machine may be strong enough to try to reverse the direction of rotation of its armature (since series dynamos run in the opposite direction as motors)." Mr. Parham apparently overlooks the fact that with an equalizer connection between the dynamos it is impossible for one to deliver current backward through the series winding of the other. The accompanying sketch will make this clear. The equalizer puts the series windings in multiple, and the current cannot pass in opposite directions through the two windings. If the statement refers to dynamos without an equalizer, it is a little misleading, because no one would ever attempt to run compound-wound dynamos that way.



GENERATORS WITH EQUALIZER.

Brooklyn, N. Y. Geo. W. Malcolm.

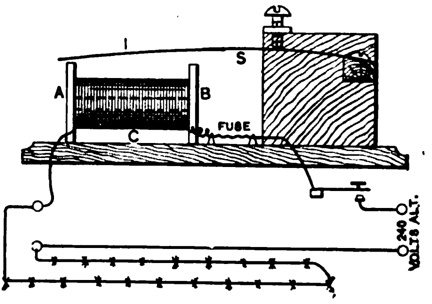
A Convenient Circuit Tester.

To the Editor, American Electrician;

Sir:—Thinking that some of your readers may be interested in an application of alternating currents for testing lighting circuits both for continuity and for grounds, in place of the familiar magneto which is, as is well known, frequently unreliable, I submit the accompanying arrangement which is used in our plant here. Referring to the engraving, C is an 80-ohm magnet coil with a soft-iron core and two thin projecting pole-pieces, A and B. A thin iron armature, I, is soldered to the end of a brass spring, S, which is mounted at its right-hand end on a wooden cleat on the side of the wooden standard. An adjusting screw is provided in an overhanging brass plate to regulate the distance of the armature, I, from the pole-pieces, A and B. The sketch shows the testing device connected to an arc circuit. On connecting the right-hand terminals to a 240-volt alternating-current circuit and closing the switch, if the arc circuit is intact the spring will be drawn down until it touches the pole-piece, A, and then gives a loud buzzing noise due to the rapid reversal of the alternating current. The spring is adjusted so that the armature cannot touch the pole-piece, B.



CIRCUIT TESTER.

This apparatus has been in use a long time and under varying conditions, and has proved more sensitive than a magneto, especially in testing circuits for grounds. On one particularly wet day all the circuits were tested for grounds with a magneto; no ring whatever was obtained, indicating that the line insulation was at least 30,000 ohms from the ground. On trying the apparatus here shown, one circuit gave a feeble buzz, showing that notwithstanding the magneto test there was a slight ground on that circuit. After setting the armature for testing the continuity of a circuit no further adjustment is necessary in order to detect grounds which a 30,000-ohm magneto will not indicate. The arrangement is also useful, of course, in testing for open circuits and grounds in various pieces of apparatus around a station, such as enclosed fuses, armature and field magnet coils, arc lamps, etc. J. A. Keniston.

Portland, Maine.

Central Station Charging.

To the Editor, American Electrician;

Sir:—In Mr. Henry L. Doherty's paper read before the Northwestern Electrical Association, on the rate question, he says: "In view of the fact that it will be inadvisable to enforce this system on old consumers, who will be injured by its adoption, I propose to adopt it first as a substitute for all special rate consumers and also for new consumers. Instead of dividing my expenses as they exist today and apportioning them among consumers on this basis, I expect to adopt such charges as will benefit the long-hour, and, therefore, the profitable, consumers, to such an extent as can be readily compensated for by the additional business which can be secured with a lower rate per kilowatt-hour. I will continue the rate cutting by small steps so long as I can protect the company's net earnings from marked shrinkage." A system which cannot be put into force without injury to customers must be wrong somewhere. Dividing his expenses as they exist to-day among the customers of a plant that may be ten times too large for their wants, is a feature that would not meet with much success in Massachusetts, for instance, where they have gas and electric-light commissions to protect the interests of the public or patrons of the company. Any discrimination in favor of one set of consumers over another set does not appeal very strongly to the other set in the same class, as the correct thing. It is proper to "protect the company's net earnings," but not at the expense of the old customers entirely.

The idea of charging for the capacity demanded is not new, as witness the Wright demand system, nor is the idea of limiting that demand a new feature, as the Wright demand meter people have advocated that same thing in connection with their plan of charging. That a charge for capacity is entirely proper no one can gainsay.

In the case of Benj. A. Gould *vs.* Edison Electric Illuminating Company in the New York Supreme Court, Judge Beekman said: "Mr. Gould desired 11 lamps, and the court holds that in view of the alleged total additional investment made necessary on the part of the company of at least $220 to comply with the demand the fixed charge ($18 per year) not based on actual consumption was not of itself improper or unreasonable. The customer does not bind himself to use any particular amount of light, so that the return to the company, based on actual consumption, would rest entirely upon his volition, and it would therefore depend upon him whether the service he has required the corporation to be in constant readiness to render is profitable or unprofitable to the latter. But this constant condition of readiness is a necessary and unavoidable obligation, which must be sustained in order to meet instantaneously the demand for light which the consumer is entitled to have at any moment that he wishes it. It thus forms part of the service to be rendered, and is an item properly to be considered when the reasonableness of the charges exacted by the company is called in question."

There is no doubt but that "readiness to serve" forms a part of the service to be rendered, and it ought not to be an impossibility for some one to devise a system that would need no further excuse for its existence. Mr. Doherty acknowledges the weakness of his system by the assertion that it is not advisable to let all customers share alike in dealing with the company, and in presenting a manifestly illegal way of introducing it. The practice of making a fixed charge for capacity demanded has been in vogue in Manchester, England, for years. The system there fixes the charge at $2.10 a month for each kilowatt capacity of load wired up, and there is a *pro rata* charge for all current of three cents per kilowatt-hour. This does not differ materially from the plan proposed by Mr. Doherty, and is manifestly unjust for the same reason—the starting point is wrong. The general argument is good, but the method of developing and putting the system in operation is certainly open to criticism. A device for limiting the number of lamps a customer may use at one time was put on the market some time before Mr. Doherty's plan was made public, and I fail to see why he should claim it as entirely original with him. R. J. P.

An Improvised Booster.

To the Editor, American Electrician;

Sir:—In Ed. S. Morgan's letter in your January issue on "An Improvised Booster," he states that he used a single-pole double-throw switch to cut out the transformer during light load and get rid of core losses. Throwing the switch to the right, as per original diagram (Fig. 1), cuts out the secondary of the transformer so far as its boosting is concerned, but does not get rid of the core loss, as the, transformer is still energized, the primary and secondary windings being connected in series across the line, as shown by Fig. 2. A double-pole double-throw switch connected as shown by Fig. 3 is necessary to cut out the transformer so as to eliminate core losses. The diagram, Fig. 4, was suggested to the writer as being what Mr. Morgan may have intended to draw instead of that shown by Fig. 1. This arrangement, however, is open to the very serious objection that while the switch lever is in transit from one side to the other, being in contact with neither of the jaws, the full line current passes through the secondary winding and induces a disastrously high e.m.f. in the primary winding. This will be apparent when it is remembered that the exciting current of the transformer is only about two per cent of the full current. The ampere turns, therefore, in the secondary winding when the switch lever is free from both contacts, will be about 50 times as great as the normal exciting ampere turns of the transformer. The result will not be 50 times the normal e.m.f. because the magnetic flux will not increase in direct proportion to the ampere turns, but it will increase sufficiently to make the e.m.f. induced in the primary winding dangerously high, and I advise against using this arrangement under any circumstances. C. C. Webster.

Asbury Park, N. J.

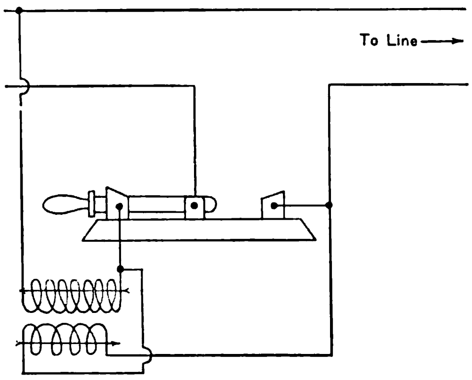

FIG. 1.

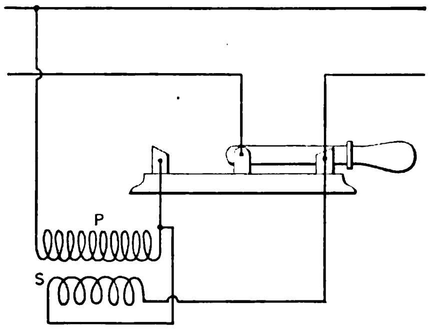

FIG. 2.

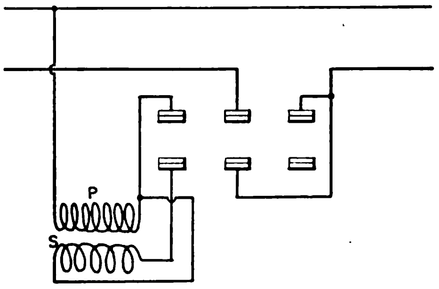

FIG. 3.

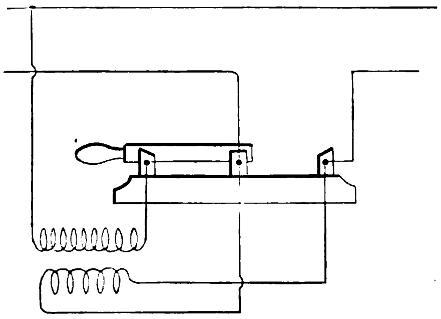

FIG. 4.

To the Editor, American Electrician;

Sir:—In the letter on "An Improvised Booster," in your January issue, a double-throw, single-pole switch is said to be employed to "cut out the booster during light load and get rid of the losses in the core." As the connections were shown, the primary and secondary coils would still be in series, with the switch in the right-hand position, and the core losses would not be appreciably lessened. A double-pole double-throw switch, connected as in the following diagram (Fig. 5), would remedy this difficulty.

Detroit, Mich. H. P. Wood.

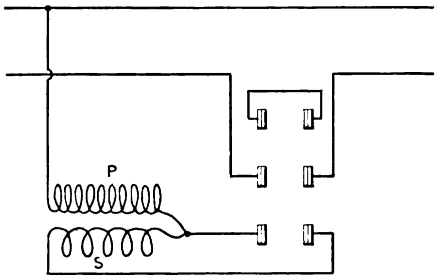

FIG. 5.

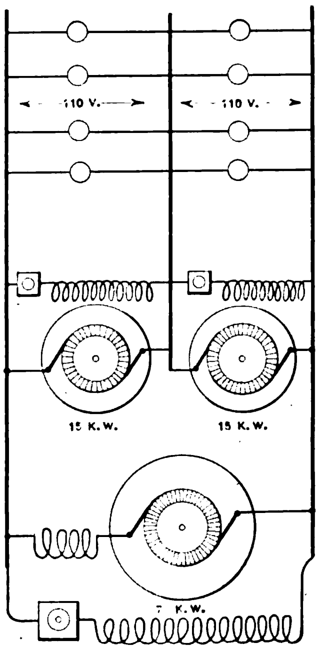
A Three-Wire Trouble.

To the Editor, American Electrician;

Sir:—I have been operating two small 110-volt shunt-wound dynamos on the three-wire system and have recently added a larger 220-volt compound-wound machine. When I attempt to operate the three together, connected up as shown by the accompanying diagram, the small machines rob each other and flash violently by turns at the commutator; the action is somewhat similar to that of two badly-adjusted arc lamps in series on a constant-potential circuit. All three dynamos are belt-driven from a single engine. I would be glad if some of your readers could suggest the cause of the trouble and a remedy.

St. Paul, Minn. R. C. Chipman.



THREE-WIRE CONNECTIONS.

Railway Motor Starting Resistance.

To the Editor, American Electrician;

Sir:—Seeing the diagram of controller connections in your last issue brings to mind a point about the connections of the starting resistance that is usually not well understood. As the diagram shows, one-half of the resistance is put in series with the motors when they are thrown in multiple. The object of using only one-half of the resistance is to make the drop in the rheostat the same as when the motors are in series and all of the resistance is in. With the motors in multiple, each one gets only half of the line current, and the total current must be twice as great as on the first notch in order to get the same torque. With twice the current, the rheostat resistance must be only one-half what it was with the motors in series in order to deliver the same e.m.f. at the brushes and keep the current proportional. If the external resistance were the same in both cases, the motors would actually run slower in multiple than in series.

New York. Edward Chilton.

Electrical Catechism

574. How is a water rheostat constructed?

The water may be contained in almost anything convenient, although it is generally safer to use a vessel of insulating material, such as a wooden box or barrel. The electrolyte may be ordinary water when pressures of 500 volts or higher are to be used. It is customary, however, to improve the conductivity of the water by the addition of a little salt or washing soda or a little acid of some kind. A tablespoonful of salt is about enough for a barrel of water when the voltage is 550. More salt should be used for lower voltages. The conductor terminals are usually plates of iron, although almost anything will do. The resistance is regulated by changing the distance between the plates, or the amount of surface of the plates, or by changing the density of the solution, the latter not being easily changed. (See Fig. 1.)

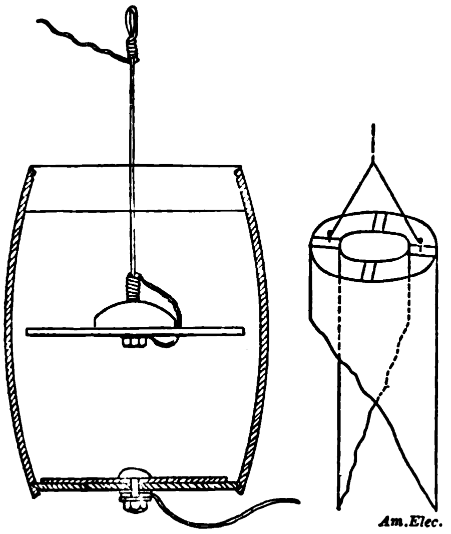


FIG. 1.—WATER RHEOSTAT.—FIG. 2.

575. How are the plates of a water rheostat made?

Two pieces of iron pipe may be fastened to the ends of two sticks and let down into the barrel; or one may be fastened to the side of the barrel and the other be adjustable up and down. The plates may be two tubes or pipes of sheet iron held apart by wooden strips and adjustable up and down by ropes over pulleys as indicated in Fig. 3. When a close adjustment for small currents is desired, the plates may be cut off spirally as suggested in Fig. 2. A convenient plan is to bolt a plate to the bottom of the barrel, being careful to make a tight fit and to paint the lower side well with pitch or asphalt; the upper plate may be a hitching weight to which is screwed a plate with larger surface, the whole being suspended by the conductor, as indicated in Fig. 1.

576. How much energy may be dissipated in a water rheostat?

A barrel containing 50 to 60 gallons will dissipate an equal number of kilowatts. Smaller rheostats sometimes take care of 20 to 150 watts per cubic inch of liquid. The allowable current varies from .25 to 3 amperes per square inch of surface on the exposed face of one electrode.

577. What precautions are desirable in handling water rheostats?

The water should not contain too much salt at first, since the resistance decreases as the temperature rises, and too much current is liable to be the result. The salt should be added from a solution since it takes some time to dissolve and diffuse through the whole body of water; hence the resistance would continue to change for some time after the salt was added. The resistance is most steady when the water is boiling quietly; it takes quite a time before this point is reached, but the time taken to warm up the rheostat is useful in getting everything into working order before the actual test begins. The water rheostat should usually be kept out of doors, unless it is to be used only for a short time, as the fumes are corrosive. Great care should be taken to prevent the plates from making contact with one another, which might cause a short circuit and thus injure the dynamo. In many cases it is also desirable not to ground the circuit, as may easily occur with leaky barrels. There is always more or less risk of getting shocks in adjusting the water rheostat. It is an excellent plan to place the barrel upon timbers, to insulate it from the ground when the water is kept boiling, it is desirable to replenish it more or less continuously, so as to keep the temperature and resistance constant; for this purpose a hose may be attached to the water mains and the valve adjusted to give the right amount of flow; care must be taken against using wire-wound hose, as this might ground the circuit or shock the attendant.

578. How are electric heating and cooking utensils made?

These generally have iron-wire conductors wound upon asbestos or mica. Sometimes the iron wire is woven with asbestos into a sort of cloth. The heat travels through the mica, asbestos and air to the surrounding case, which may be a soldering copper, a flat iron, a cooking utensil or any other desired receiver.

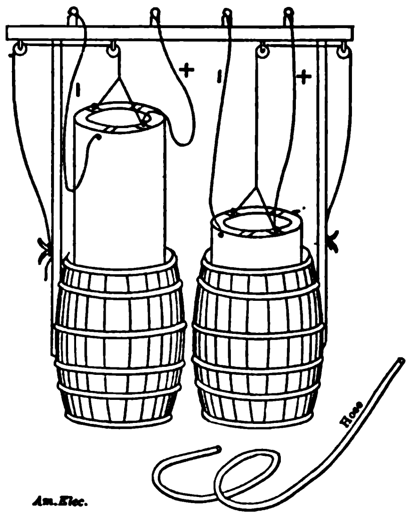

FIG. 3.—PLATES FOR RHEOSTAT.

579. What are the advantages of electrically heated domestic utensils?

The electric irons do not vitiate the atmosphere as do the gas-heated irons, do not allow the starch to stick to the bottoms as they are always at the right temperature and remain highly polished by constant use. The handles are always cool. The cost of operation is found to be less than when heated by gas, and as the resistance is constant, the temperature is always right and uniform, so that they may be used economically and satisfactorily by the most ignorant persons.

FIG. 4.

580. How do surgeons use electric heat?

They use it principally for cautery purposes. Platinum wires are heated by an electric current and applied to parts to be burned off or to be seared. By heating the cautery wire white hot and pressing it against fleshy tissue it acts like a knife and makes a smooth cut. By applying a lower temperature the wire will sear the parts and form a sort of scab for stopping hemorrhages, etc. Cauteries are made in various shapes, some being arranged like a snare to be placed around some undesirable growth which may then be cut off by tightening the loop while the wire is incandescent. Electric cautery is applicable in many places where the knife would be used with great difficulty, and the wounds heal rapidly with less danger from after complications. Cauteries require from 2 to 30 amperes.

FIG. 5.—FLAT IRON.

FIG. 6.—PAD.

581. How do physicians use electric heat?

They use it to some extent for heating poultices and pads to be applied to various parts of the body. They also use it for small incandescent lamps which may be introduced into or near various parts of the body for illuminating purposes.

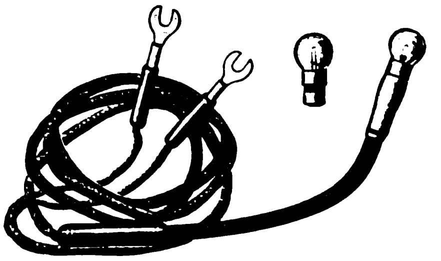

FIG. 7.—PHYSICIAN'S LAMP.

Queries and Answers

IMPORTANT.—No attention will be given to inquiries which do not give the full name and address of the inquirer.

What size motor will it take to run a screw-cutting lathe with a 9-in. swing? W. H.

One-half horse-power.

What power will the 75-light dynamo described in the January number develop running as a motor? W. S. F.

About 5½ horse-power.

With what size wire should I wind the magnets of a telegraph sounder for maximum strength with two or three gravity batteries? A. L.

No. 24 B. & S. gauge, silk-covered wire.

What is the relative conductivity of carbon and copper? C. W. J.

The conductivity of carbon varies so widely that no fixed ratio can be given. The average ratio, cold, is about 2500 to 1.

What is the approximate e.m.f. required to force a spark through one inch of air space? R. B. K.

Twenty thousand volts, provided the sparking terminals are needle points; otherwise a greater e.m.f. will be required.

A G. E. alternator has a commutator on the shaft in addition to the collector rings. The machine is separately excited. What is the commutator for? L. M. P.

To rectify the main current which passes through the compound windings of the field magnet.

Can I make a transformer to change 110-volts direct current to the amount necessary for operating annunciators and vibrating bells? W. F. G.

No. A transformer is an alternating-current apparatus. You can change the voltage by using either a motor-dynamo or a dynamotor.

What difference does it make whether the primaries of two transformers are connected in series or in parallel, the secondary windings being independent? (2). Does changing the connections between two transformers alter their ratio of transformation? J. L.

When the two primaries are connected in series the e.m.f. of the primary circuit must be twice as great as when they are connected in parallel. (2). No.

What is the cause of an engine exhaust being alternately strong and weak? R. D.

Probably the valve setting is bad, so that steam is cut off much earlier at one end of the cylinder than at the other, giving a higher terminal pressure in the latter end than in the end where the cut-off is earlier.

If an engine running under load at 140 r.p.m. has an additional load thrown on which brings the speed down to, say, 130 r.p.m., will the engine be doing more work at the lower speed than it did at the higher speed? A. S. D.

Ordinarily, no. The fact that the additional load reduces the speed of the engine indicates that the governor has reached its limit and can no longer increase the cut-off of the engine. This being true, the mean-effective pressure on the piston remains unchanged, and as the speed is reduced the output of the engine is also reduced.

How should I rewind a 20-ampere Westinghouse meter built for 140 cycles to run on 60 cycles? (2). If the meter starts up at one-half ampere will it run correct on all other loads? F. V.

Better get the Westinghouse Company to exchange meters; you will find it impossible to rewind your meter properly. (2). Not necessarily.

Can I use No. 12 galvanized wire to carry charging current 1¼ miles from a 110-volt circuit to a 10-volt storage battery plant? (2). The capacity of the battery is 10 amperes; how can I keep the current down to this limit? A. G. S.

No. 12 wire will be too small. Use No. 2, Birmingham gauge, E. B. B. quality. (2). Your current will not exceed 8 amperes. Even with the storage battery cut out and the ends of the line connected together the current would not exceed 10 amperes.

Can two direct-current motors of the same voltage but of different sizes and speeds be belted to the same shaft, provided the pulleys are of the right size? W. J. E.

Yes. It is advisable, however, to calculate the pulleys on the basis of the actual speeds of the motors under full load. Then any discrepancy between the speeds will occur at lesser loads and will result only in dividing the load unequally without harming the motors.

How much resistance is necessary in series with a projector arc lamp for use on a 110-volt circuit, and how is it figured? J. J. T.

Assuming that the lamp is a 10-ampere lamp, the amount of resistance required will be about six ohms. The resistance required can be figured from the formula: $\frac{110 - V}{C} = R$, in which "V" represents the volts required at the terminals of the lamp, "C" is the current which it is to pass, and "R" is the resistance of the coil to be placed in series with it.

How can the losses due to eddy currents and hysteresis in a large armature be ascertained? H. W. A.

Drive the armature perfectly free with the fields unexcited and measure the power required to drive it. Then separately excite the fields to the normal point and drive the armature at the same speed as before measuring the power taken; the difference between the two measurements shows the power absorbed by hysteresis and eddy currents. The brushes must not be allowed to come in contact with the commutator at any time during the test.

Please define the term "phase." (2). What is the difference between a single-phase and a three-phase alternator? (3). What is the ratio between the resistance of platinum wire and that of copper wire of the same size? L. V.

See Lessons Department, February issue. (2). A single-phase alternator delivers a single current; a three-phase alternator delivers three currents which are symmetrically out of phase with each other. (3). Platinum has 5.6 times the resistance of copper.

Please give rules for safe carrying capacity of magnet wire for armature and field windings. A. F.

No rule will apply to all cases. The amount of current a wire will carry is determined by the radiating surface and not directly by the size of the wire. A fair average in practice is to allow 500 circular mils per ampere for amature windings and about 800 or 900 circular mils per ampere for field windings.

Can the dynamo described in the January number be built one-half the size shown, using the same size of wire called for in the article? (2). Can it be operated with two brushes instead of four? E. H. J.

No; if you wish to build a machine of the same type for one-half the output such a design is given in the September, 1900, number. (2). It would hardly be practical to use only one brush on each brush-holder. No machine should have less than two brushes per set so that one brush at a time may be adjusted or changed without shutting down.

What is the formula for calibrating a photometer scale? F. B. R.

The general formula is as follows:

$$L \times \frac{\sqrt{CP}}{\sqrt{S} + \sqrt{CP}} = \text{inches.}$$

In this formula "L" is the distance in inches from lamp to lamp; "S" is the candle-power of the standard lamp used, and "C P" is the candle-power mark on the scale. For a 5-ft. scale and a 16-c.p. standard lamp the formula would read:

$$\frac{60 \times \sqrt{CP}}{4 + \sqrt{CP}} = \text{inches.}$$

What changes and connections are necessary to change the direction of rotation of an alternator? (2). How are the connections made to the commutator of an alternator when there are 10 or 12 segments and only two wires leading from the armature? L. A. V.

If the machine has a rectifying commutator, transpose the cables leading to the brushes of this commutator. The only other change necessary is to turn all the brushes around so that they trail in the opposite direction. (2). One-half of the segments are connected to one wire and the other half to the other wire; every other segment is connected in one group and the alternate segments are connected into the other group.

Please give a simple formula for calculating the ohmic and inductive drop in an alternating-current circuit. G. B.

There is no simple formula for calculating the drop in alternating-current circuits. The formula for single-phase circuits is as follows:

$$\sqrt{(Ep + CR)^2 + (Eq + CX)^2} - E = V.$$

In this formula "E" is the e.m.f. delivered at the far end of the line; "C" is the current; "R" is the resistance of the line; "X" is its reactance; "p" is the power factor of the whole circuit; "q" is the inductance factor of the whole circuit, and "V" is the drop in volts in the line. The drop in a three-phase line may be figured by counting the resistance of only two of the three wires and multiplying the current per wire by 0.87, and using the above formula with the substituted values.

NEW GANG LIGHTNING ARRESTER AND SELF-RESTORING SWITCHBOARD DROP.

The accompanying illustrations, Figs. 1, 2 and 3, represent a form of gang lightning arrester and fuse-holder recently brought out by the Phoenix Electric Telephone Company, New York City, for which application for patents has been made. Fig. 1 represents an outfit for 100 metallic circuit lines, and Fig. 3 shows an equipment for 400 lines, which was installed in a South Carolina exchange, where thunderstorms are unusually severe. The frame work is of iron piping on which are mounted the slate slabs containing the metal work of the arresters. These parts consist, for each line, of two brass plates connected by a fuse link, as shown at the upper part of the right-hand slab in Fig. 3. The left-hand brass plates also contain one terminal of the lightning arrester, and a carbon rod is mounted parallel with the face of the slate and at such a distance from it as to clear the left-hand row of brass plates. The line terminals are connected to the right-hand brass plates, and wires lead from the left-hand plates to the switchboard. The carbon rod parallel with the face of the slate is connected to earth. Fig. 2 shows more clearly the relation of the carbon ground rod to the lightning arrester terminals on the plates. These terminals consist each of a pointed carbon pencil set into the head of a brass screw, which is threaded into the line terminal plate. The distance between the tip of the carbon pencil and the carbon rod is adjustable by turning the brass screw, and a jam nut is provided to hold the screw in any desired position.

Another feature of the Phoenix arrester is that any cleaning that may be necessary between the carbons can be accomplished without resulting in disagreeable and hindering noises in the circuits affected, whereas, it is stated that with the ordinary type of arrester any manipulating gives rise to annoying sounds in the instruments on the lines which are receiving attention. Another advantage possessed by this arrester is that any number of sections may be added from time to time without in the least interfering with those already in service or affecting the switchboard construction or arrangement. In practice, it is stated, the sharp points on the individual carbon tips are not affected by lightning discharges but discharges from heavy-current circuits will pit the ground rod. This trouble is corrected, however, very easily by twisting the ground rod in its socket sufficiently to remove the pitted surface from alignment with the carbon tips and present a fresh smooth surface.

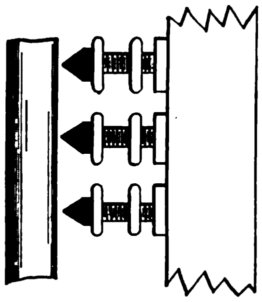

FIG. 2—LIGHTNING ARRESTER TERMINAL.

Fig. 4 illustrates the construction of the Phoenix switchboard drop. The mechanism of the drop is mounted on a hard-rubber disc which in turn is mounted on a wooden panel ⅞ in. thick, made up of five layers of wood put together with the grain running in different directions so as to avoid warping. A section of this wooden panel is shown in the background of the illustration. The drop terminals are two metal prongs arranged to fit into binding posts on the rubber strip at the extreme right of the engraving. In the complete switchboard this rubber strip extends entirely across the back of the board, so that there is no wiring whatever in the interior of the drop sections. The line wires are brought to the two binding posts into which the drop prongs fit. The drops may be removed and inserted, therefore, without disturbing the line wires at all, so that a board may be fitted up with any number of line terminals and equipped with only a portion of the drops without involving any derangement of parts or interference with the existing equipment when additional drops are installed. The drop is a combination drop and jack and is restored by the action of inserting the plug into the jack, which occupies the center of the rubber disc; the plug is inserted through the hole in the drop shutter.

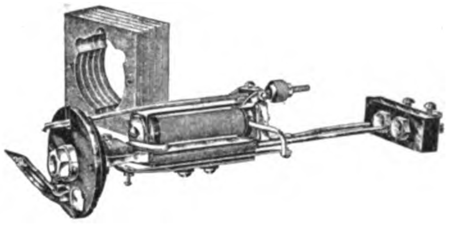

FIG. 4.—SWITCHBOARD DROP.

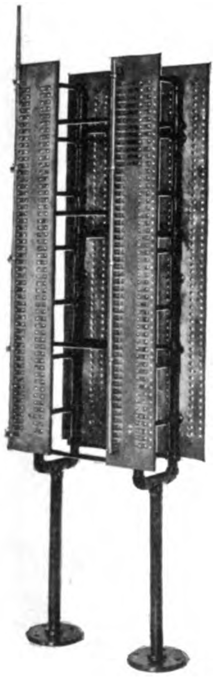

FIG. 1.

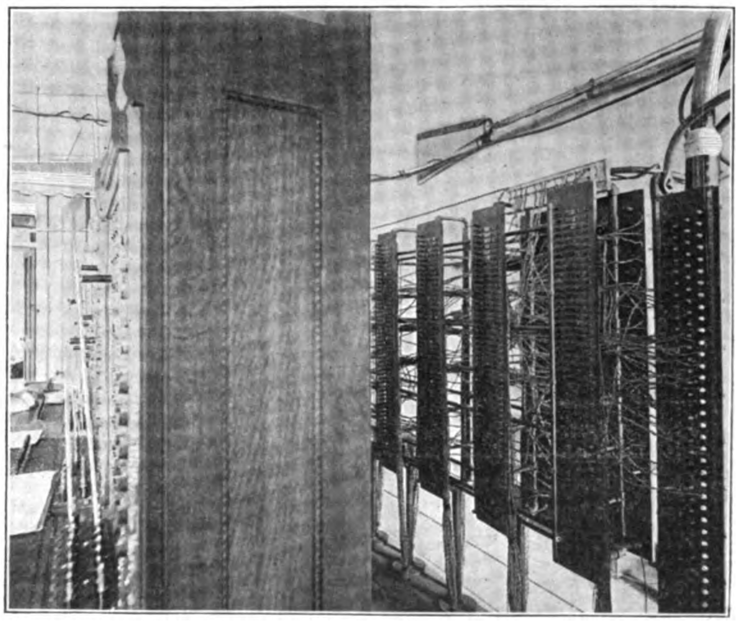

FIG. 3.—LIGHTNING ARRESTERS IN A SOUTH CAROLINA EXCHANGE.

"SOLID" TELEPHONE RECEIVER.

A unique form of telephone receiver has just been introduced by William J. Murdock & Co., of Chelsea, Mass., under the name of the "Solid" receiver. It is illustrated in cross-section by Fig. 1. The distinctive feature of this receiver is that the magnet, the pole-pieces, the binding posts, the wires connecting with the binding posts and extending through the case and the supporting rings, are covered with the insulating material which forms the case and are solidly moulded therein, making the case and all these

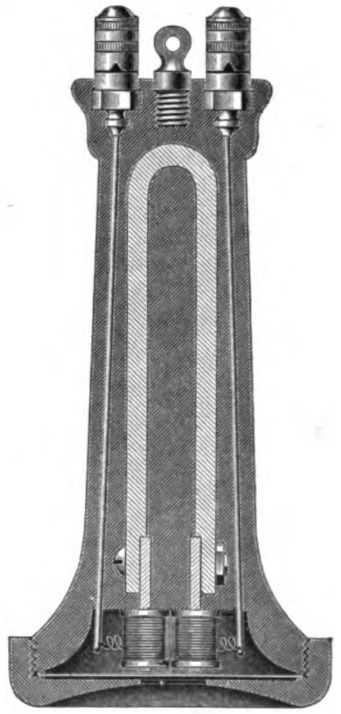

FIG. 1.—"SOLID" TELEPHONE RECEIVER.

parts practically one piece. This gives the magnet a permanent position, and keeps the pole-pieces always in the same relative position with respect to the diaphragm seat. The binding posts are made hexagonal in shape and grooved, this shape preventing their turning; the grooves insure them against pulling out of the moulded case. The claims of the manufacturers are that the adjustment of their receivers being exact on the outset, this construction makes it permanently so.

EUREKA TELEPHONE SWITCHBOARD.

The accompanying illustrations represent a 1000-line express switchboard built by the Eureka Electric Company, of Chicago, Ill., and two of its individual devices. The board here illustrated is equipped with supervisory flash-light signal, trunking and transfer systems, and self-restoring line drops. Like all of the Eureka boards, this one is built in 100-line sections or frames, and arranged so that by removing the molding from one end of the cabinet additional sections or frames can be added side by side, the molding being replaced on the last section added. Each 100-line section is provided with the usual operator's equipment of transmitter, head receiver, and 10 pairs of plugs with reinforced cords, together with self-contained clearing-out drops and operator's cams. One of these self-contained clearing-out drops with its cam switch is illustrated by Fig. 2; this device contributes greatly to the simplicity of the system. The line drops and jacks are the combination type, and can be removed and replaced on the board without disturbing any line connections or using tools of any sort. The line-drop shutter falls sidewise instead of away from the board, as most drops fall, and the restoration of the drop is accomplished by the insertion of the plug in the jack. The shutter does not cover the line jack socket, as is the case in most plug-restoring drops; the restoration is done by an auxiliary lever which is thrown up by the insertion of the plug in the jack socket and resets the shutter through the medium of a finger at the rear end of the shutter pivot. A back view of the combined drop and jack is shown by Fig. 3, and will make this description clear.

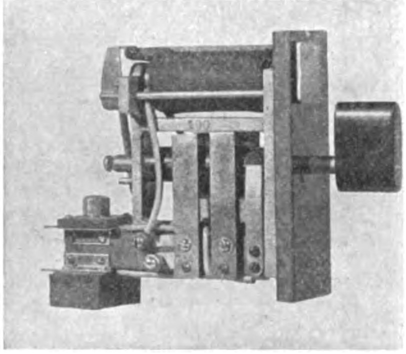

FIG. 2—SELF-CONTAINED CAM AND CLEARING-OUT DROP.

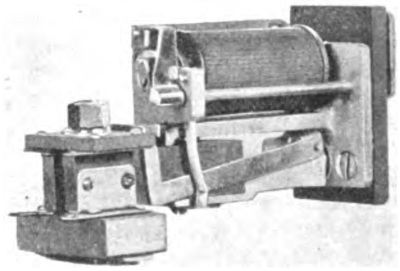

FIG. 3.—METALLIC DROP, SHOWING RESTORER.

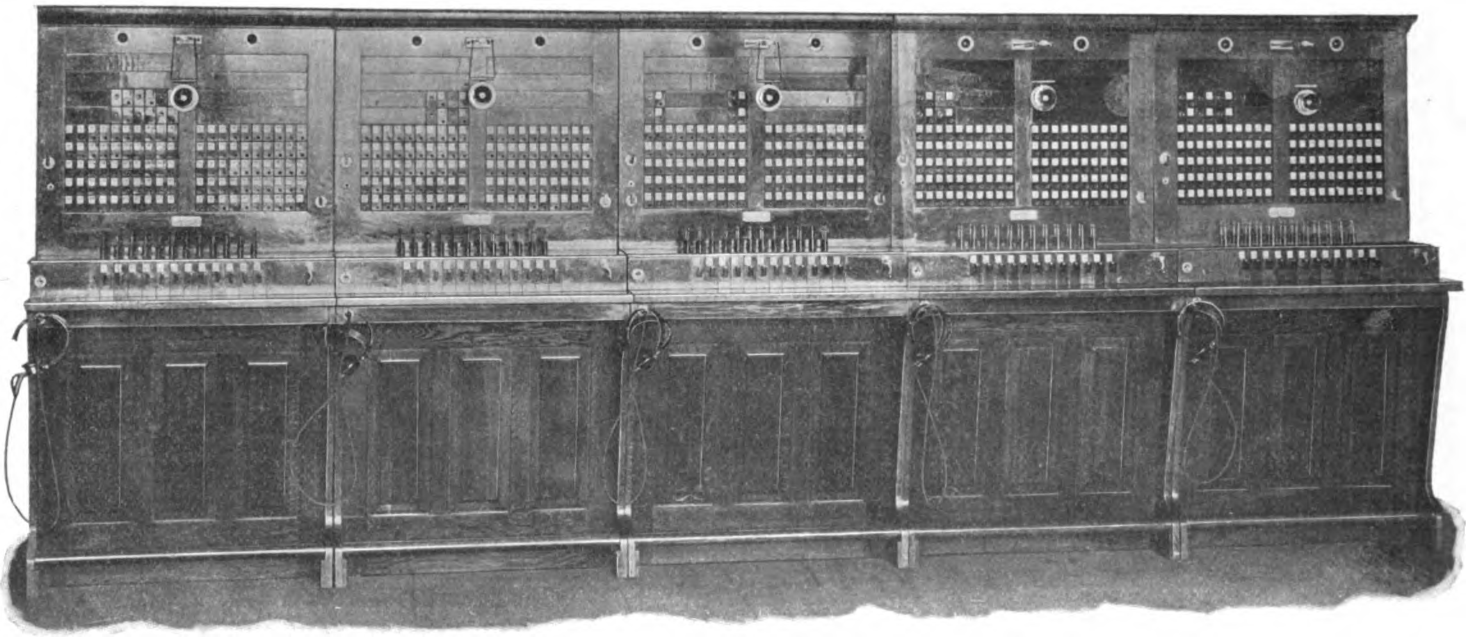

FIG. 1.—TELEPHONE SWITCHBOARD WITH PILOT FLASH LIGHT, TRUNKING AND TRANSFER SYSTEMS.

The form of combined listening and ringing key which is usually employed in switchboard work independently of the clearing-out drop is not used here. After a call has been made and the operator has inserted the answering plug in the line jack, restoring the shutter, the operator's set is in connection with the subscriber making the call without the use of a listening cam. After learning the number desired, the operator inserts the second plug in the line jack of the desired subscriber in the usual way, connecting the two subscribers through the cord circuit. Then the operator's cam is moved over to the left and rings up the subscriber wanted without ringing back into the first subscriber's line. (Ringing back is accomplished by throwing the cam over to the right.) The movement of the cam from its central position also cuts out the operator's set from the cord circuit. At any time that it may be desirable to cut in the operator's set on the cord circuit all that is necessary is to return the cam to its normal midway position. When the plugs are inserted in the jacks the main-line drops are cut out and the automatic clearing-out drop, which has a high-impedance bridging winding, is cut in. When a subscriber finishes talking, and rings off, the clearing-out drop is thrown, and the operator restores the cam to its normal position, which movement automatically restores the clearing-out drop. The clearing-out drop is mounted along with the operator's cam in a hard-rubber case, and is readily removable and replaceable, like the combination line drops and jacks. The features of the mechanical construction of the various parts are strength and the utmost simplicity. Each line drop, for example, contains only a single spring, namely, the tip spring. The switchboard is arranged so that the pilot-lamp system can be installed at any time on any 100-line section, and it is provided with circuit-changing switches actuated by draw-knobs, by means of which the operator may change the ringing circuit from the hand to the power generator and also cut on and off the auxiliary night-bell circuit.

THE STROUD TOLL-SERVICE RECORDER.

A simple system for recording the number of calls made at telephone toll stations has been brought out by the National Measured Service Company, Chicago, Ill. Figs. 1 and 2 herewith illustrate the essential apparatus of the system. At the subscriber's station a small auxiliary instrument shown by Fig. 1, is installed. In calling up, the subscriber presses the button in the top of the case, which notifies the exchange operator of the call. This call is registered by the dial wheels in the instrument, and is also "stored" by clock-work mechanism within the meter. At the end of a certain period, say once a month, when it is required to take readings of the various meters, the central office operator calls up each subscriber and asks him to press the button just as in signalling for ordinary connection. The circuits, however, are so arranged this time that this call does not count against the subscriber but merely starts the mechanism of the record-taker; shown in Fig. 2, which instrument is located at the exchange. The mechanism of the record-taker then reproduces the total number of calls stored in the meter at the subscriber's station. The face of the meter at the subscriber's station shows all the calls from the time the meter is installed up to 9999, and then reverts to zero. The central office machine takes the statement since the last reading and is then turned back to zero, so that the total calls on the face of the meter at the subscriber's station should correspond with the number of calls shown by the books of the company added to the last reading of the record-taker. The meter at the subscriber's station is sealed so that it cannot be deranged or tampered with, and both of the machines are very substantially built. It is stated that one or two portable record-takers will suffice for the work of an entire exchange. The advantage of the instrument obviously lies in the fact that it saves the time and expense of sending an attendant around to take the readings of the various meters.

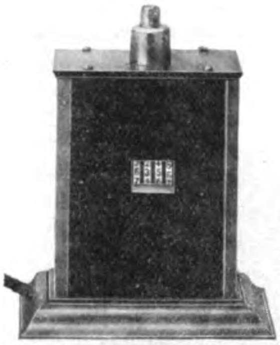

FIG. 1.—METER.

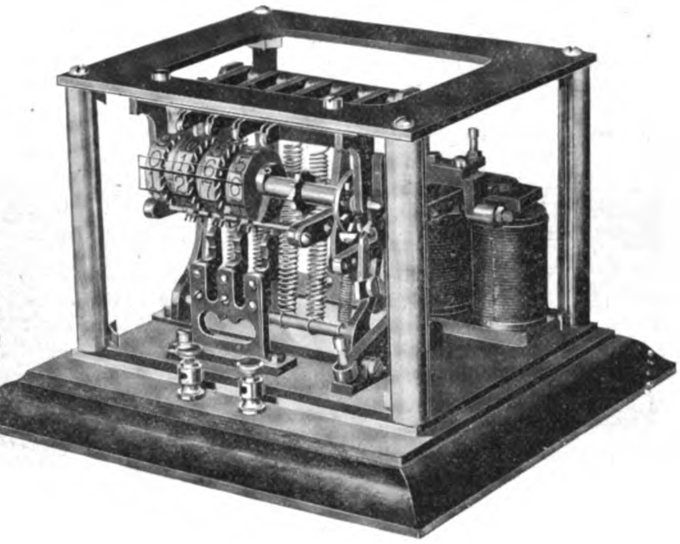

FIG. 2.- RECORD TAKER.

CLARKE AUTOMATIC TELEPHONE SYSTEM.

The accompanying engravings, Figs. 1 to 4, inclusive, are illustrative of a new automatic telephone switchboard system manufactured by the Clarke Automatic Telephone Switchboard Company, of Providence, R. I., and especially designed for use in mills, factories, mines, warehouses, offices and small towns. The Standard desk telephone having the Clarke dial for a base is shown in Fig. 1, and a switchboard wired for twelve telephones, and having the front and back removed, is illustrated by Fig. 3. The Clarke dial and automatic switch are illustrated by Figs. 2 and 4. The dial case, which forms the base of the desk outfit and is mounted alongside the wall outfit, contains a clock-work mechanism consisting of two brass wheels having 75 teeth, each mounted on a central axle with a smaller wheel, the latter engaging a retarding mechanism which regulates the speed of rotation of the lower of the two main wheels. This mechanism is mounted on a cast-iron base and covered by a nickel case. On the side of the case is a small plunger which engages a locking lever. The top wheel on the spindle acts as a dummy and is used to store power in a spiral spring for operating the lower wheel, the two being connected only by this spring. The operation is as follows:

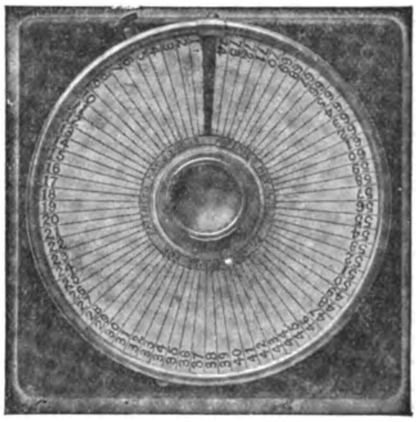

FIG. 2.—SUBSCRIBER'S DIAL.

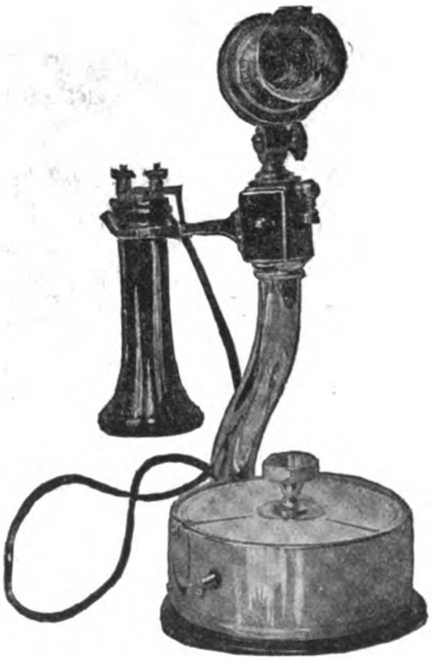

FIG. 1 —DESK OUTFIT.

The locking lever is held normally by means of a small spring so that it engages the dummy wheel, which is prevented by a pawl from any backward motion after a tooth on this wheel has once passed the pawl. On pushing the plunger in, the dummy wheel is released from the locking lever and at the same time the lower wheel is locked. It is then possible to turn the dummy forward by means of the knob on the axle, thereby storing up power in the clock spring, and setting the dial to whatever number it is desired to call. The numbers 1 to 75 appear on a disc, which is mounted on the central axle and turns with the dummy wheel, the pointer being stationary and fastened on the nickel case. On releasing the plunger the dummy wheel is again locked and the spiral spring pulls the lower wheel forward until a pin on its rim engages a pin on the rim of the dummy wheel, this being the normal relation of the two wheels. For example, if the dummy be turned forward seven teeth, then the lower wheel will be moved forward seven teeth by the coil spring. Mounted on a red fiber block is a small contact spring which is set so that its point normally rests between two teeth on the lower wheel and touches each tooth as the wheel is turned forward. The making of the contact serves to close an electric circuit through a magnet mounted on the automatic switch.

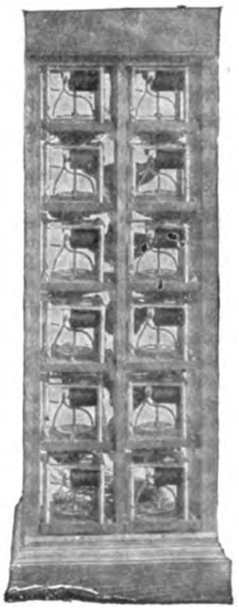

FIG. 3 —SWITCHBOARD.

The automatic switch consists of a small red fiber base, having 75 contact points mounted on it in a circle, each being the terminal of a subscriber's line. Four upright posts support a top frame on which is mounted a magnet, whose armature is mounted on one end of a lever, the other end of which is bifurcated and engages a wheel mounted on a spindle; a spring attached to this wheel makes a sliding connection with each of the contact points in turn as it passes them. Each impulse sent through the magnet by the dial at the subscriber's station causes the switch wheel to turn 1/75 of a revolution; as the teeth on the switch wheel correspond in number to the teeth on the dial wheel and the number of contact points on the base of the switch, the contact spring of the switch wheel will evidently be brought into contact with any subscriber's line by setting the dial to the number corresponding to the subscriber's number.

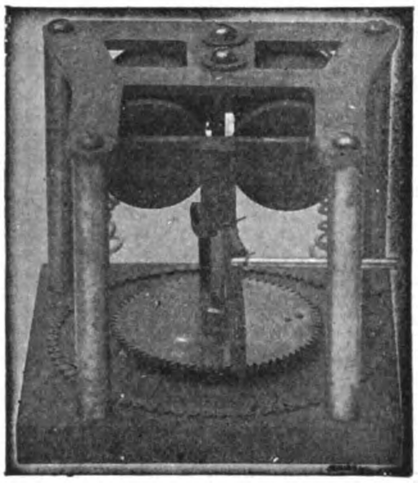

FIG. 4.—AUTOMATIC SWITCH.

◆◆◆

A NEW SHELL-TYPE TRANSFORMER.

The relative merits of core-type and shell-type transformer construction have been the subject of much discussion and contention, some manufacturers favoring the one, while others declare that the other is greatly preferable. Advocates of the core-type transformer argue that the greater area of exposed coil surface is an advantage which overweighs the advantages embodied in the shell-type construction. On the other hand, shell-type advocates insist that the core-type transformer is at a disadvantage because the most of its core is covered with windings. Among the latter advocates is the Fort Wayne Electric Works, Fort Wayne, Ind., who has steadfastly adhered to the shell-type form.

One of the disadvantages of the shell-type transformer from a manufacturer's standpoint has been the waste of the material cut out from the core for the reception of the winding. Mr. Jas. J. Wood, of the Fort Wayne Company, overcomes this disadvantage by the use of a peculiarly-shaped core plate, illustrated by Fig. 1. This core plate is stamped in two pieces which dove-tail into each other. If the reader will imagine the right-hand half of the core plate shifted upward until its center tongue touches the upper tongue of the left-hand half, it will be seen that the two can be closed in together without leaving any open spaces. Fig. 3 shows the complete core and coils assembled, and Fig. 2 is a cross-section of the transformer taken parallel with the core plates. It will be noticed that the primary winding is divided into two parts and the secondary winding into four parts, each half of the primary winding being sandwiched between two of the secondary sections. The object of this arrangement is, of course, to reduce magnetic leakage to the lowest possible extent. The coils are machine-wound, of course, and the transformer is designed for oil insulation. A crevice is left, therefore, between the two halves of the total winding for the circulation of oil.

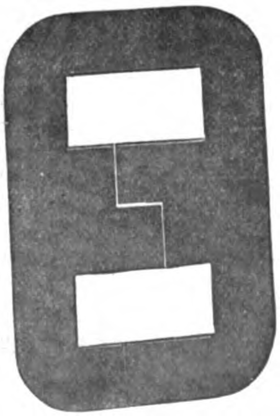

FIG. I.—TRANSFORMER PLATE.

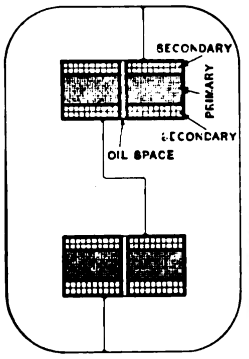

FIG. 2.—CROSS-SECTION.

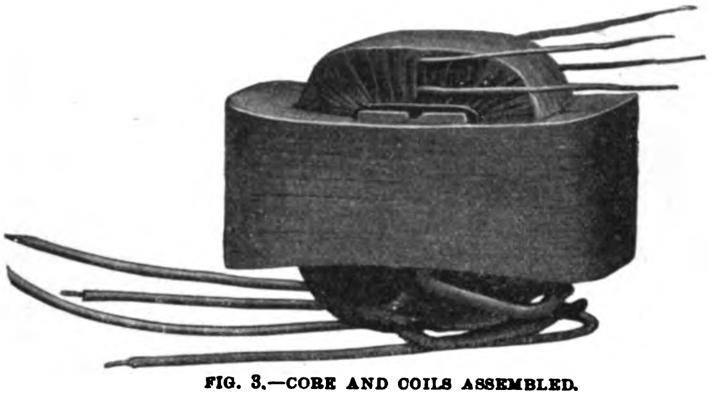

FIG. 3.—CORE AND COILS ASSEMBLED.

Fig. 4 illustrates the method of hanging the transformer; the hanging irons are provided with strong buttons, the shanks of which slip into the U-shaped slots on the casing, the heads occupying recesses beneath the overhanging plates in which the ∩-shaped slots are made. The transformers are built for the usual ranges of voltage.

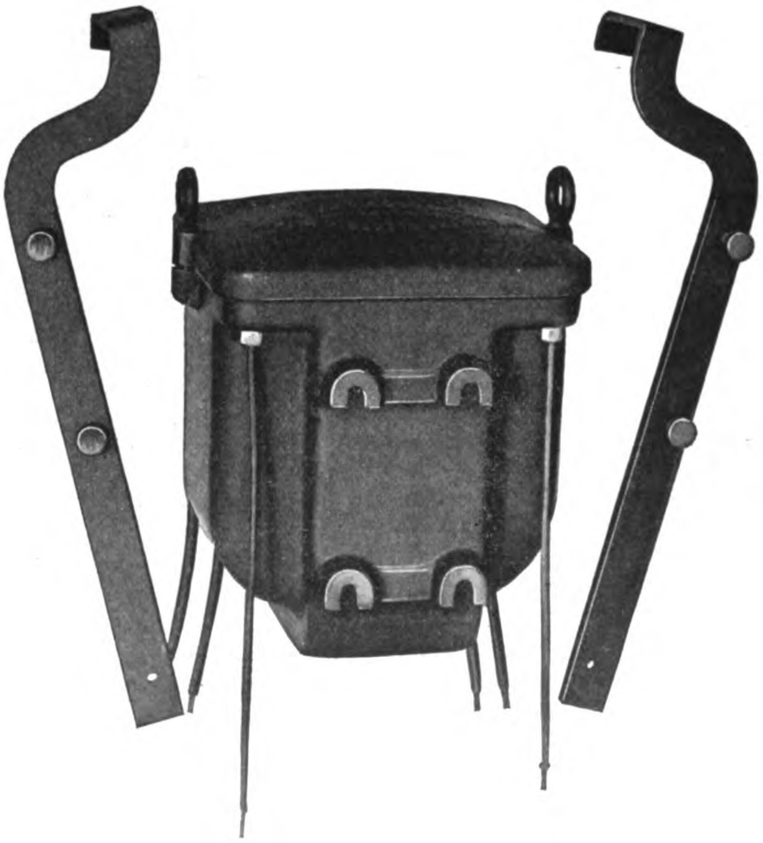

FIG. 4.—REAR VIEW OF 5-KW. TRANSFORMER SHOWING HANGER IRONS DETACHED.

New Apparatus and Appliances

A NEW TYPE OF EXTENSION BELL.

There are places where the ordinary type of telephone extension bell is considered too bulky and too awkward in appearance to be desirable. To meet objections of this sort the Holtzer-Cabot Electric Company, of Brookline, Mass., has put on the market the form of extension bell illustrated by Fig. 1. The cover is shown transparent in the engraving in order to show the arrangement of the internal parts, but it will be understood, of course, that it is an ordinary wooden cover, similar to that of the familiar box bell used in connection with battery service. The magnets and mechanism are the same as those used in the standard Holtzer-Cabot ringers, and are provided with the same means for rapid and accurate adjustment. The magnets are wound for either series or bridging work, and are fully as sensitive as the usual form of extension bell.

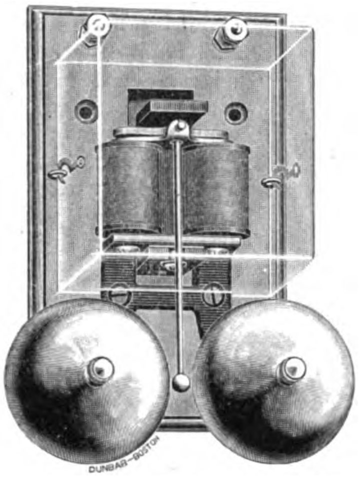

FIG. 1.—EXTENSION BELL.

The Holtzer-Cabot Company is also putting out a neat form of double-pole telephone receiver, which is said to embody several new features. One of these is the manner of adjusting the cord terminals; another is the shape of the pole-pieces, which are plane on the sides facing each other and convex on the outer sides. Fig. 2 shows the field set up at the poles of the receiver, as indicated by iron filings sifted on a piece of paper which was substituted for the diaphragm. The claim of superiority is based on the fact that the outer curves of the pole-pieces are normal to the natural path of the magnetic lines.

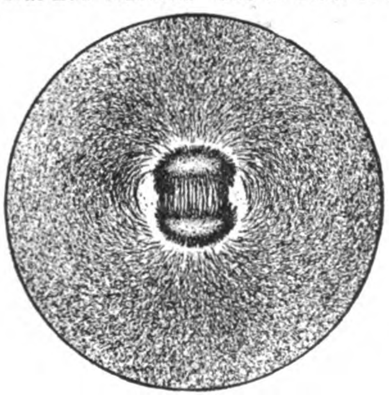

FIG. 2.—FIELD OF RECEIVER.

NATIONAL AUTOMATIC TELEPHONE EXCHANGE SWITCH.

Fig. 3 illustrates the principal feature of the latest form of automatic telephone exchange switch brought out by the National Automatic Telephone Company, Chicago, Ill. The subject of the illustration is what is known as "Automatic Switch No. 3." The exchange is equipped with one of these switches for each subscriber's line. The switch is a step-by-step arrangement with a gravity release, and is very simple in construction and operation. Each subscriber's telephone set, in addition to the usual signalling magneto, is provided with a push-button and dial switch, the numbers on the dial switch extending up to 99. In operation the subscriber takes down the receiver, presses the push-button the number of times that there are hundreds in the desired subscriber's number, turns the dial switch to the number of tens and units in the subscriber's number, and then rings up in the usual manner. For example, if the subscriber who is wanted is No. 216, the calling subscriber presses his push-button twice for the first figure of the number and then turns the dial switch to 16; then turning the magnetic handle will call up subscriber No. 216. The dial switch is constructed to send an impulse over the line for each number that its pointer passes. For example, in turning the pointer to No. 16, the switch will send 16 impulses over the line. These impulses operate a step-by-step mechanism which carries a contact finger around to the proper contact for the desired subscriber. The "hundreds" push-button sends impulses over a separate line, designated the "hundreds" line; these impulses operate a step-by-step mechanism like that before mentioned and which co-operates with the tens-and-units mechanism to establish the proper connection. The automatic switches at the exchange are provided with lock-out arrangements so that if a subscriber's line is busy and another subscriber attempts to call up, the connection already existing will not be disturbed.

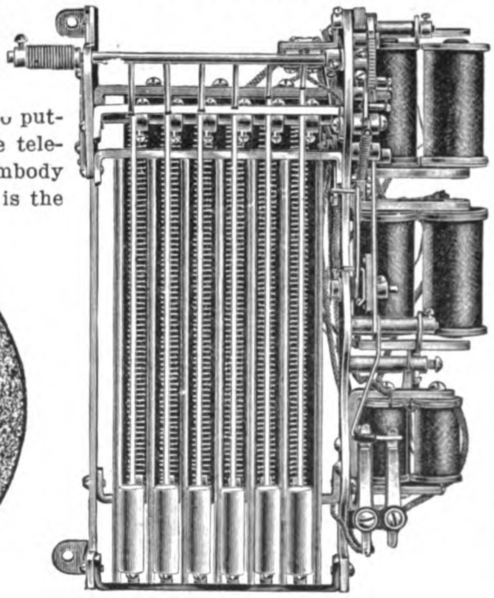

FIG. 3.—AUTOMATIC TELEPHONE SWITCH.

A NEW DOUBLE-POLE TELEPHONE RECEIVER.

Figs. 4 and 5 illustrate the latest type of double-pole and telephone receiver made by the Lambert-Schmidt Telephone Manufacturing Company, of New York. The magnet is of special Wolfram steel, highly saturated and horse-shoe shaped, with broad coils at the poles. These coils have the usual soft iron cores and are wound with silk-insulated wire. At the intersection of the bobbins with the magnet is set a disc of brass for fastening the magnet to the outside shell. The receiver case consists of a heavy brass cup at the head, the handle being one piece of hard rubber covering the body of the magnet and threaded on the inner surface at the open end; this handle is screwed to a tubular projection on the under side of the metal cup. The magnet itself is fastened to the brass cup by two machine screws extending through the brass disc above mentioned, these screws projecting into the rubber shell to prevent this shell from twisting. By this design, the metal cup and the magnet become one solid structure and the contraction, expansion or breakage of the rubber shell does not change the relative position of the magnet poles to the diaphragm. The diaphragm is tinplated soft iron lying evenly on the metal cup. The receiver cap is hard rubber, shaped to clamp the diaphragm at exactly the same point with the edge of the metal case. The binding posts are peculiarly constructed. The body is an arch

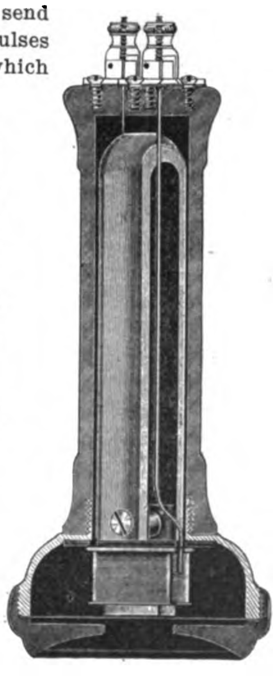

FIG. 4.—DOUBLE-POLE TELEPHONE RECEIVER.—

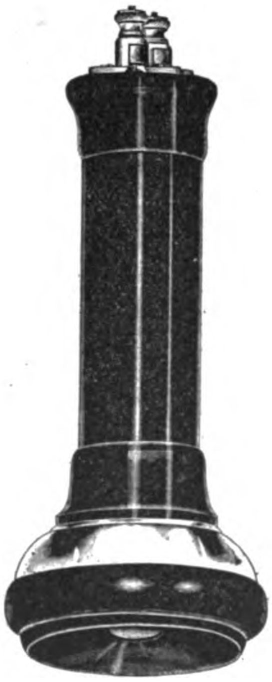

FIG. 5.

with a partially flat top; inside the arch is a square block not filling the entire space and with a long-threaded pin extending through a hole at the top of the arch, but not screwed to it; the pin fits loosely in this hole. A finger nut is screwed to this pin and is located directly over the arch. On the opposite sides of the arch are two small holes; there is also a similar hole through the metal block. The block is brought into position so that these three holes are in alignment and the cord tip is then pushed through. The finger nut is turned, thus drawing up the block and clamping the cord tip on each side of the arch so that it cannot possibly work loose.

A 30-DROP DESK TELEPHONE SWITCHBOARD.

The compact and ornamental desk switchboard illustrated by Fig. 8 is manufactured by the Haines & Noyes Company, of Chicago, Ill., and embodies several features of interest. The switchboard is of the express type, equipped with plug-restoring drops and combined listening and ringing keys with auxiliary ring back. The drops are of the combined jack and drop type, in which the shutter is restored by the action of inserting the plug in the jack. Fig. 9 shows the jack with the shutter down, and Fig. 6 shows it with the shutter restored by the insertion of the plug. This drop differs mechanically from most others in that the shutter instead of falling outward falls sidewise, being mounted on a pivot parallel with the magnet. In restoring it by the movement of the plug, therefore, the plug is pressed against the shutter sidewise, giving a sort of sliding cam action. The combined drops and jacks are mounted on independent face plates and can be removed from the switchboard by simply taking off the two thumb screws at the back. The combined cam and listening key with ring-back key is illustrated by Fig. 7. This does not differ radically from the ordinary type of combination key, the movement of the main lever in one direction serving to make the listening connection and in the opposite direction to ring up the desired subscriber. All of the springs are of German silver with rubbing contacts, tending to keep the contacts bright. All of the wiring is soldered without acid and is readily accessible by removing the back panels of the switchboard. The clearing-out drops are of the tubular type bridged across the cord circuit and the operator's equipment comprises the usual long-distance instruments.

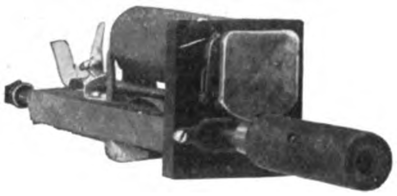

FIG. 6.—DROP RESTORED.

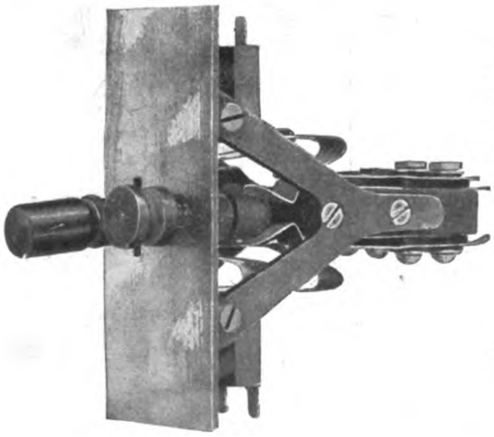

FIG. 7.—CAM, LISTENING KEY AND RING BACK.

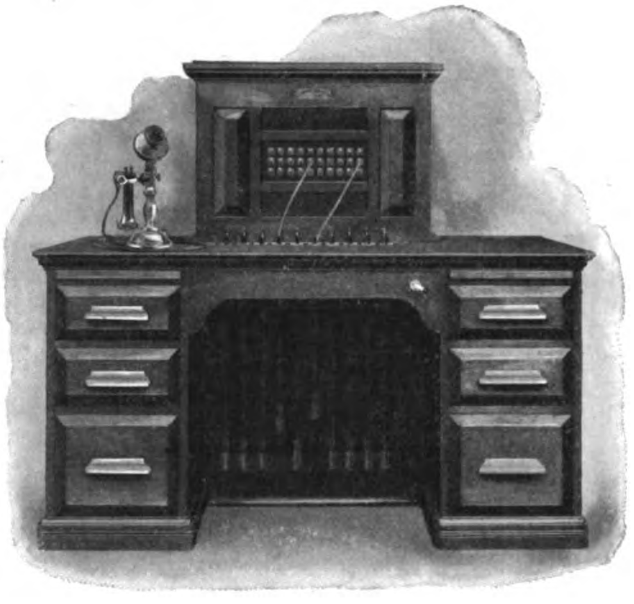

FIG. 8.—30-DROP DESK SWITCHBOARD.

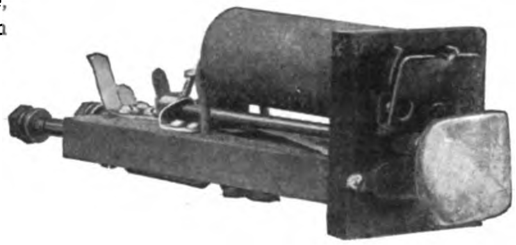

FIG. 9.—DROP DOWN.

COMBINED JACK AND TUBULAR DROP.

The subject of Fig. 10 is the No. 40 combined jack and tubular drop of the Couch & Seeley Company, Boston, Mass. Referring to the engraving, *A* is the tube enclosing the magnet coil, the core of which is screwed at one end to the closed end of the tube; the other end forms one pole of the magnet, and the rim of the open end of the tube, the opposite pole.

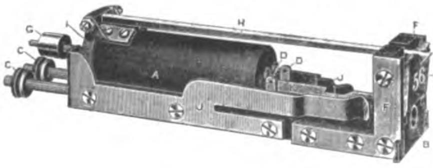

FIG. 10.—JACK AND TUBULAR DROP.

The ends of the windings of the magnet are brought through rubber bushings in the tube and soldered to the tags of drop-springs, *d*, *d*, which are in connection with the line-springs, *j*, *j*, when drop is in normal condition. The line terminals are shown at *c*, *c*. When plug is inserted at *b* into the jack-frame, *k*, the line-springs, *j*, *j*, are separated from the drop-springs, *d*, *d*, thus cutting the drop entirely out of circuit. The shutter, *e*, has two spurs, one on each side, formed at right-angles with its face, and when it falls these spurs come in contact with night-alarm springs fastened to the side pieces, *f*, *f*. The side pieces are of brass, and carry the night-alarm circuit to the upright brass bars notched out to receive the drops when mounted up in regular form in a complete switchboard. The wiring of the complete board using this drop is, therefore, practically done when the drops are set in place. The armature, *i*, is provided with the counter weight, *g*. A very close and sensitive adjustment can be made in the single drop. Current furnished by an ordinary three-bar generator will throw the shutter on a bridging line with a 25-ohm shunt.

D. & W. TELEPHONE PROTECTOR.

A suitable protector for telephone circuits must provide an easy path to earth for the static discharge of lightning and must be provided with a fuse capable of rupturing the circuit upon the passage of heavy current due to a cross with a power or lighting circuit; it must also be so sensitive that it will operate in the case of an imperfect cross with a heavy-current circuit, resulting in what are usually known as "sneak" currents, which, while not large enough to create any instantaneous damage, will ultimately destroy the delicate telephone apparatus. Fig. 11 illustrates a protector made by the D. & W. Fuse Company, Providence, R. I., which is said to fulfill all these requirements, and Fig. 12 is a diagrammatic illustration of the device. It consists of a high-tension enclosed fuse connected in series with a sneak coil, as indicated by the dotted lines. The double-pole arrangement comprises two fuses and sneak coils. The lower terminal of each sneak coil is also connected to

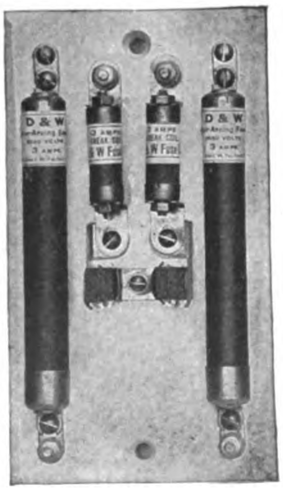

FIG. 11.—TELEPHONE PROTECTOR.

a carbon lightning arrester consisting of two carbon blocks separated by mica. The fuse is of the familiar D. & W. non-arcing type, and is said to be capable of handling a current due to a short-circuit on a 2400-volt alternating circuit without an arc or a flash. The sneak coils are supplied to operate at any desired point from 1/10 ampere up, but the manufacturers recommend for telephone service a 2/10-ampere coil which will operate at 3/10 ampere in less than 15 seconds. Under ordinary conditions the sneak coil alone serves to protect the apparatus, as trouble due to slight crosses between outdoor circuits is more common than a dead cross. Resetting tools are furnished with the protector, by means of which the sneak coils may be easily repaired at slight cost. The device is also made in single-pole form, consisting simply of one-half of the arrangement here illustrated.

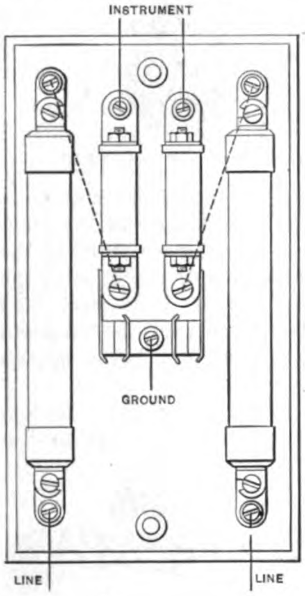

FIG. 12.—CONNECTIONS.

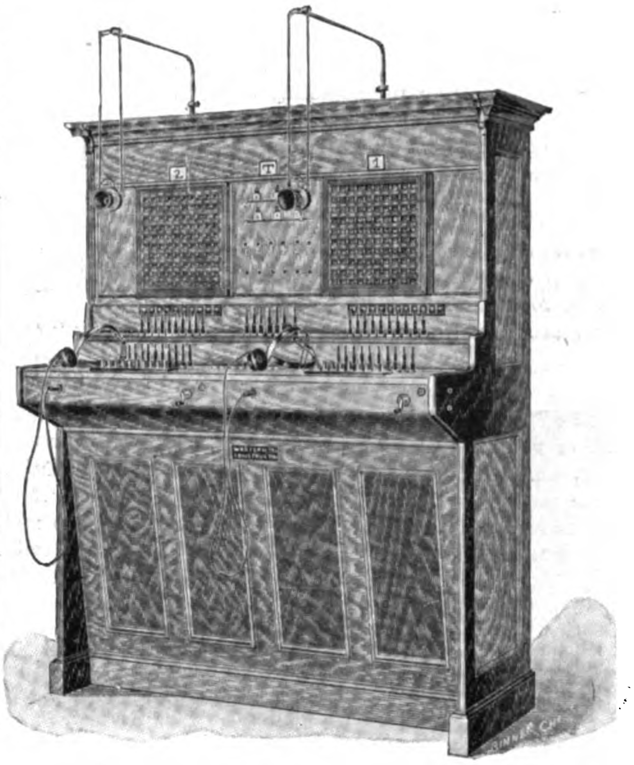

FIG. 14.—EXCHANGE AND TOLL LINE SWITCHBOARD.

COMBINED EXCHANGE AND TOLL-LINE SWITCHBOARD.

Fig. 14 illustrates a very convenient combination of exchange and toll-line switchboard for exchanges of moderate size, which is being supplied by the Western Telephone Construction Company, of Chicago. The arrangement consists of two standard exchange boards of 100 drops each, between which is interposed a six-drop toll-line board. The exchange switchboard can be wired either for all metallic circuits, common-return or grounded circuits, or for any combination of these systems. The jacks and drops are self-contained, and the drop plug restoring. Any jack or drop or coil can be removed and renewed without disconnecting the wiring or interfering with any other connection on the board. Fig. 13 illustrates the combined spring jack and plug-restoring drop. The jack consists of a solid brass casting, A, bored for the reception of the plug, as indicated at N, and mounted on a rubber base, M, along with the magnet and drop; the jack spring is located at F. The magnet, I, has its armature pivoted at C. The finger, H, constitutes the latch which holds and releases the shutter, E. When the subscriber calls up, the finger, H, which is an extension of the magnet armature, releases the drop, E, the latter falling in front of the plug socket in the jack; consequently, in order for the operator to insert the answering plug in the jack she must first raise the shutter or drop and restore it, to clear the jack for insertion of the plug; this is done, of course, by the movement of the plug toward the socket. The operation of making a connection is extremely simple. When a subscriber's drop falls, the operator inserts an answering plug in the jack, restoring the shutter, and moves the handle of a combination listening and calling key or circuit-changer forward, which connects her with the calling subscriber. Having ascertained the number of the subscriber desired, the operator inserts the calling plug corresponding with the answering plug first used, in the desired subscriber's line jack and calls up that subscriber by pulling the handle of the circuit-changer backward. When the handle is restored to its normal position the two subscribers are connected and the exchange operator is cut out. The whole operation, therefore, consists of four motions on the part of the operator; two insertions of jacks and two motions of the combined listening and calling key or circuit-changer. The lever of the circuit-changer returns to its normal position automatically when released. All of the springs in the talking circuits are platinum-plated and rest on platinum-pointed contacts. The plugs are of the metallic-circuit type. It is claimed that these switchboards are absolutely free from any cross-talk.

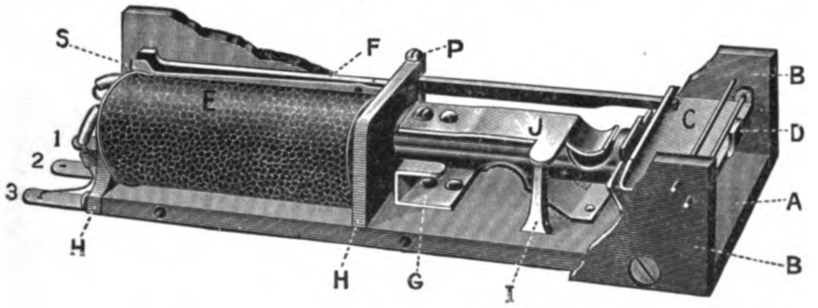

FIG. 13.—SPRING JACK AND PLUG-RESTORING DROP.

A NEW LONG-DISTANCE TELEPHONE OUTFIT.

Fig. 15 represents the latest type of magneto telephone outfit manufactured by the Stoddard Telephone Construction Company, Monroe, Mich., and known as Set No. 85. This outfit is made for both series and bridging circuits, and is said to be radically different from old models. The transmitter is of the solid-back type, and the transmitter cord is concealed in the arm; the receiver is the regular Stoddard bipolar instrument with the permanent magnet fastened at its pole ends. The induction coil is extra long and wound with silk-covered wire, of course. The receiver hook is of the long lever type, as shown in Fig. 15, with the contact springs mounted vertically, and with a Bell-style receiver fork. The magneto is unusually powerful and supplied with noiseless gearing; the armature is wound with silk-covered wire and equipped with an automatic cut-out.

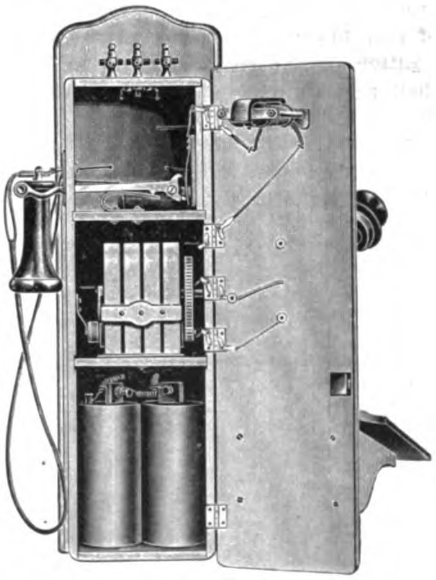

FIG. 15.—STODDARD TELEPHONE OUTFIT.

NEW TELEPHONE MAGNETOS.

Figs. 16 and 19, shown herewith, illustrate the two latest types of magetos built by the Connecticut Telephone & Electric Company, Meriden, Conn. The magnetos are similar as to general construction, the chief difference being in the size. The magnets are made from the best grade of magnet steel obtainable, carefully tempered and bent to such a form that they spring on to the pole-pieces and grip them tightly, the pole-pieces being held apart, of course, by a non-magnetic distance piece. Screws are used, however, as an additional precaution to secure the pole-pieces to the magnets, and ridges are provided on the back of each pole-piece which fit in the spaces between the magnet bars and prevent any tendency to lateral shifting. The armature core is laminated, carefully insulated, and compressed on a drawn steel shaft. The bearings are made extra long and of a close fit. The gears are extra heavy, made of a special grade of cast brass and are turned and cut in position on the shaft in order to insure their running absolutely true. The pole-pieces, which are made of the best grade of iron obtainable, are carefully bored out and fitted as close to the armature as mechanical conditions will allow, thus giving a minimum air gap. These magnetos are made for all of the usual arrangements of telephone circuits, and are mounted either on blocks or in cases with ringers and switch hooks. They are provided with either a series automatic shunt device or a bridging automatic cut-in arrangement. The latter is new, and consists of a small drum mounted on the end of the armature shaft and contains metal filings. These filings when the armature is in repose are in contact with only one terminal, but when it is rotated they are thrown outward by centrifugal force and complete the circuit between the armature and the line. The company also manufactures a double eight-magnet generator for use on lines where extra heavy output is desired.

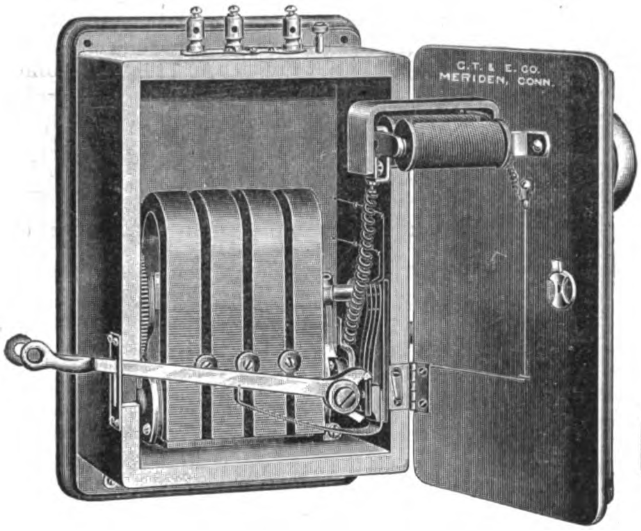

FIG. 16.—CONNECTICUT MAGNETO.

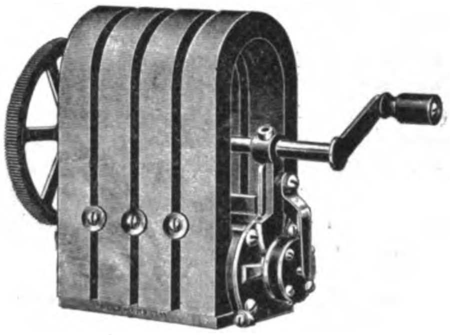

FIG. 19 —CONNECTICUT MAGNETO.

A SINGLE-POLE TELEPHONE LIGHTNING ARRESTER AND FUSE BLOCK.

Fig. 20 represents a single-pole type of combined telephone lightning arrester and fuse-block which is being marketed by the American Electric Fuse Company, Chicago. The construction will be familiar to those who are in touch with telephone work. The two vertical carbon blocks at the left-hand end of the device are separated by a sheet of dielectric material and form the lightning arrester, while the fuse is the familiar fuse link which has been in use for several years.

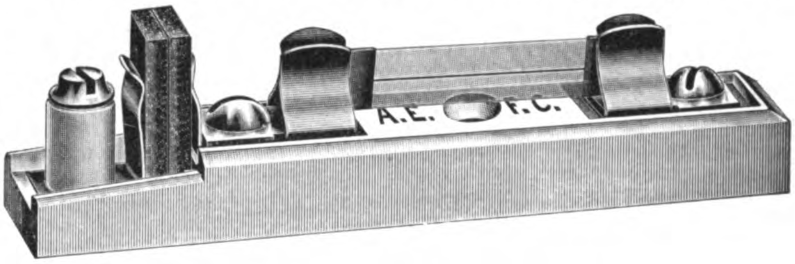

FIG. 20.—LIGHTNING ARRESTER AND FUSE BLOCK.

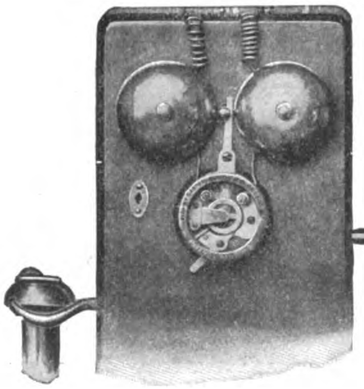
NEW EXTENSION CIRCUIT SIGNALLING APPARATUS.

A telephone extension signalling device, without magnet coils of any description, that does not insert any extra resistance in the circuit, and that resets itself after every signal, has been considered an ideal arrangement, but has not, we are informed, hitherto been offered on the market. The Garton-Daniels Company, of Keokuk, Iowa, maker of the well-known Garton Lightning Arresters, has recently brought out such an extension circuit ringer, illustrated by Figs. 17 and 18. Fig. 17 shows the ringer attached to the front of a magneto box, and Fig. 18 gives a larger view of it, detached. It will be noted that a lever, extending upward, is held against the bell-clapper of the magneto. When the bell-clapper vibrates, the extension circuit is closed, reproducing the signal wherever the bell is located. As soon as the bell-clapper of the magneto comes to rest, the circuit is again opened automatically.

In other forms of extension circuit-closing devices, a coil is depended upon to release a shutter, which closes the circuit when it falls. It is necessary to reset this shutter at once, or the battery will soon become exhausted. It frequently happens that calls come in when no one is around, and, again, lightning will sometimes throw the shutter at night when no one is present; in either case, the relay is not reset and the battery becomes exhausted. This trouble is obviated altogether by the ringer here described, as it resets itself after each signal. This device may also be used on party lines, where an ordinary drop would be of no value. The fact that the G.-D. ringer puts no resistance in the circuit will appeal to practical telephone men.



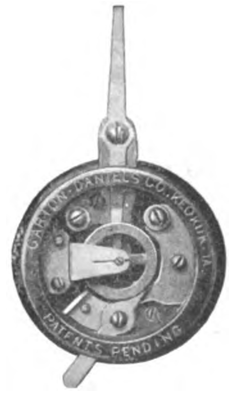


FIG. 17.—EXTENSION CIRCUIT RINGER—FIG. 18.

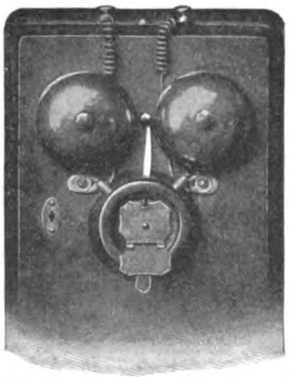

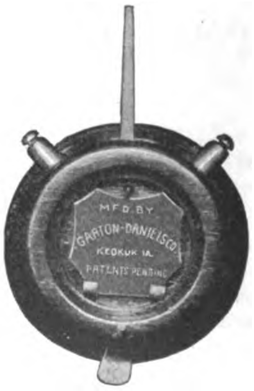

FIG. 21.—EXTENSION CIRCUIT CLOSER.—FIG. 22.

Fig. 22 shows an ordinary drop shutter circuit-closing relay now being placed on the market by the same company. This differs from other forms in that it is not dependent on the action of a magnet but is entirely mechanical, like the extension ringer just described. It is actuated by the motion of the bell-clapper of the magneto, the same as the extension ringer, but differs from the latter in that it must be reset after each signal. It is offered to meet the views of those who prefer the old form of circuit-closing drop. Fig. 21 shows the G.-D. circuit-closing drop in position on a magneto box.

A NEW FORM OF WALL TELEPHONE SET.

The Central Telephone & Electric Company, St. Louis, Mo., has just brought out the new form of wall set illustrated by Fig. 24. The feature of this set is the unusual arrangement of the instruments, which is said to be much more convenient than that of the more conventional style. Instead of mounting the transmitter on the magnetic box, the latter is brought down and combined with the battery box, the transmitter and induction coil being mounted alone on the upper part of the back board. This arrangement is evidently more convenient physically, as it is not necessary for one to reach upward in order to call up the central office or to remove the receiver from its hook. The set is handsomely finished, and the instruments are of the Central Company's standard long-distance types.

NEW GASOLINE RUNABOUT.

The Olds Motor Works, of Detroit, has introduced a new model of gasoline runabout illustrated by Fig. 23, which it has called the "Oldsmobile." The body is mounted, independent of motor and running gear, on rubber cushions about two feet from the ground. An Olds 4-h.p. gasoline motor furnishes the motive power, which is transmitted to the wheels by a roller chain, and is sufficient to drive the vehicle at speeds ranging from 10 to 25 miles an hour on a 22 degree gradient. The axle is provided with a differential gear, of course, as a single motor is used. The tank will hold sufficient gasoline for a 150-mile run, which has been found to require about 4 gallons. The runabout weighs less than 600 pounds, and is capable of sustaining over three times its own weight. It is furnished with heavy pneumatic rubber tires and a powerful brake.

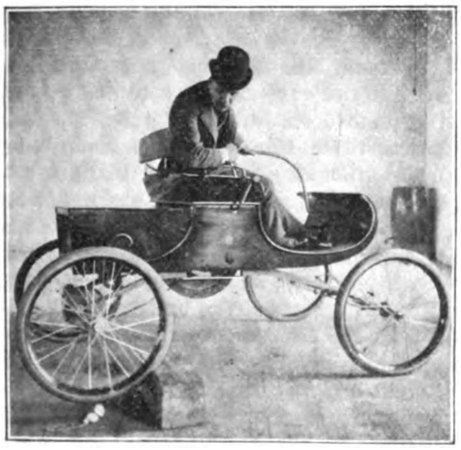

FIG. 23.—GASOLINE RUNABOUT.

MIANUS TELEPHONE OUTFIT.

Fig. 25 represents the standard telephone equipment of the Mianus Electric Company, Mianus, Conn. The set consists of a granular-carbon transmitter mounted on a Bell-type transmitter arm, a long induction coil, a Bell-type receiver and a 10,000-ohm magneto and bell. The battery box shown is extra size, for two cells of battery, but the set is furnished with any size of battery box desired up to three cells capacity. The transmitter is said to be a particularly loud talker, and to transmit articulation very clearly. The magneto is provided with a four-bar magnet arranged with two horse-shoes side by side and two others within the first two, thus securing the full advantage of compounding the magnets and at the same time making the machine unusually compact.

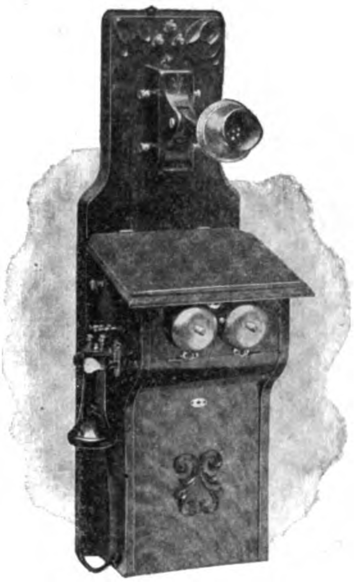

FIG. 24.—NEW WALL SET.

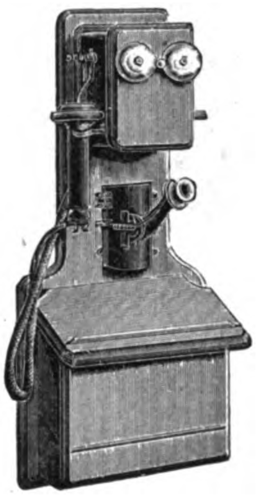

FIG. 25.

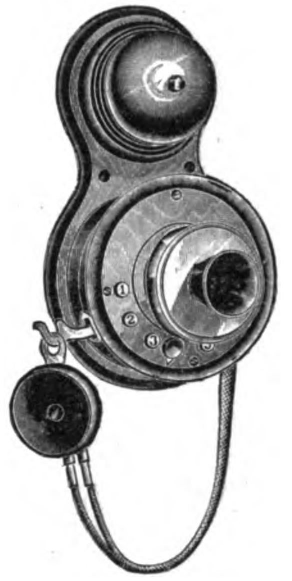

FIG. 26.

A COMPACT INTERCOMMUNICATING OUTFIT

The Spencer Electrical Company, New York, has just brought out the extremely compact and efficient intercommunicating set illustrated by Fig. 26 herewith. The features which differentiate this set from those of other intercommunicating systems are the use of a single centrally-located induction coil and the mounting of the transmitter on the pivot of the selective switch lever. The engraving shows very clearly the method of mounting the transmitter and switch, and it will be evident that this method secures greater compactness than could otherwise be obtained. The transmitter embodies special construction; the diaphragm is compound, consisting of an aluminum disc and a thin tin plated disc between which is interposed a tissue sheet. The diaphragm is held in place by a non-conducting washer which is faced with cork so as to avoid a harsh contact, and at the same time secure the positive location of the diaphragm. On the rear side of the diaphragm is bolted the usual carbon disc which works with a piston motion within a casing of yielding material secured to the rear electrode. The back electrode is soldered permanently to its metal mounting and held in a substantial metal cup which forms the center of a bridge or yoke across the back of the transmitter.

The system is a central-battery system, of course, as there is only one induction coil for all of the stations. The selective switch is of the simplest possible type, consisting of a spring lever which normally stands away from the contact buttons. In operating it is only necessary to swing the lever around until it is opposite the desired button and press it inward against the button. This calls up the station whose individual line is connected to that button. There is no interrelation between the receiver hook switch and the selective switch; stations can be called whether the receiver is on the hook or not. All of the connections in the outfit are thoroughly soldered except the receiver cord terminals. The binding posts used to hold these, however, are of such design that they cannot work loose nor twist in their sockets. These outfits are made for systems containing any number of stations up to twenty.

SPECIAL BRIDGING TELEPHONE OUTFIT.

Fig. 27 illustrates the No. 9-A bridging telephone outfit of the Farr Telephone & Construction Supply Company, Chicago, Ill. The component parts of this outfit are a solid back transmitter, bipolar receiver, long induction coil, a special five-magnet generator and a 1600-ohm ringer. The transmitter contains the unique feature of an aluminum diaphragm, for which strong claims are made. A carbon button is fastened to the rear side of the diaphragm, and between this and the stationary carbon electrode are the usual granular carbon particles. The re-

ceiver is bipolar. The magnet is mounted at its pole ends on a block of non-magnetic material, a part of which is threaded to fit a female thread in the receiver shell. The poles are of the usual oblong type wound with No. 37 silk-covered magnet wire to a resistance of 125 ohms. These receivers, it is stated, give the best results on long lines heavily loaded with instruments. The magneto is unusually powerful, being capable of ringing through 50,000 ohms resistance. The armature core is laminated and carefully fitted to the pole-pieces. The ringer has

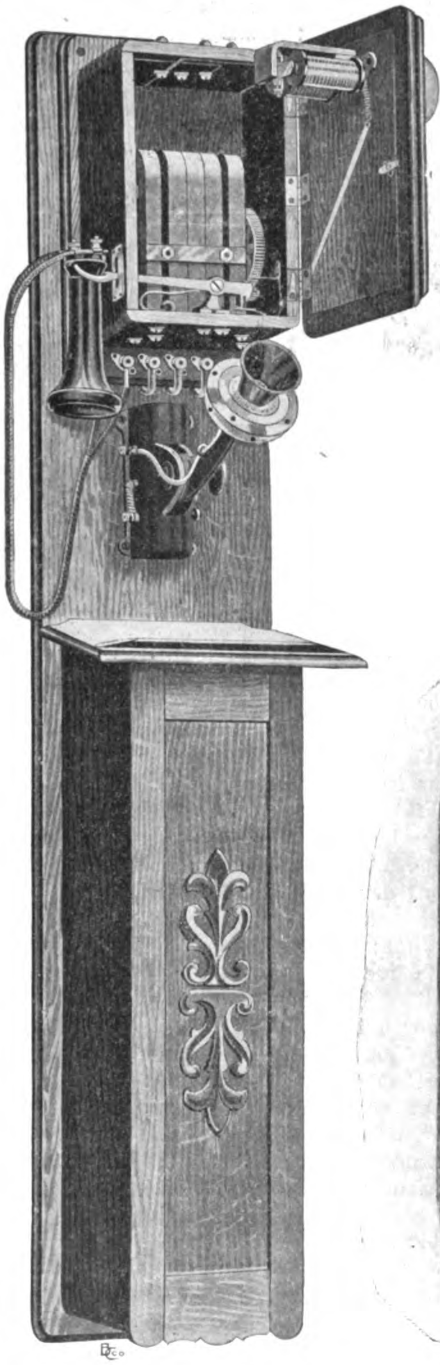

FIG. 27.—BRIDGING OUTFIT.

1600-ohm magnet coils. The set is built for bridging lines where 20 to 25 telephones are connected up on one circuit. The case is made of either oak or walnut with a high-grade piano finish.

KEELYN RECEIVER AND TRANSMITTER.

Fig. 28 illustrates a telephone receiver and transmitter equipment of very grace**ful design which is being marketed by the Keelyn Telephone Manufacturing Company, Chicago, Ill. The receiver is of the bipolar type, with the magnet supported at its poles, so as to obviate trouble from unequal expansion of the case and the magnet. A feature upon which the manufacturer lays particular stress is the high insulation of the receiver circuits and the arrangement of the flexible cord. There are no metallic parts exposed on the receiver, the connections of the cord being made within the case. The cord is held mechanically by a button, so as to** remove the strain from the conductors and the terminals inside the receiver shell. The transmitter is of the usual granular-carbon type, but its construction is unusual in that the back half of the case is cast in one piece with the transmitter arm. The parts of the transmitter consist simply of a diaphragm, a carbon block and carbon granules lying between the diaphragm and the block. The design is such that there is a deep recess around the circular carbon block, which is filled by granular carbon; this arrangement, it is claimed, adds to the efficiency of the transmitter by providing a larger **variable contact area. The base of the transmitter arm contains an induction coil, as usual.**

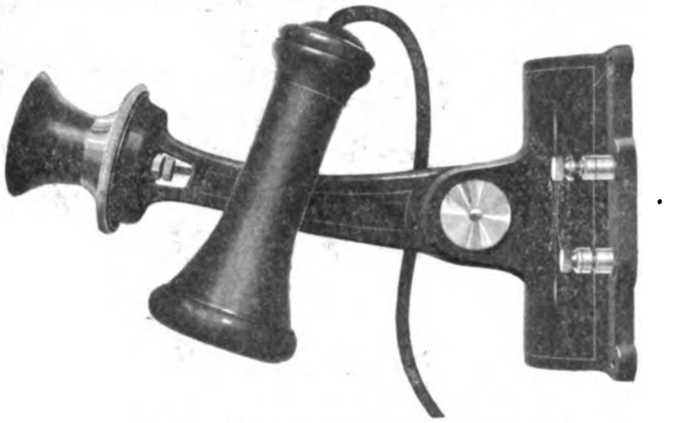

FIG. 28.—KEELYN RECEIVER AND TRANSMITTER.

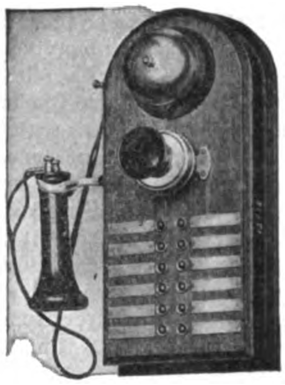

FIG. 30.

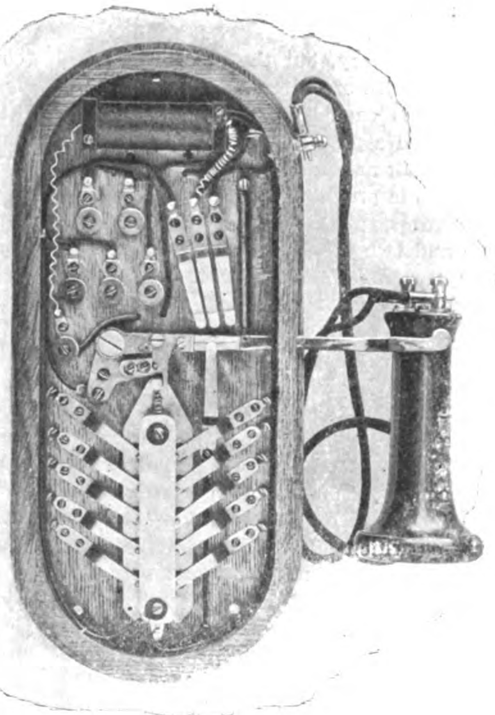

FIG. 29.—SWITCHLESS INTERCOMMUNICATING SYSTEM.

DE VEAU SWITCHLESS INTERCOMMUNICATING SYSTEM.

Stanley & Patterson, of New York City, are just bringing out an entirely new intercommunicating system, a feature of which is that no switches are employed, except the ordinary receiver hook switch. Fig. 30 shows the front of an intercommunicating set, and Fig. 29 is a rear view, showing the mechanism. The diagonal springs are the line springs connected to the individual lines of the various stations; the vertical strip in the foreground is the battery connection, and the plate just back of this strip and the line springs, the upper end of which is triangular, is the common-return connection. This common-return plate is arranged to move up and down on guides, and is perforated with a series of holes corresponding in number and position to the line springs and push-buttons. The plate is normally held in its upper position by a spring. There is a series of push-buttons mounted in the front of the box, as shown in Fig. 30. **These buttons have each a shank with** a tapered head exactly like the pointed head of an upset rivet. **Pressing one of the push buttons forces this tapered head through a hole in the common-return plate and the tapering edge impinges** against the edge of this hole and presses the plate downward until after the head passes through, when the plate is pulled up by its spring and keeps the push-button from springing back. The tapered head of the push-button shank engages the line spring opposite to it, and when the button is pushed to its extreme limit it forces this spring against the battery plate, calling up the desired subscriber. When the button is released it flies back but is caught half way by the movable common-return plate, as above described, and connects the line spring with this plate.

When the receiver is placed on the hook after the conversation is finished a pawl mounted on the hook lever engages a lug on the common-return plate and pushes the plate downward just far enough to release the push button, which thereupon springs outward into its normal position. Continuing in its downward movement, however, the pawl on the receiver hook lever is thrown out of engagement with the lug on the common-return plate, and this plate returns to its upper position. It is plain that conversation may be carried on with any number of stations simultaneously as it is only necessary to press the push buttons of the various stations in order to connect them all in multiple between their individual lines and the common-return line.

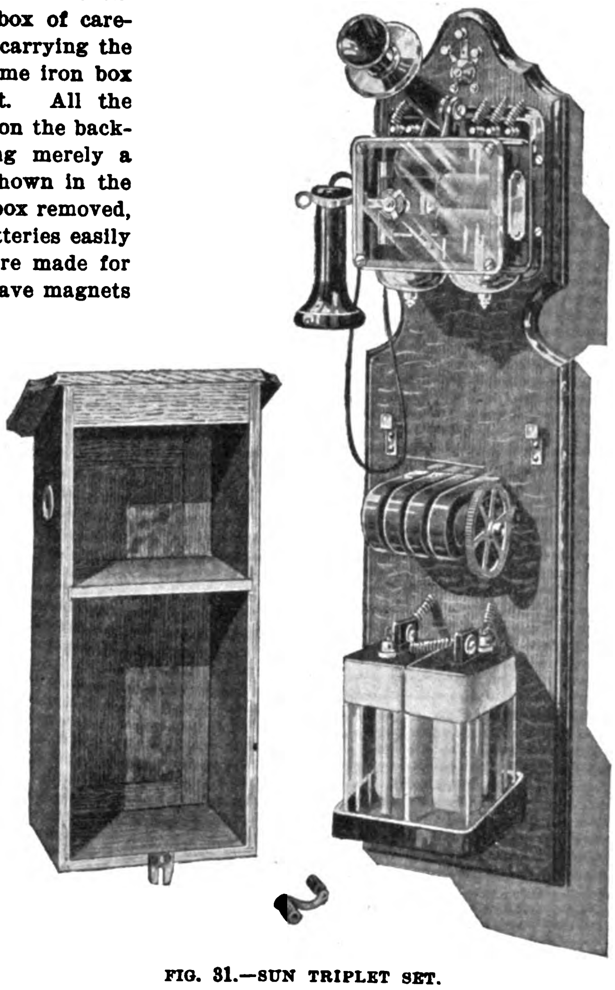

FIG. 31.—SUN TRIPLET SET.

A HANDSOME TELEPHONE OUTFIT.

Fig. 31 illustrates a very handsomely finished telephone equipment made by the Sun Electric Manufacturing Company, Philadelphia, and known as Wall Set Type A, No. 1. It has an ornamental backboard and panelled battery box of carefully selected quartered oak, carrying the Sun "triplet set" in a handsome iron box with heavy plate-glass front. All the parts are mounted directly upon the backboard, the battery box being merely a protective cover, as clearly shown in the engraving, which shows this box removed, making the generator and batteries easily accessible. The generators are made for series or bridged work, and have magnets of the highest quality of magnet steel purchasable. The armatures are laminated, of the best quality soft Swedish iron, carefully trued up, and turned so as to secure as small an air gap between the armature and the pole-pieces as it is possible to obtain.

In the transmitter the familiar piston movement is employed, the front electrode being solidly attached to the diaphragm and working in a chamber hollowed out of the solid metal which forms the rear half of the shell. The two halves of the shell are of cast brass, both being accurately turned so as to be true in their fit and perfect in their centering. The electrode chamber, being formed directly in the rear half of the shell and centered therein in the making of the shell, is true not only in its conformation but in regard to the other elements in the structure. This enables the company to make all parts interchangeable and the adjustment permanent. It is adjusted once for all at the factory, and then sealed up.

The receiver is new, like the transmitter. It has a genuine hard-rubber shell, and a cap that contains a series of small perforations instead of the single large opening usually used. The magnet structure is made as a unit, assembled and adjusted without regard to the shell. The magnet steel is specially made under a formula and guaranteed to preserve its magnetism at full strength. The cord is secured to the magnet structure, and there are no external binding posts. The entire magnet structure is carried on a metal disc adjustable in a metal ring which carries the diaphragm. The induction coil is 5 ins. in length by 1⅛ ins. in diameter, with hard-rubber ends; the primary and secondary windings are of silk-insulated magnet wire, brought out to terminals on the rubber ends and soldered. The resistance and talking qualities of these coils are the same as those used by the Bell company.

The hook switch is said to be different from that used by other manufacturers. It has a metal base made in one piece, with upturned ends to which the contact springs are secured solidly by screws and metal nuts. Insulation is secured by interposed non-conducting washers and bushings. The springs rest under tension on a central post, which has a rubber jacket for the purpose; the hook itself is secured on a sleeve which slips over a second post on the base. Around the sleeve is a coiled steel spring held in place by a spider, and the contact arm of the hook is also carried on the sleeve. The entire hook, spring and all, may be slipped off the base post and removed at will, for inspection, repairs, or testing, and as easily slipped back. All parts are standardized and interchangeable.

The lightning arrester is also of a new design and said to possess certain advantages not found in others. It has two line strips arranged in the general outline of a shield, with an intermediate strip for ground.

LEGAL NOTES.

IDE ENGINE PATENTS.—In an infringement suit of Addie F. Ide, et al., executors of the late A. L. Ide, vs. Trorlicht, Duncker & Renard Carpet Company, et al. and J. F. Chuse and Richard Heap, defendants, in the Circuit Court of the United States for the Eastern Division of Eastern Judicial District of Missouri, Judge Adams handed down a decision to the effect that the engines manufactured by the last-named defendants do not infringe the Ide patents.

TESLA SPLIT-PHASE MOTOR PATENTS.—The United States Circuit Court for the southern district of Ohio has rendered a decision in favor of the Westinghouse Company in two suits brought by that company against the Dayton Fan & Motor Company for infringement of the Tesla patents Nos. 401,520, 511,559 and 511,560. The first-named patent covers the method of operating single-phase motors by "splitting the phase," and the latter two patents cover means for accomplishing the necessary phase-splitting.

PERSONALS.

MR. E. T. PARDEE has joined the staff of the Bullock Electric Manufacturing Company at its New England office in Boston.

MR. C. E. COLLINGS, a well-known electrical engineer, formerly of Mobile, Ala., has joined forces with the Century Electric Wiring Company, Turtle Creek, Pa.

MR. W. F. GREENWOOD, general manager and chief engineer of the Havana Electric Company, Havana, Cuba, was recently in New York City on a short business trip.

MR. R. H. KLAUDER, formerly of the Philadelphia staff of the Electric Storage Battery Company, has been appointed manager of the company's new branch office at St. Louis, Mo.

MR. C. C. WARREN, president of the Warren Electric Manufacturing Company, Sandusky, Ohio, sailed from New York with his wife on the steamship Trinidad for Bermuda, on February 16.

MR. STEWART S. NEFF has been appointed superintendent for the Boston Elevated Railway Company. Mr. Neff is a well-known railroad man and amply qualified for his new position.

MR. A. J. BAGNALL, of the well-known firm of Bagnall & Hilles, of Yokohama, Singapore and Manila, is on a visit to the United States for the purpose of purchasing supplies for a projected electric railway in Tokyo, Japan.

THE ELECTRIC APPLIANCE COMPANY, of Chicago, has put on the market a new hotel telephone system which is said to have many points of advantage over the ordinary intercommunicating systems previously marketed.

MR. PAUL BIGELOW, formerly electrician in charge of the Department of Yards and Docks at the New York Navy Yard, has resigned his position to accept the representation of the Buckeye Engine Company, of Salem, Ohio, in this city.

MR. GEORGE P. LOW, editor of the "Journal of Electricity, Power and Gas," has been appointed local honorary secretary at San Francisco by the American Institute of Electrical Engineers, to succeed Dr. F. A. C. Perrine, who recently resigned this office.

MR. E. F. SEIXAS has resigned his position as general manager of the Amsterdam (N. Y.) Street Railway to take a similar position with the Niagara, St. Catherines & Toronto Railway, and the Niagara Falls, Wesley Park & Clifton Tramway Company.

MR. J. W. PETERSON, of Chicago, has joined the Chicago staff of the Northern Electrical Manufacturing Company and the Stanley Electrical Manufacturing Company, and will hereafter concentrate his well-known ability upon the sale of Northern and Stanley apparatus.

MR. EDWIN BURHORNE has engaged in general engineering and contract work with offices at 62 Wall Street, New York. Mr. Burhorne has made a specialty of designing and erecting steam and electric plants, and states that he is glad to handle cases involving unusual difficulties.

MR. F. A. WUNDER, who for several years represented the Fort Wayne Electric Works and the Siemens & Halske Electric Company of America in New York City, has been appointed general sales agent for the Ball Electric Company, with headquarters at 95 Liberty Street, New York.

MR. W. S. BROWN, formerly with the Sprague Electric Company, has severed his connection with that company to take the management of the Eastern sales department of the Richmondt Electric Wire Conduit Company. Mr. Brown's headquarters will be at 39 Cortlandt Street, New York.

MR. JOHN B. BENNETT, for several years business manager of the "Street Railway Journal," has resigned his position on that paper and acquired an interest in the "Municipal Journal and Engineer," of which he will be the business manager. The American Electrician joins with Mr. Bennett's many friends in wishing him the full measure of success which his high ability merits.

MR. LEVI TEAL, of the S. S. White Dental Manufacturing Company, Philadelphia, Pa., was quietly married on Tuesday, February 26, to Miss Annie E. Haas, of Philadelphia. Mr. and Mrs. Teal will spend their honeymoon in the South, and upon returning to Philadelphia will reside at 2109 N. Twelfth Street. The American Electrician joins with their many friends in wishing them a happy and prosperous future.

MR. THEO. G. SEIXAS was married on February 14 to Miss Amelie L. Bunout, at the home of the bride's mother, in New York City. Mr. Seixas is vice-president and superintendent of the Germantown Electric Light Company, Philadelphia, and was for several years associated with Mr. Edison at his laboratory. The American Electrician joins the numerous friends of the young couple in wishing them a happy and prosperous life. Mr. and Mrs. Seixas will reside in Philadelphia.

MR. A. WILFORD ZAHM has resigned his position of secretary and general manager of the Manhattan Light, Heat & Power Company, of St. Paul, Minn., to accept a similar position with the Light, Heat, Transit & Public Service Company, of St. Cloud, Minn. This company is a consolidation of the Benton Power & Traction Company and the Hertig Light & Heat Company, and operates the St. Cloud and Sauk Rapids Street Railway and an electric-lighting and steam-heating plant for furnishing light and heat in St. Cloud and Sauk Rapids.

TRADE PUBLICATIONS.

CALENDARS.—The Cutter Company, Philadelphia.—Two attractive calendars consisting of red cardboard sheets bearing the usual calendar blocks divided into monthly leaves, and also showing pictures of I. T. E. circuit-breakers.

BLOW-OFF VALVES AND SWING JOINTS. The Bordo Valve Company, Philadelphia.—A pamphlet catalogue, vest-pocket size, containing illustrations, descriptions and price lists of the Bordo plug valves and swing pipe-joints.

KNIFE-BLADE SWITCHES. H. P. White Company, Ltd., Philadelphia.—A pocket-size pamphlet catalogue of White knife-blade switches which are made in all of the usual combinations. The peculiar feature of these switches is an inturned flexible jaw.

LIST OF PRODUCTS. American Steel & Wire Company, Chicago.—A pamphlet of small pocket size containing an enumeration of all of the products of the American Steel & Wire Company. This is not in any sense a price list, but merely a list of the articles manufactured.

MEMORANDUM BOOK. Hugo Reisinger, New York.—A neat little vest-pocket memorandum book with a leather cover and removable pad of leaves. The leaves are lined in cross-section with blue ink, and an auxiliary pad accompanies the cover and the pad already within it.

CALENDAR. The D. M. Steward Manufacturing Company, Chattanooga, Tenn.—A hanging calendar carrying a monthly-leaf pad of large size, and bearing an allegorical picture in colors which represents Uncle Sam using the Steward 4-H lava burner as a cannon to demolish British fortifications.

CALENDAR. D. L. Bates & Bro., Dayton, Ohio.—A hanging calendar comprising a stout pasteboard backing, on which are mounted a handsome photograph of two dogs and a small monthly-leaf calendar pad. The photograph includes also a picture of a Dayton fan motor, and is captioned "Prize Winners."

HEATING AND VENTILATING THE LARGEST ROUND HOUSE IN THE WORLD. B. F. Sturtevant Company, Boston, Mass.—An ornamental double-fold pamphlet containing a brief description of the Sturtevant heating and ventilating plant in a round house on the Chicago & Northwestern Railroad.

STEAM TURBINES. The Westinghouse Machine Company.—This is a handsomely-executed reprint of the paper read by Mr. Francis Hodgkinson last November before the Engineers' Society of Western Pennsylvania. The paper is extremely interesting and contains a considerable amount of useful information.

DIARY AND CATALOGUE OF SMALL TOOLS. Smith & Hemenway Company, New York.—This is a diary, or rather a dated memorandum book, for the current year. Each page is divided into seven spaces, so that a page covers exactly a week. The small tools illustrated in the book are plyers, glass cutters, snips, shears, etc.

SERIES-PARALLEL SYSTEM OF MOTOR CONTROL.—The C & C Electric Company, New York.—This is Bulletin No. 138, containing a resume of methods employed in the operation of newspaper presses, and a detailed description of the company's new system of motor control for such presses, which was described in our January number. The book is of the standard catalogue size and well illustrated.

DIRECT-CURRENT MOTORS. The Emerson Electric Manufacturing Company, St. Louis, Mo.—This is Bulletin No. 3,028, containing illustrations, a description and price list of a new line of direct-current motors which the Emerson Company has just brought out. The motors are made in three sizes, ¼, ½ and 1/3 horse-power, and are supplied wound for slow speed, medium speed or high speed, and for either 110 or 220 volts.

ELECTRICAL APPARATUS AND SUPPLIES.—Varney Electrical Supply Company, Indianapolis, Ind.—This is a general catalogue of dynamos, motors, telephones, telephone apparatus, arc lamps, and electric light and railway supplies. Its distinctive feature, however, lies in the arrangement of the leaves, which are removable and may be therefore changed from time to time as prices and types of appliances change. This characteristic has led the Varney Company to designate it a "perpetual catalogue."

COMPARATIVE INCANDESCENT LAMP TESTS. Western Electric Company.—This is a most elaborate and handsomely-executed book, containing diagrams of tests made with incandescent lamps of various makes, the object being to obtain a comparison between the Sunbeam and other lamps. The tests are plotted on charts 10 x 12 ins., and to a correspondingly large scale, but they do not seem to have been accurately taken, as the candle-hour curves show several "saw teeth" beyond the initial rise and fall which is always obtained.

CALENDAR. The Electric Motor & Equipment Company, Newark, N. J.—This is the most ornamental advertising calendar that has come to light so far this year. It comprises a celluloid face plate of ornamental shape and bearing tasteful pictures of flowers and birds executed accurately in natural colors; together with a revolving dial pivoted back of the face plate. The dial bears the days of the week and the names of the months, which show through slots in the

face plate. The latter bears the days of the month and the years. The calendar is good up to 1909, and is worthy of a place on any desk.

BUSINESS NEWS.

THE GORDON BATTERY COMPANY, New York, has moved its place of business to 13 and 15 Laight Street.

THE HUDSON PORCELAIN WORKS, New York, is now manufacturing a full line of insulators, cleats, etc., for telephone, telegraph and electric-light construction.

THE PELTON ENGINEERING COMPANY, Cleveland, Ohio, has removed its office and factory to No. 16 Merwin Street, where it has larger facilities than heretofore.

MR. ROBERT HUTCHIN JEFFREY, of Columbus, Ohio, general manager of the Jeffrey Manufacturing Company, was married on February 6 to Miss Alice Kilbourne, of Columbus.

THE INTERNATIONAL CORRESPONDENCE SCHOOLS, Scranton, Pa., have removed their New York office to larger and more suitable quarters at No. 7 West Twenty-second Street.

THE EASTERN ELECTRIC COMPANY, Middleton, Mass., has moved its business to Lynn, Mass. The company manufactures incandescent lamps and expects to double its output in the Lynn plant.

GEORGE W. HOFFMAN, Indianapolis, Ind., reports a brisk trade in his U. S. metal polish. Among other orders recently received was one for five barrels and ten cases to be forwarded immediately.

THE NORTH ELECTRIC COMPANY, of Cleveland, Ohio, has opened an office for its telephone trade in the West, at 1511 Monadnock Block, Chicago, which is under the management of Mr. George W. Conover.

THE BURT MANUFACTURING COMPANY, Akron, Ohio, recently received an order from the Havana Street Railway Company, Havana, Cuba, for two 150-gallon Cross oil filters for the new Havana power house.

BAKER & CO., Newark, N. J., dealers in platinum, state that this metal has never been so high as at the present time. Indications, as a result of this condition, point to an early and considerable increase over present quotations for platinum.

THE PITTSBURG BOILER SCALE RESOLVENT COMPANY, Pittsburg, Pa., has received an order from the United States Government for a quantity of boiler scale resolvent to be used in the boilers of the government ice plant at Iloilo, Philippine Islands.

THE VARLEY DUPLEX MAGNET COMPANY has removed its factory from Jersey City, N. J. to Phillipsdale, R. I. This change in location will enable the company to avoid all delays incident to the transportation of raw material, as it will obtain wire from the American Electrical Works located at the same place.

I. P. FRINK, New York, has just completed a notable installation of lighting fixtures in one of the New York City churches The illumination is secured almost entirely by concealed lamps backed by powerful Frink reflectors which throw the light upon a large domed ceiling, the ceiling serving to again reflect and diffuse the light.

H. M. SHAW & CO., New York, manufacturers of Shaw's non-arcing lightning arrester, have secured the exclusive management and control of the Medbury insulation, so well and favorably known to the street railway trade, and is in position to supply promptly all the designs of overhead material at prices consistent with high grade workmanship.

WARD LEONARD ELECTRIC COMPANY, Bronxville, N. Y., calls attention to the importance of patent No. 668,140, which was issued to Mr. H. B. Cutter on February 12 and is owned by Mr. H. Ward Leonard. This patent covers the use of an automatic circuit-breaker in series with an automatic motor-starter, which combination is now almost universally used.

H. J. LINDER & COMPANY.—The copartnership doing business under the firm name of H. J. Linder & Company, at 128 Liberty Street, New York, was, on January 31, dissolved by mutual consent. The firm consisted of James W. Sturges and Herbert J. Linder. Mr. Sturges will continue the business of supplying complete power and electrical appliances under his own name and at the old address.

McKENNA BROTHERS BRASS COMPANY, Pittsburg, Pa., has had plans made for an eight-story factory building to cost about $100,000, the work on which is to begin not later than April 1. The new building will occupy a ground area of 84 x 100 ft., and will be provided with the most modern machinery, much of which will be specially designed for the manufacture of the brass specialties constituting the company's line.

BALL ENGINE COMPANY, Erie, Pa., reports the following recent export shipments of Ball engines: One 40-h.p. simple engine and one 75-h.p. compound direct-connected engine to Japan; two 125-h.p. tandem compound engines to Russia; one 50-h.p. simple engine to Honolulu; one 60-h.p. direct-connected engine to Vera Cruz, Mexico; one 150-h.p. cross compound engine to British Columbia, and one 400-h.p. direct-connected engine to England.

PLATINUM
In Sheet or Wire, any Degree of Hardness.
FOR ALL PURPOSES.
BAKER & CO.,
NEWARK, N. J.
New York Office, 120 Liberty Street,

JAS. LEFFEL & CO., Springfield, Ohio, have in progress an addition to their factory covering a ground space 90 x 220 feet. The new part of the factory will be built of brick and steel, and fully equipped with new machinery for the manufacture of the well-known Samson water wheel. The company has just received an order for a 3000-h.p. pair of horizontal wheels from Minneapolis, and a contract from Michigan for ten 68-in. Samson wheels to drive electric generators.

THE TRIUMPH ELECTRIC COMPANY, Cincinnati, Ohio, has sold for installation in the steamer "Exporter," running between St. Louis and New Orleans, a complete electric plant consisting of a vertical engine with direct-connected generator. The same company has sold through Thebaud Brothers, exporters, several machines to go to Merida, Mexico, one to Mexico City, and one for British Honduras. The consignment to Mexico and British Honduras is intended for lighting service.

RICHMONDT ELECTRIC WIRE CONDUIT COMPANY, Milwaukee, Wis., recently filed articles of incorporation with a capitalization of $50,000. The incorporators are Daniel E. Murphy, C. D. Richmondt and D. Hayes Murphy. This company manufactures a unique type of interior iron conduit, the feature of which is that the inner wall is smoothly enameled throughout. The company will shortly occupy a new building 85 x 400 ft. and will then have ample facilities for taking care of its rapidly growing business.

THE BULLOCK ELECTRIC MANUFACTURING COMPANY, Cincinnati, Ohio, has added to its well-known line of direct-current machinery a full line of alternating-current generators, motors, rotary converters and transformers for all standard voltages and phases. The designs are those which have been made well known through Europe by the Oerlikon Company, of Switzerland. The Bullock Company has recently opened an office at 675 Ellicott Square, Buffalo, which will be under the management of Francis B. Smith, an electrical engineer of wide practical experience.

WALKER ELECTRICAL CONSTRUCTION COMPANY, Philadelphia, under which style Mr. F. Dinwiddie Walker has heretofore traded, has been succeeded by a new limited co-partnership with the name and style of Walker Electric Company, Registered. Mr. H. H. Walker will liquidate the affairs of the old concern. The new firm will carry on the manufacture and sale of switchboards and other electrical appliances at the corner of Eighteenth and Hamilton Streets, Philadelphia. The members of the company are Henry H. Walker, F. Dinwiddie Walker, Bennett L. Johnson and Hervey S. Walker.

MONTAUK MULTIPHASE CABLE.—Montauk Multiphase Cable Company, New York, has made repeated applications to the Board of Fire Underwriters for recognition, but this has heretofore been withheld for the reason that the individual members of the Board, while conceding the merits of the cable, were unwilling to indorse a patented device by name. At a meeting of the Board held Feb. 22 the Committee on Patents submitted a report recommending the approval of a fire-detecting wire as a valuable adjunct, and the Board adopted the Committee's report without a dissenting voice. While no name was mentioned, it is understood that the wire was that of the Montauk Multiphase Cable Company.

THE GILLILAND ELECTRIC COMPANY, Adrian, Michigan, has resumed on a large scale the manufacture of telephone and electrical specialties. The Gilliland Company, which was organized in 1887, for many years manufactured all the pins and brackets for the largest telephone and telegraph companies in the United States. Mr. James F. Gilliland, the manager of the company, is an experienced telephone man, and has invented and patented large numbers of electrical and telephonic devices. The company has installed complete wood and metal working machinery and is prepared to furnish all forms of cabinet work, pins and brackets and is also equipped to manufacture many specialties. Its well-equipped plant with capacity for 1,000 men enables it to fill all orders with promptness, and its favorable situation gives it exceptional advantages with regard to the cost of manufacture.

THE LARGEST SINGLE ORDER FOR TRANSFORMERS EVER RECORDED.—The Westinghouse Electric & Manufacturing Company recently received from the Chambly Manufacturing Company an order for twenty 2750-kw. transformers of the Westinghouse air-blast type. Each of these, with an output of over 3600 horse-power of electrical energy, weighs approximately 11 tons and stands 9 ft. high. Of the twenty units, ten are to be used to raise the voltage from 2200 to 25,000 volts at 66 2/3 cycles. The input is two-phase and the output three-phase. The remaining ten transformers, for lowering the voltage, receive the three-phase line currents at 22,000 volts and deliver two-phase currents at 2400 or 4800 volts as required. The well-known Westinghouse methods of construction are employed in these transformers, both primary and secondary being divided into several flat coils wound with many layers, and few turns per layer, each coil being insulated separately. Iron and copper have been carefully proportioned to secure the minimum losses, and the efficiency of the transformers is very high, being considerably over 98 per cent. The iron is specially treated to minimize the increase in iron losses from "ageing." We are informed that this is the largest order for transformers that has ever been placed.

A. L. IDE & SONS, Springfield, Ill., report among other recent orders the following sales of engines for lighting and power service: Great Northern Railway, one 125-h.p., direct-connected; Bemis Brothers Bag Company, one 80-h.p., direct-connected; Northwestern Fixture Company, one 300-h.p., belted; Village of Ada, one 125-h.p., direct-connected; Nixon & Snell, one 125-h.p., belted; B. S. Sivley, one 125-h.p., belted; S. E. Olson Company, one 200-h.p., direct-connected; Illinois Central Railroad, two 470-h.p., and one 160-h.p., direct-connected; Urbana Light, Heat & Power Company, one 175-h.p., and one 100-h.p., direct-connected; City of Hastings, two 150-h.p., direct-connected; Pennsylvania Lines, one 80-h.p., direct-connected, and one 80-h.p., belted; City of Bellevue, one 100-h.p., belted; State Capitol, two 125-h.p., direct-connected; Central Investment Company, one 50-h.p., and one 125-h.p., direct-connected; Cass Land Company, one 100-h.p., direct-connected; Electric Light Company, one 125-h.p., belted; Otis Elevator Company, one 160-h.p., and one 250-h.p., direct-connected; Illinois State Reformatory, one 175-h.p., belted; American Smelting & Refining Company, one 60-h.p., belted; Iowa State University, one 150-h.p., direct-connected; Imgri. Giorgi, one 50-h.p., belted; Daniel Adamson & Co., one 80-h.p., belted, and one 150-h.p., direct-connected; Soldiers' Home, one 100-h.p., direct-connected; Crane Company, one 100-h.p., direct-connected; Lincoln Trust Building, one 150-h.p., direct-connected; Hospital for Insane, two 125-h.p., direct-connected; City Gas & Electric Company, one 250-h.p., belted; James Mitchell & Co., one 50-h.p., belted; Marshall-Wells Hardware Company, one 125-h.p., and one 160-h.p., direct-connected; City of Iola, one 80-h.p., belted; Stiefel Building, one 125-h.p., direct-connected; Village of Blue Island, one 175-h.p., belted; City of Coffeyville, two 100-h.p., belted; Northern Pacific Railroad, one 175-h.p., belted; Lake City Electric Company, one 150-h.p., direct-connected; State Reform School, one 100-h.p., direct-connected; Seattle Lumber Company, one 110-h.p., belted; Lincoln Gas & Electric Company, one 250-h.p., direct-connected; Dwight Furness Company, one 100-h.p., belted; American Car & Foundry Company, two 175-h.p., direct-connected; Thompson-Taylor Spice Company, one 100-h.p., direct-connected; School for the Deaf, one 100-h.p., direct-connected; Union Restaurant, one 125-h.p., direct-connected; Klausman Brewery, one 125-h.p., direct-connected.

SOLID TRAINS TO NORTHERN MICHIGAN.

The Chicago, Milwaukee & St. Paul Railway is now running solid trains of palace sleeping cars, dining cars (serving meals a la carte) and first-class day coaches, through from Chicago to Calumet, Houghton, Hancock and other points in the Copper Country without change of cars, with direct connection for Marquette, Negaunee, Ishpeming, etc., and passengers from the East, South and Southwest will find this a most desirable route.

All coupon ticket agents sell tickets via the Chicago, Milwaukee & St. Paul Railway.

A TRACY
OIL FILTER
costs a little more but it is sure to be the cheapest in the end: and it is SURE to clean your waste oil. Let us send you one on approval to be returned at our expense if it cannot do the work. Send for Circular.

THE MASON GOVERNOR
For ELEVATOR PUMPS.
The important feature with this governor is that it operates on the slightest change of pressure, opening and closing the steam valve to its full extent promptly and with a certainty.
The Mason By-Pass or Water Relief Valve.
In many cases it is desirable to use a power pump for elevator or other service, driven from a line shaft or motor which has other work to perform, and cannot be constantly stopping and starting, but must run continuously. It is for this purpose that our by-pass valve is used.
CATALOGUE MAILED UPON APPLICATION.

Vol. XIII. New York, April, 1901. No. 4.

ALTERNATING CURRENT POWER EQUIPMENT IN A PACKING HOUSE.

CENTRALIZED POWER PLANTS OF SWIFT & COMPANY, AT CHICAGO AND ST. JOSEPH.

The introduction of electric transmission has made possible a revolution in methods of operation in packing houses. In all the largest packing plants of the west the numerous small steam plants of former days are being eliminated as far as possible and power is being generated in one large central plant, and transmitted electrically to the numerous and scattered points of actual application. The utilization of this method by Swift & Company, the world's largest packers, is worthy of note. This concern has a number of plants in which electric power transmission is used to a greater or less extent, but the most complete installations are located in the Chicago and St. Joseph (Mo.) houses.

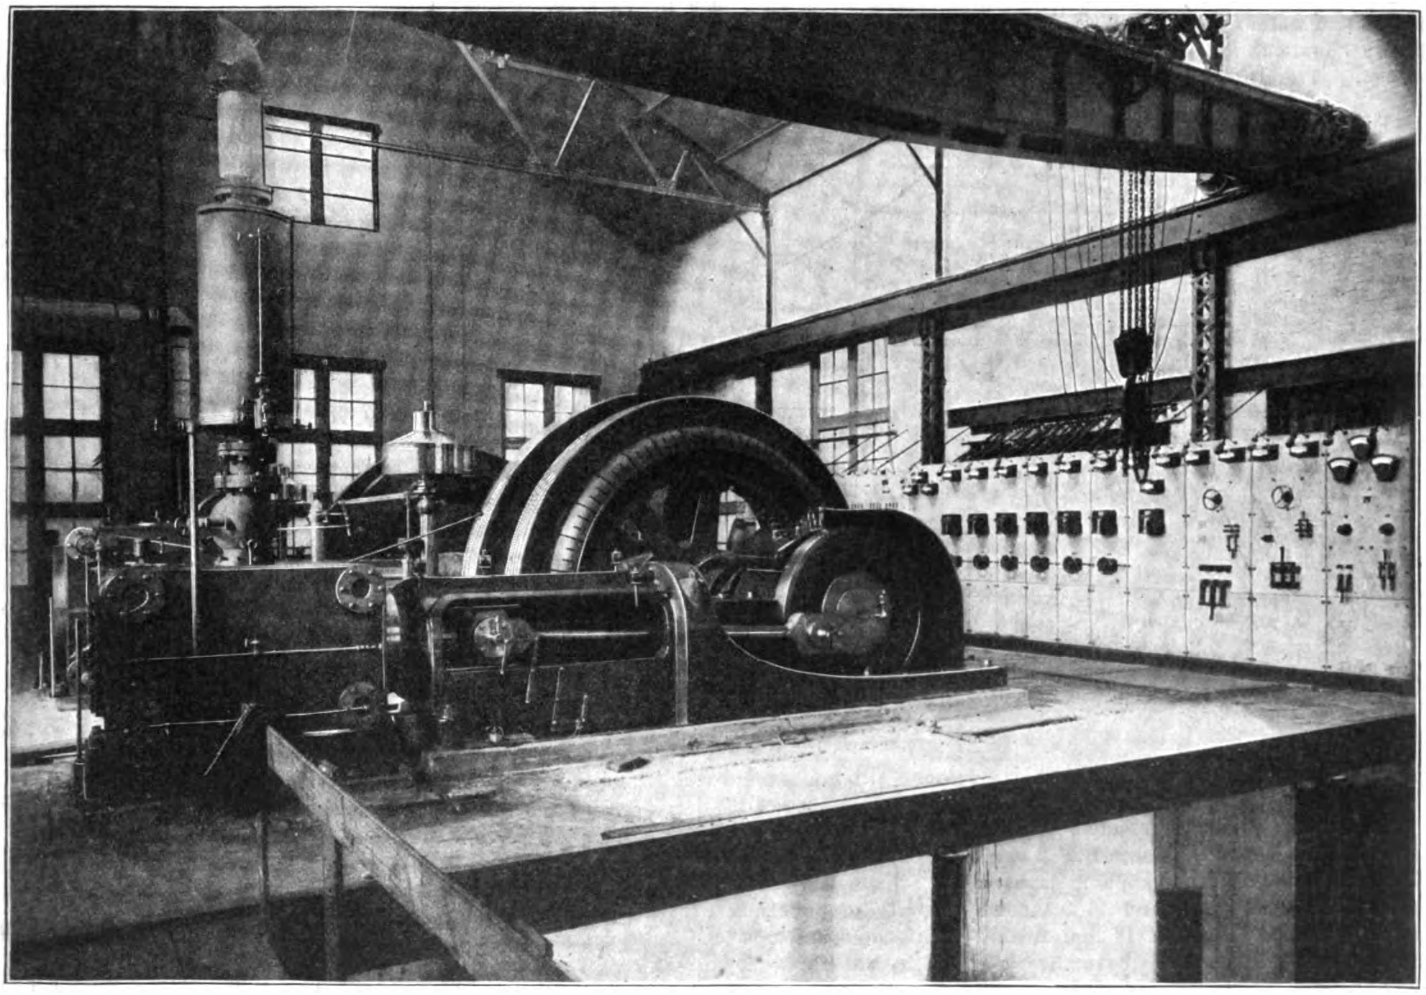

FIG. 1.—THE PRESENT ENGINES, GENERATORS AND SWITCHBOARD OF THE CHICAGO PLANT.

CHICAGO PLANT.

The packing plant covers 48 acres. Many of the buildings thereon are several stories in height. This fact alone would be enough to make the advantage of electric transmission apparent, and it is still more emphasized when it is known that there were formerly thirteen independent steam plants, eleven of which will be done away with by the establishment of the central electric generating plant here described. A large packing plant of this kind is really an aggregation of different kinds of factories all put under one management on one tract of land. In addition to the slaughtering, refrigerating and packing of the meat there are numerous by-product factories for butterine, soap, glue, fertilizers, etc.

Owing to local conditions and surrounding buildings the new central power station had to be divided, the boiler house being on one side of a couple of railroad tracks and the stack and engine room on the other side. The fuel economizers are in the smoke flues over the railroad track, the elevation being such that cars can pass under. The plans of various parts of the steam plant can be seen from the accompanying drawings. Beginning with the coal on the siding between the boiler room and stack we find it being taken up into storage bins above the boilers by Link-Belt Machinery Company's conveyors. These conveyors return beneath the ash pits under the boilers so that they can also be used for carrying away ashes, by opening the trap doors in the floors of the ash pits and letting the ashes fall on the conveyors. The coal conveyors can be made to run the coal through an electrically-driven coal crusher or it can be shunted around the crusher as desired. From the storage hoppers the coal is fed to automatic stokers built by the Murphy Iron Works, Detroit, Mich. Here it is worth while to note what the centralizing of power generation into large plants with automatic stokers is gradually accomplishing in the stock yards at Chicago. The packing houses in the Chicago Union Stock Yards have long been the worst smoke nuisances of that smoky city; the stack of the large central plant with automatic stokers is practically smokeless and forms an object lesson for less progressive establishments.

The boiler plant comprises eight 400-h.p. Babcock & Wilcox water-tube boilers. They are fed with Blake Admiralty-type pumps in duplicate, compound condensing with steam cylinders 7 and 14 ins. and water cylinders 7 ins. x 12 ins. stroke. The plant has a cooling tower for condensing water, and to circulate this a Blake simplex compound-condensing pump is used with steam cylinders 8 and 16 ins., and water cylinders 18 ins. x 18 ins. stroke. The economizers, located above the railroad tracks, as mentioned before, are of the Green type made by the Fuel Economizer Company, of Matteawan, N. Y. The stack is the second highest in the city; a sectional view of it is given by Fig. 3. Its height is 264 ft., inside diameter 16½ ft., base 26 ft. square. Its foundation is on 125 piles 30 ft. long. The cooling tower for furnishing condensing water is on top of the boiler house, as shown in Fig. 2. The condensers are of the siphon type. Two engine-generator sets are now installed and there is room for a third one, as shown in Figs. 1 and 5. The engines are notable as having a rather high speed for the type and size. They are cross-compound Corliss engines and are run condensing, with 150 lbs. boiler pressure. One engine is 13 and 26 ins. x 42 ins. stroke, direct-connected to a 300-kw. three-phase 250-volt alternator, running at 120 revolutions per minute; it is provided with a 32,000-lb. fly-wheel. The other engine is 19 and 38 ins. x 42 ins. stroke, with a 60,000-lb. fly-wheel, and is direct-connected to a three-phase 250-volt 600-kw. generator; its speed is also 120 r.p.m. The engines were both built by the Filer & Stowell Company, of Milwaukee, Wis., and the generators are General Electric machines. The exciters are belted from the fly-wheels of the engines. The generators are arranged so as to be operated in parallel or separately.

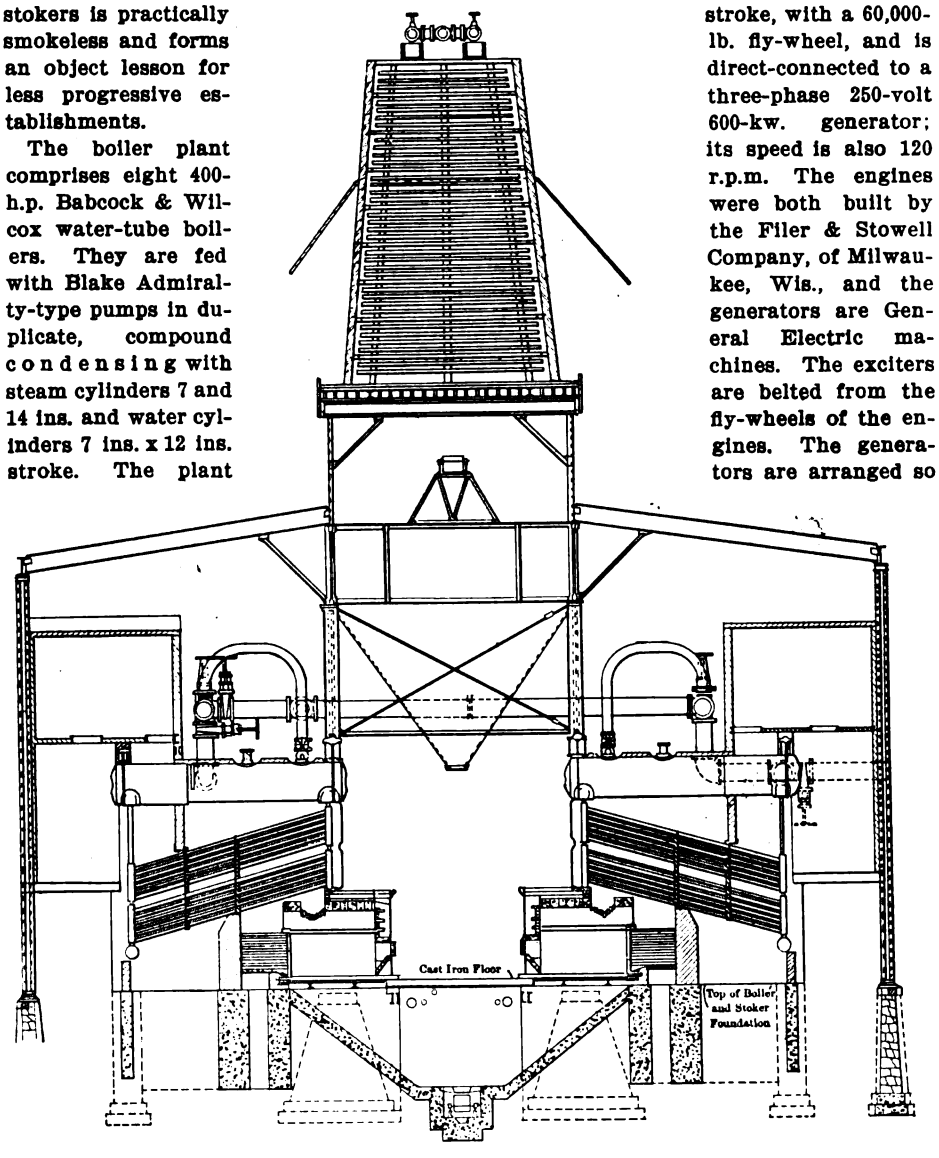

FIG. 2.—SECTION OF BOILER HOUSE AND COOLING TOWER.

The switchboard is an interesting piece of work, and necessarily has quite a variety of panels to provide for all the various operations to be accomplished with the three-phase service. The 250-volt three-phase currents are, of course, carried directly from the generators to the motors without transformation. Higher voltage was not used because of the danger to life from a higher voltage alternating current in such damp places as exist around packing plants. The marble switchboard has one panel devoted to the total output and for use in throwing generators together. It has two voltmeters, one for constant use, the other for testing the voltage of a generator that is to be thrown in; a recording Thomson wattmeter for the total output and a synchronizing voltmeter, the latter being an

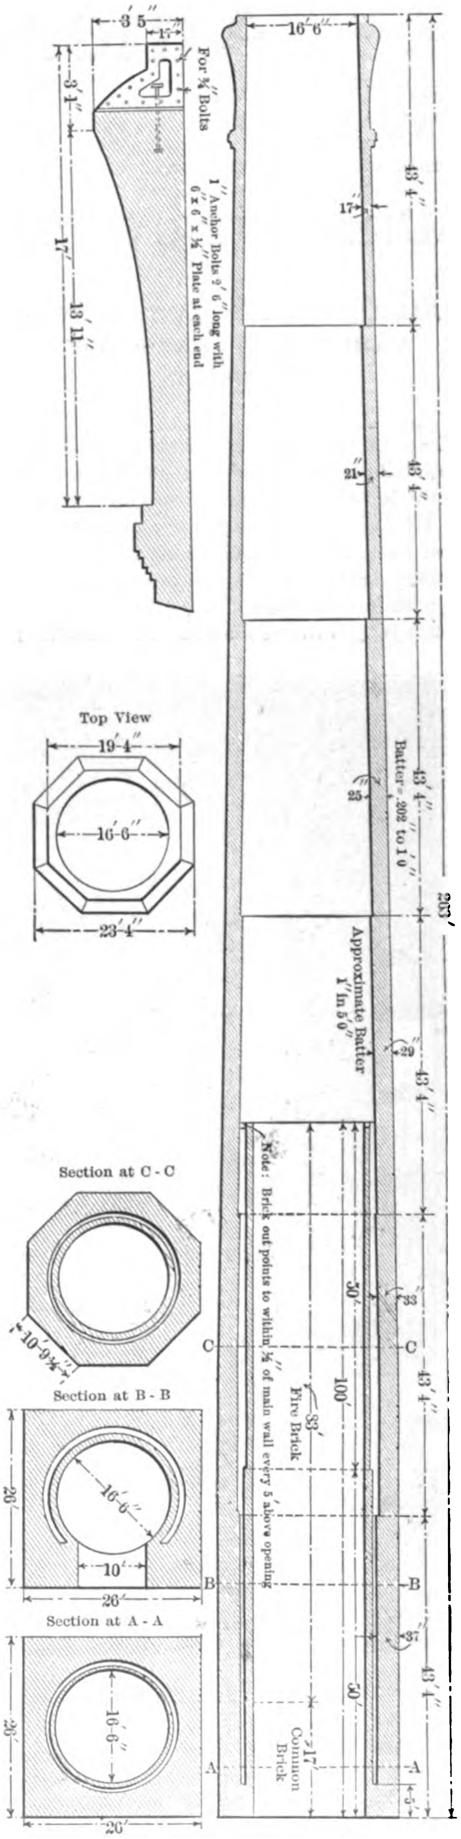

FIG. 3.—DETAILS OF CHIMNEY.

improvement on the old method of synchronizing with lamps. With lamps there is chance for a considerable change in phase without sufficiently dimming or brightening the lamps to make the difference in phase apparent to the attendant who is throwing the machines together. With a synchronizing voltmeter plugged in between two machines that are to be thrown together one may know exactly whether they are in step. The synchronizing voltmeter has a 700-volt scale.

Referring to the diagrams, Fig. 6 shows the connections of the arc and incandescent lighting sections of the board and Fig. 9 shows those of the generator, exciter and power feeder panels. The three bus-bars at the top of Fig. 6 are connected directly to those in Fig. 9 and the same is true of the three leads at the bottom of Fig. 6 marked "To 300-kw. generator," and the three at the bottom of Fig. 9 marked "Leads to Incandescent Lighting Board." These latter leads allow the incandescent circuits to be supplied either directly from the 300-kw. machine or from the general bus-bars. The arc lighting

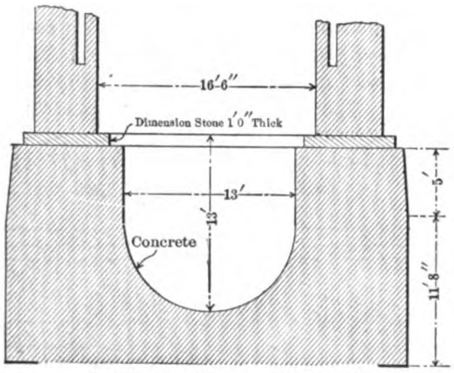

FIG. 4.—SECTION OF CHIMNEY BASE.

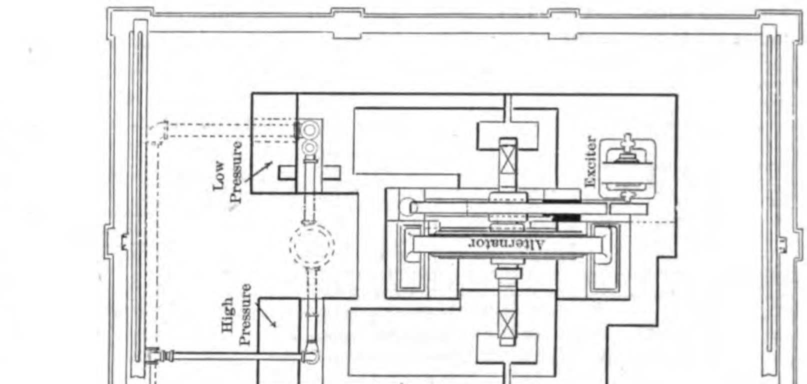

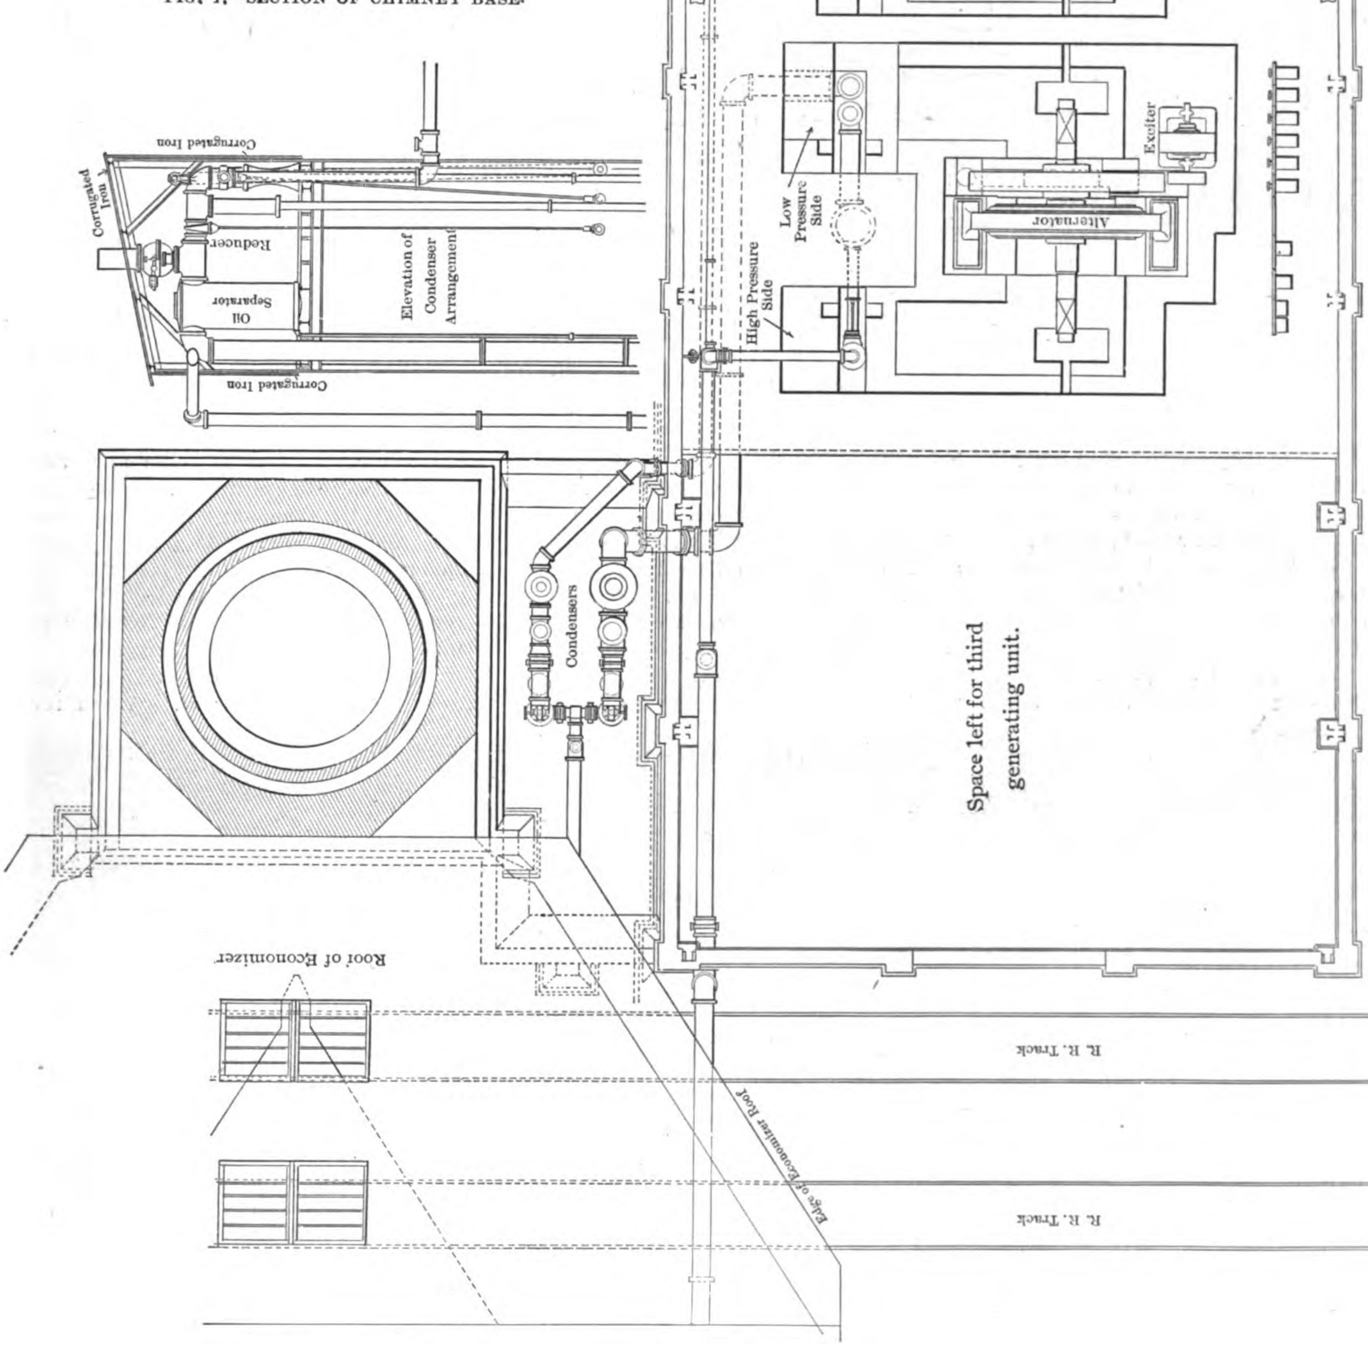

FIG. 5.—PLAN OF THE CHICAGO POWER HOUSE; WITH ELEVATION OF CONDENSER PLANT IN UPPER PART OF ENGRAVING.

transformers are supplied only from the general bus-bars. They are ordinary constant-potential apparatus, of 30 kilowatts capacity each, and were built by the Wagner Electric Manufacturing Company, of St. Louis, Mo.

The generator panels have each an indicator ammeter and wattmeter at the top, a field rheostat, a synchronizing plug for connecting the generator to the synchronizing voltmeter, a voltmeter switch, a main three-pole knife switch, and a 200-ampere field circuit switch. The latter has an arrangement for shunting the field through a non-inductive resistance as soon as the supply circuit is opened. There are six feeder panels for power circuits, each one having an ammeter, a recording wattmeter, and an oil switch, the mechanism of which is behind the board. All the switchboard instruments are of General Electric manufacture with horizontal scales. There is also a panel for the exciter dynamos, shown in Fig. 8.

FIG 6 – DIAGRAM OF SWITCHBOARD CONNECTIONS, LEFT-HAND HALF.

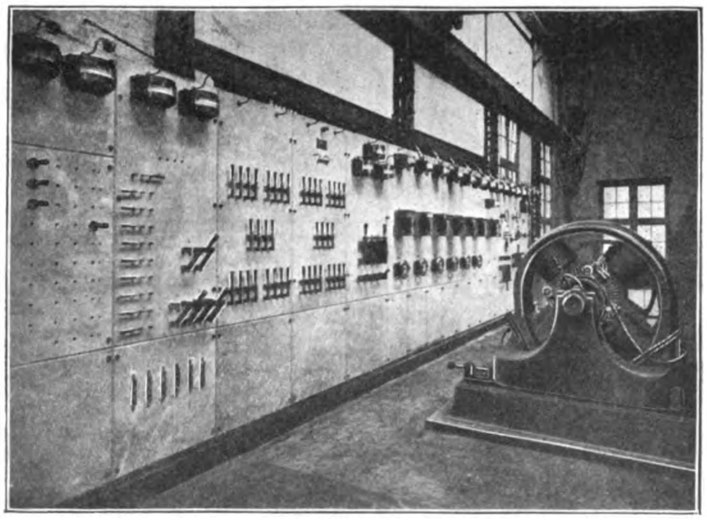

FIG. 7.—ARC LIGHTING AND INCANDESCENT LIGHTING PANELS.

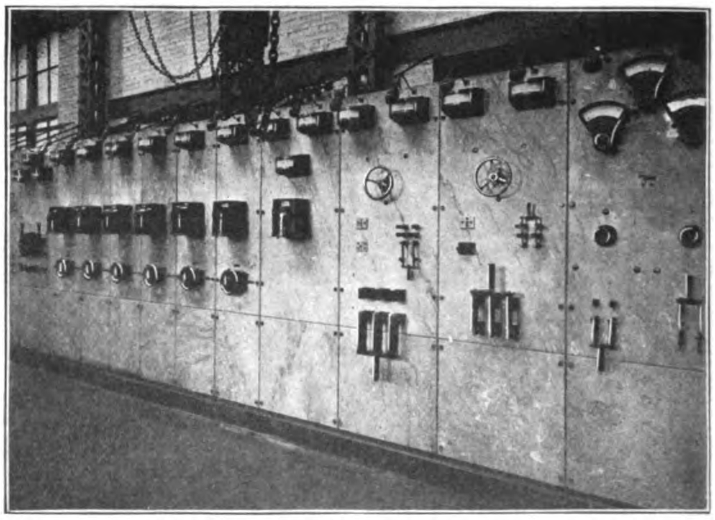

FIG. 8.—FEEDER, GENERATOR AND EXCITER PANELS.

One of the interesting features of the new plant is the extensive use of enclosed alternating-current series arc lamps. Manhattan arc lamps were the ones selected. From each of the three 30-kw. Wagner transformers two arc circuits are run. Each circuit has a Manhattan regulator for maintaining constant current, with varying loads. The principle of this regulator is that of a counter-balanced solenoid in the circuit to be regulated which is drawn down a varying distance over an iron core as the number of lamps in circuit varies. Two circuits are run in parallel off each transformer, and no circuit includes more than 20 lamps. The current is 6.8 amperes. An arc-circuit plug board is provided for the arc circuits so that when not many lights are in use they can be put all on one transformer to avoid running the other transformers underloaded. The arc-circuit boards have voltmeters calibrated to read in lamps and in volts.

The station has connected to it about 1800 horse-power in motors, 10,500 incandescent lamps and 150 arc lamps. It is hardly necessary to enumerate the various uses of these motors, but among the important uses are for conveyors and elevators. All motors are of the constant-speed type, no success having been made of this company's attempt to secure variable-speed polyphase motors. In one case five elevators are driven from one motor.

The wiring around a packing plant is necessarily of high grade. All specifications call for a wire having a white-rubber core, then a layer of best gutta-percha composition, a layer of tape and two braids separately saturated. American Steel & Wire Company's wire has been used. All wires are run on glass or porcelain insulators.

THE ST. JOSEPH PLANT.

The packing plant of the company at South St. Joseph, Mo., is a comparatively new one and has had electric transmission throughout since the start. When the plant was first installed it was the smallest of this company's plants; it has since had a remarkably rapid growth and is now second in size only to the Chicago plant. It is a combination refrigerating and electric power plant. Babcock & Wilcox water-tube boilers are used, half of them being hand fired and the other half, which were recently installed, being fitted with the Green Engineering Company's chain grates. There are two steel stacks, one 166 ft. high and 8 ft. in diameter, the other 166 ft. high and 10 ft. in diameter. Ash conveyors made by the Link-Belt Machinery Company run directly under the ash pits the whole length of the boiler room. An interesting set of tests was being carried on at the time the writer visited the plant, the object of which was to determine which fireman was the most skillful, and incidentally to enable the firemen to intelligently improve the general quality of their work. One boiler was set aside for testing purposes and the firemen took turns firing the test boiler a day at a time; a record of each man's work was kept and posted.

This boiler plant has economizers in the flues, of a type designed by Swift & Company's engineers. The hot water from these economizers is used not only for feeding the boilers, but for the entire packing plant, which requires considerable hot water. The engines of the plant are run condensing, with water supplied from numerous artesian wells, but the discharge from the condensers is all used around the packing house, hence no cooling tower is needed for this. This artesian-well water is all pumped by triplex pumps geared to large Westinghouse two-phase induction motors. The motors were originally geared to the pumps with double-reduction gears, but the noise of the motor gears caused the engineers to discard them. The motors are now belted to the intermediate shafts, and these are geared to the pump shafts.

The power plant now has three electrical units. The first two units consisted of Filer & Stowell engines driving Westinghouse two-phase alternators. One compound-condensing engine with cylinders 14 and 26 ins. in diameter by 36 ins. stroke drives a 180-kw. alternator, and another engine of the same type with cylinders 16 and 30 ins. in diameter by 36 ins. stroke drives a 250-kw. alternator; both engines run at 95 r.p.m. Rope drive is used in this plant on all three units.

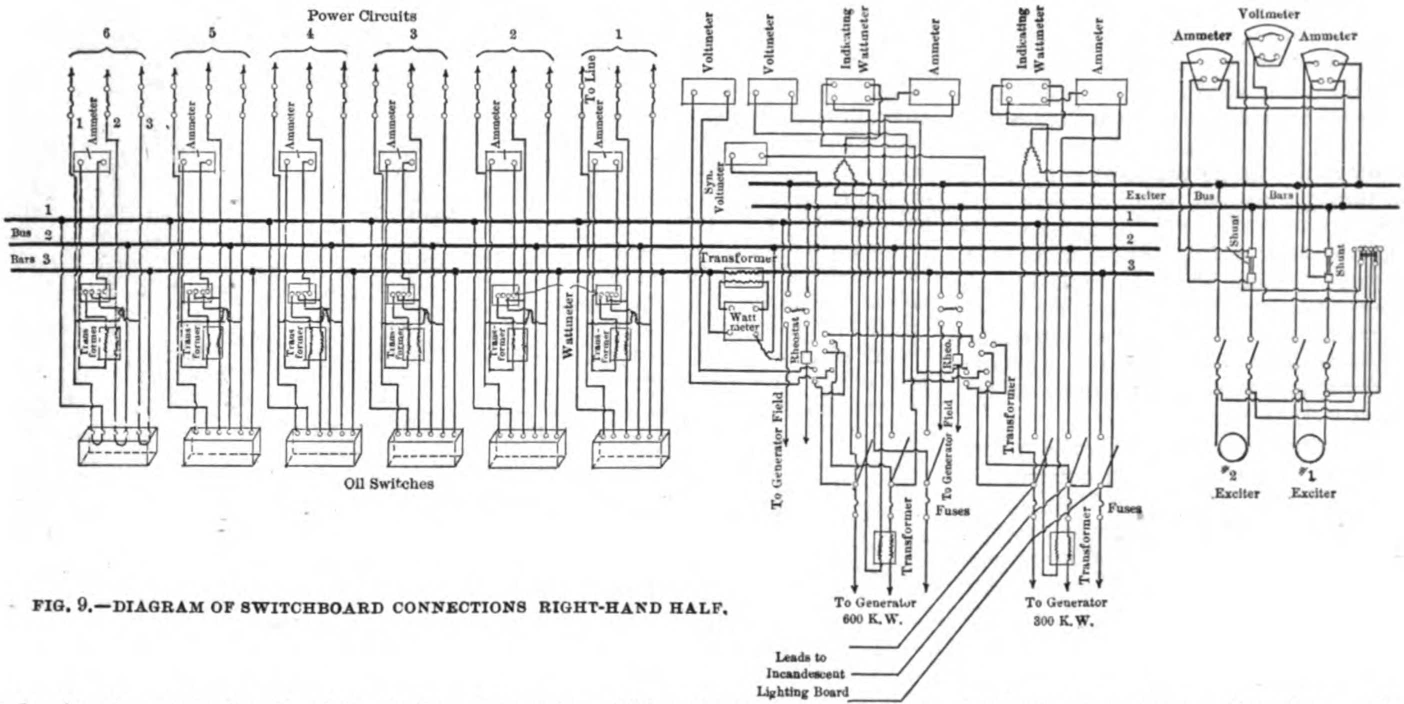

FIG. 9.—DIAGRAM OF SWITCHBOARD CONNECTIONS RIGHT-HAND HALF.

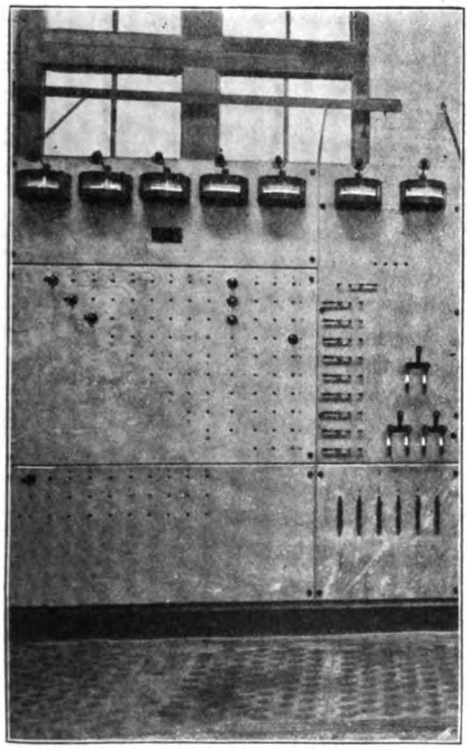

FIG. 10.—ARC-CIRCUIT SWITCHBOARD.

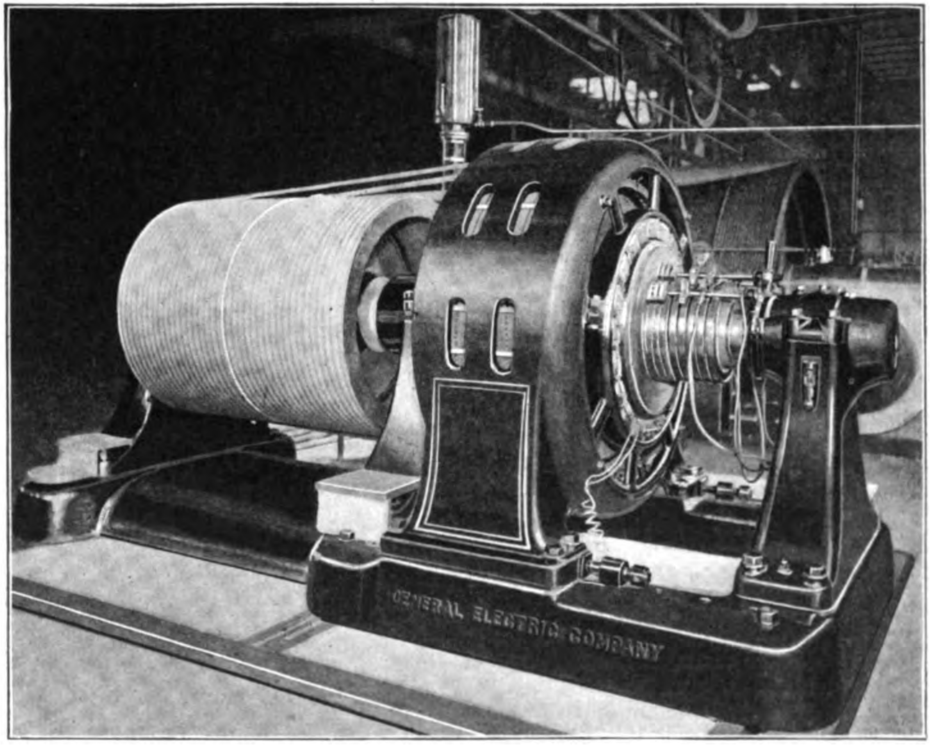

FIG. 11.—500-KW. COMPENSATED-FIELD ALTERNATOR IN ST. JOSEPH PLANT.

The two Westinghouse alternators just mentioned have compounded fields. The latest addition is a Filer & Stowell engine with cylinders 21 and 40 ins. x 42 ins. driving a General Electric 500-kw. two-phase alternator of the new compensated-field type, having the exciter armature on the main shaft between the collector rings and the armature; this machine is shown in Fig. 11. This machine runs at 360 r.p.m.; although of different make and design from the other alternators (being the revolving-field type and the others having revolving armatures), this new machine is run in parallel with the other two. The smallest alternator has a double-throw switch on its panel, whereby it can be thrown onto the lights alone or onto the main bus-bars; thus the lights can be supplied direct or from the main bus-bars. During the day when there is enough power in use to give an economical load to one or two generators it is desirable to run the lights separately on one generator to avoid the fluctuations caused by the power circuits.

The switchboard has a power feeder panel for each one of seven different departments and each one of these panels has a Westinghouse ammeter and recording wattmeter, the amount of power used being charged up against each department. A recording instrument is put in each phase. There are also two recording wattmeters for the total output. There are about 100 motors, aggregating 1000 horse-power, around this plant, and 50 General Electric enclosed arc lamps. The voltage of the plant is 220. An important use of motors is for freight elevators. Some of these elevators are run by a friction device, the motor running constantly. Another interesting type is one in which the motor is geared to the winding drum, like a direct-current motor, and the motor is started and stopped with the elevator. The voltage is reduced with an ordinary transformer to about 140 and the current is thrown directly on at this pressure. The motors are 15-h.p. machines, built for heavy temporary overload and take 36 horse-power at the instant of starting. Although the fluctuation is a drawback, it does away with the constant running of a motor and consequent waste of power with the friction-gear elevator. The control apparatus of the reversing type of elevator is very simple and one of the elevator motors and machines is shown herewith. The movement of the elevator-controlling cable to start the car releases a mechanical brake and turns the motor controller drum to the "on" position. This operation is reversed when the car is stopped.

The plants were both designed and installed by the Construction and Mechanical Department of Swift & Company, and are a credit to all concerned. Mr. H. C. Gardner is manager of these departments, and George M. Brill, now a consulting engineer of Chicago, was assistant manager at the time these plans were designed and installed and gave special attention to this work.

ELECTRICAL ILLUMINATION AND FOUNTAINS AT THE PAN-AMERICAN EXPOSITION.

It was decided at the outset that illumination at the Pan-American Exposition, soon to be opened at Buffalo, should be accomplished exclusively by incandescent electric lamps of 8 candle-power and 16 candle-power; consequently no arc lights, acetylene gas or illuminating gas lamps will be used in the decorative illumination, it being considered impracticable to enter these lights in competition with each other for this class of work. The scheme of lighting at the Exposition will depend for its success on the exceptionally advantageous arrangement of the buildings with reference to the enclosed courts, in the shape of an inverted "T." This makes it possible to obtain a gradual increase of illumination leading toward the stately Electric Tower which stands at the base of the "T," and which is to furnish the climax of the display at night. The number of lights and the quantity of light will exceed that of any other equal area ever artificially illuminated.

It is stated that unusual spectacular effects will be produced by the many combinations of light and water and these combinations are to be so graded as to be in keeping with the decorative lights of the Electric Tower, while the Tower basin will be the stage of the display for electric fountains using 1,500,000 gallons of water an hour and illuminated by a hundred powerful searchlights. The open courts about the grounds are to be illuminated by incandescent lamps mounted on nearly 2000 columns, each carrying from 25 to 100 lamps. Part of these columns will be wired for all-night lamps and others for service only during certain hours of the evening. The staff-covered columns will be 9 ft. high, and columns three times this

FIG. 2.—SYMBOLIC FIGURE ON TOWER.

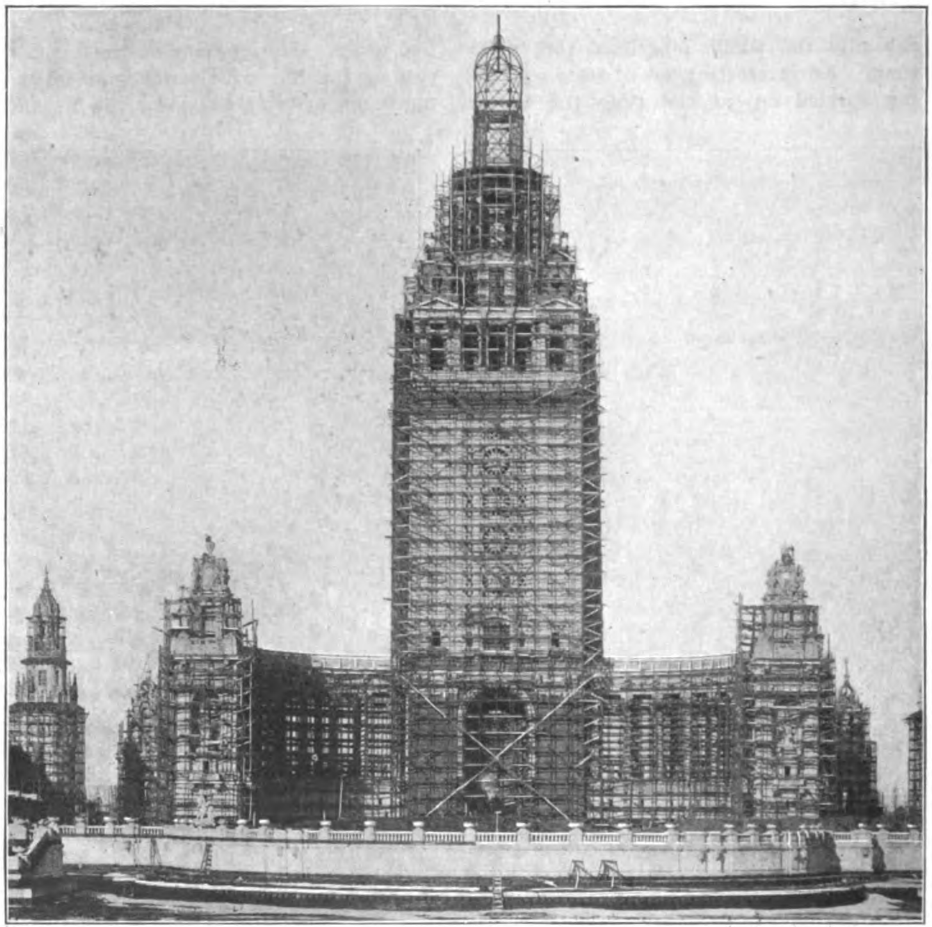

FIG. 1.—ELECTRIC TOWER, PAN-AMERICAN EXPOSITION.

height will be used at each of the entrances to the principal avenues.

Entering the main Lincoln Parkway gate one sees a pretty lake on the right, with banks covered by trees, plants and flowers, lighted by concealed incandescent lamps as in the sunken gardens at the right and left of the forecourt. Over to the left from the bridge may be seen the artistically-arranged artificial rock work of the base of the electric fountain, which is to be nearly 200 ft. long and 100 ft. wide, occupying a central position in a little sheet of water about a fifth of a mile across. The chamber from which the water and lighting effects will be controlled is located below the artificial rock work and the current for operating the various pumps and arc light projectors will be carried by underground cables. The fountain at the North Bay is to be operated only from fifteen minutes to half an hour each evening, but it will be well worth a visit as there will be many color effects which have never before been attempted.

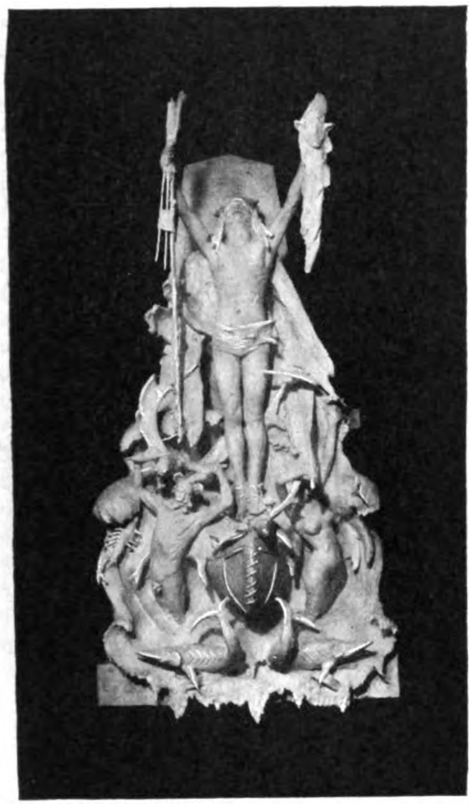

FIG. 3.—SYMBOLIC GROUP ON TOWER.

Nearly a dozen different pumping schemes are to be employed, with water pressures of 50 lbs. and 150 lbs. Westinghouse 500-volt motors will drive two Root pumps, which will supply water at 150 lbs. and 50 lbs. pressure, respectively. The high-pressure pump will supply the "grand geyser," which will throw a stream nearly as large as a man's wrist 250 ft. high, forming the highest jet of the fountain. It will be operated alone and in combination with ring curtains, fog bank, fan jets of various shapes and numerous other designs, such as sheaves of wheat, lilies of pure white and varied colors. Twenty-two orifices will be equipped with 20-ampere Bogue focusing arc lamps specially designed for this purpose.

After leaving the illuminated fountain in the North Bay, the spectacle will increase in grandeur as the visitor crosses the forecourt and bridge and enters the esplanade and Court of Fountains, and the water and light effects will reach a maximum at the Electric Tower. From a point high up in a niche of the tower more than half a million gallons of water an hour will pour out, striking a curved deflector and steel lip and breaking into an immense screen, behind which several powerful projectors will send lights of various hues through the falling sheet of water. There will be 26 pillar jets of changing color, each stream reaching 40 ft. in height, while about 50 other large jets will throw parabolic streams of water into the cascades in front of the tower niche.

The Electric Tower, which is nearly completed, is shown by Fig. 1. Many beautiful pieces of statuary have been prepared for the Tower, one of which is intended to represent "The Great Waters in the Days of the Indians," and is illustrated by Fig. 3. Another piece, shown by Fig. 2, represents "Lake Erie."

The pumping plant will be in the Machinery and Transportation Building; 2,000,000 gals. of water an hour will be required and this will be supplied by a dozen or more Root pumps operated by American, Ames, Fitchburg, Harrisburg, Watertown and other well-known makes of engines, and the motors mentioned above. The fountains will be supplied at 110 lbs. pressure through 16-in. and 20-in. mains, while the intake at the Court of Fountains will be 4 ft. in diameter.

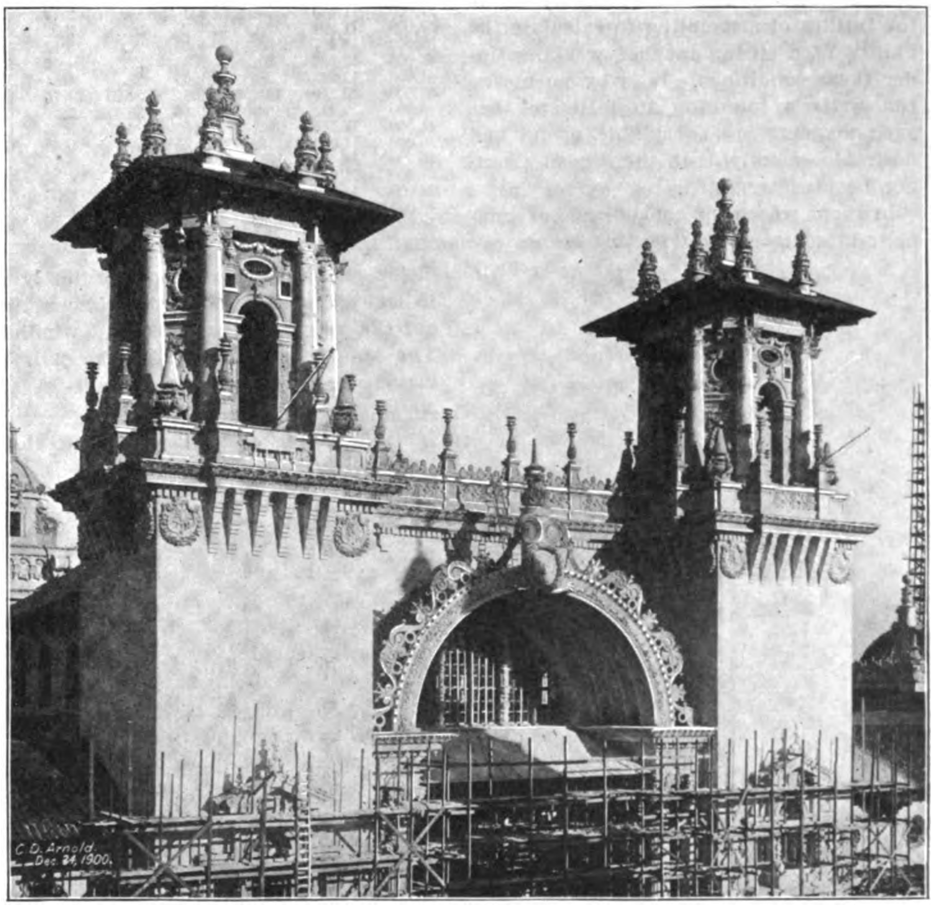

FIG. 4.—COMPLETED TOWERS OF ELECTRICITY BUILDING.

ELECTROMAGNETS AND SOLENOIDS.

In order to construct an electromagnet or a solenoid intelligently, the service which it is to perform must be the prime consideration. This statement may seem trite to some readers, but the fact is that a very large proportion of the electromagnets that one finds in use are built almost without regard to their mechanical functions.

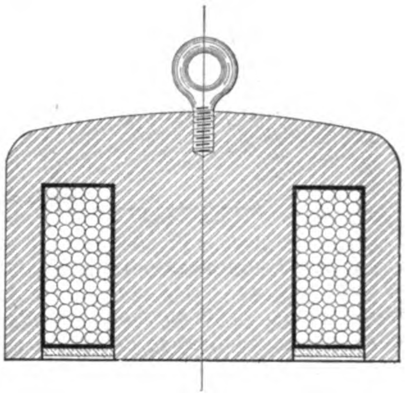

FIG. 1.—IRONCLAD MAGNET.

The subject of electromagnets for lifting such objects as iron plates was so fully considered in recent articles* that there is little left to be said. Such magnets operate under the disadvantage of a variable and indeterminable air-gap reluctance. Unless the surface of the object to be lifted has been planed off, the area of actual contact surface cannot be predetermined, and the magnet must be made many times more powerful than a calculation based on zero air-gap would prescribe. The magnet represented by Fig. 1 herewith and described in Mr. Clark's second article will serve to illustrate this statement. This magnet had a pole-face area of 204 sq. ins. and lifted 24,000 pounds. The magnetic density at the pole-faces required to do this, according to Maxwell's formula for the law of traction, is 108,460 lines per square inch, ignoring leakage.

---

*Lifting Electromagnets, by E. B. Clark, American Electrician for December, 1900, and February, 1901.

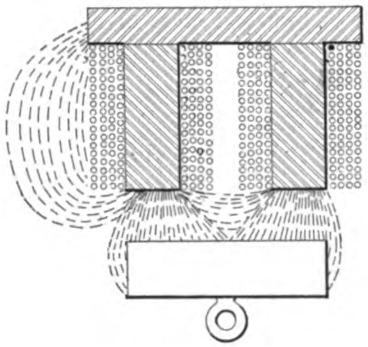

FIG. 2.—ORDINARY MAGNET.

If the plate lifted by the magnet had polar surface and of a cross-section equal to that of the magnet core, the ampere-turns required to produce this degree of saturation would have been from 6000 to 8000, according to the magnetic quality of the magnet core; in actual experiment, however, 37,750 ampere-turns were required. This is sufficient to demonstrate the futility of attempting to calculate the ability of a lifting magnet working under these conditions. It is by no means the writer's intention to intimate that such magnets are not highly useful and desirable—merely that their power cannot be predetermined.

In shops where the convenience of magnetic attachments to traveling cranes can be made to justify the expense of using them for carrying objects of an irregular surface which cannot be picked up without the intervention of an armature, the ability of the magnet can be closely approximated without resort to cut-and-try methods. Tables I and II give the theoretical lifting power of magnets at different pole-face densities, figured on the assumption that the armature touches every part of the pole-face surface. When lifting armatures are employed, this condition can be approximated so closely as to make these tables of value in working out the magnet dimensions and winding. The column which gives the pull in pounds per square inch of pole-face is figured for total pole-face area, not for the area per pole. The columns giving the pull with round cores of different diameters are figured for a single pole; consequently, for a horseshoe magnet the figures should be doubled to get the total pull on the armature.

Where it is desired to operate mechanism by means of an electromagnet, the ordinary form will not suffice unless the range of movement is extremely small, as in the case of telegraph instruments. An inspection of Fig. 2 will show why this is so; when the armature is moved far away from the poles the reluctance of the air-gap becomes so high that a large percentage of the flux leaks back around the outside of the coils into the yoke, and these lines exert no force upon the armature. A point is soon reached where the gap between the armature and the poles is so great that even with the magnet cores fully saturated, only a few magnetic lines go over to the armature, most of them going around the outside of the coils to the yoke; the result is that the pull on the armature is so reduced as to be useless. Hence it is that a magnet of the ordinary type is never employed by intelligent designers for actuating mechanism through a considerable range of movement.

An arrangement most commonly used for this class of work is the solenoid, or magnet coil, with a plunger core, as illustrated by Fig. 3. This is about the worst form possible, from an economical standpoint. The magnetic circuit is composed chiefly of air, and the result is that an enormous expenditure of electrical energy in the winding produces an insignificant amount of mechanical work at the plunger. A much better form is the ironclad solenoid shown by Fig. 4. Here, the magnetic circuit is chiefly iron, so that the efficiency is immensely higher than that of the simple solenoid of Fig. 3. In this construction the solenoid coil is provided with two short tubular cores, one at each end, between which there is an air-gap in the center of the coil. These cores are united on the outside of the coil by an iron shell, so that the only air-gap in the magnetic circuit is that in the interior of the coil where the field is very intense. This makes the air-gap itself use more energy than one in which the field might be more diffused, but as the gap is short, and as the remainder of the magnetic circuit is so much better than that of the old form shown by Fig. 3, the resultant efficiency is higher.

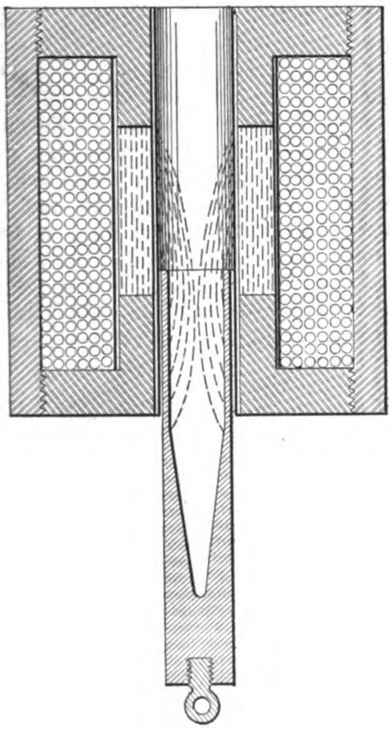

FIG. 4.—IRONCLAD SOLENOID.

It will be noticed that the plunger of this solenoid (Fig. 4) is hollowed out peculiarly. The upper end is tubular with parallel walls for a distance equal to the length of the air-gap between the two sections of the solenoid core. Below this the bore is tapered, until the plunger becomes a solid rod. The object of this arrangement is to make the pull more gradual and extend its range. If the plunger were a straight rod or a tube the pull would diminish very rapidly as soon as the air-gap was bridged by the plunger in its upward movement. With the construction shown, however, each increment of upward movement strengthens the flux and maintains the pull upon the plunger after the air-gap has been bridged. The disadvantage of this type is that it is utterly impracticable to predetermine the strength of the magnetic pull with any degree of accuracy, but it is a highly useful form of solenoid, and the only one yet devised which gives economically a powerful pull over a wide range.

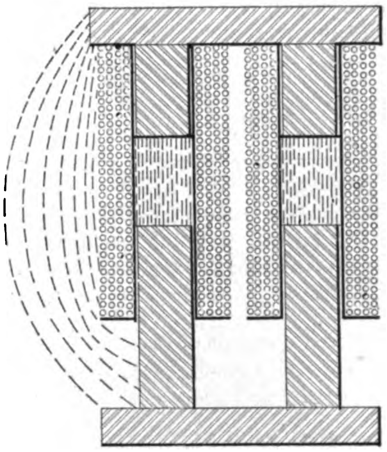

FIG. 5.—DOUBLE "STOPPED" SOLENOID.

A much more manageable design is that of the double "stopped" solenoid, shown by Fig. 5. In this case the tractive force of the magnetic lines is exerted in a straight line directly between the opposing faces of the stationary cores and the movable ones, and as the air-gap is enclosed by the magnetizing coils the amount of waste leakage is almost negligible. When the plungers or movable cores are down, as shown in the sketch, there is considerable leakage of lines of force around the outside of the coils, as indicated by the dotted lines on the left-hand side of the drawing. This leakage flux, however, is by no means wasted, as it joins with the flux which passes through the iron, and contributes to the pull in the air-gap. Moreover, although the exterior leakage renders the calculation of the power of the magnet inaccurate, if it is based simply on the law of magnetic traction, the inaccuracy is in favor of the magnet; that is to say, it will be more powerful than the calculation indicates. For all ordinary purposes, therefore, it will be sufficiently accurate to calculate the pull exerted by such a magnet by means of Maxwell's formula, which is the basis of the tables given.

In applying the fifth column of Table I or the fourth column of Table II to this construction the polar area should be taken as that of both of the cores. The length of the magnetic circuit, of course, will be taken as the total length of both cores plus the length of both yokes from center to center of the cores, for the iron part of the circuit; and the length of the two air-gaps for the air part of the circuit. This form of magnet, however, is inconvenient mechanically in that the armature or movable part of the core must be provided with a guide of considerable length in order that it may slide freely within the coils without binding; otherwise, if the bore of the coils is made to fit the cores snugly, as it should, the slightest tilting will cause the sliding cores to bind.

On this account the form illustrated by Fig. 6 is preferable. This form also possesses the advantage of being entirely ironclad, so that the coil is mechanically protected, and it is somewhat cheaper to construct because there is only one coil to be wound and all of the machine fitting is circular. This arrangement might be termed a "stopped" ironclad solenoid, and like Fig. 5, it is a combination of solenoid and magnet proper. It possesses the advantage of having no magnetic leakage whatever, and only a single air-gap; consequently, for the same range of movement the air-gap will be approximately one-half the length of the air-gap in the double-coil type shown in Fig. 5.

There is a small constant air-gap between the plunger and the iron disc through which it moves, but this can easily be reduced to 1/64 in., and constitutes an almost negligible part of the total air-gap. The pull exerted by this form of magnet can be predetermined with sufficient accuracy for practice by the application of the law of traction, and consequently by means of the accompanying tables. For operating mechanisms where a graduated pull is of not so much consequence as a good strong initial pull, and where the range of movement is reasonable, as in the case of a semaphore signal, for example, this type of magnet is

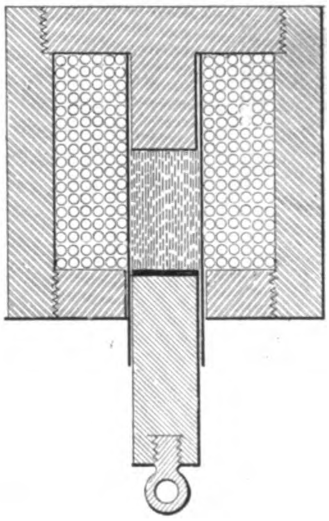

FIG. 6.—"STOPPED" SOLENOID.

probably the best of any of the existing forms.

When applying either this form or that of Fig. 5 to service in which the plunger is to be drawn solidly against the stationary core, the face of the plunger should be covered with a thin sheet of non-magnetic metal, such as brass or copper, so that when the circuit is broken the plunger will fall promptly. It might be well to call attention also to the fact that in the case of any magnet the power of which is considerable, and which is thrown into and out of circuit, the coil should contain in addition to the exciting winding a short-circuited winding for eliminating the inductive effect due to the sudden opening of the circuit. Where the magnet is constantly in circuit, however, and merely responds to variations in current strength, such an arrangement is usually not necessary.

Fan Motors for 1901.

The approach of warm weather brings the fan-motor industry to the fore again, and in accordance with the custom established by this paper four years ago, we publish herewith descriptions of the standard machines of this class that will be offered for the coming season. Not many changes are apparent since last spring, so far as essential features of construction are concerned; as stated last year, these little machines are practically standardized and their design has reached a point beyond which no radical improvement seems commercially practicable.

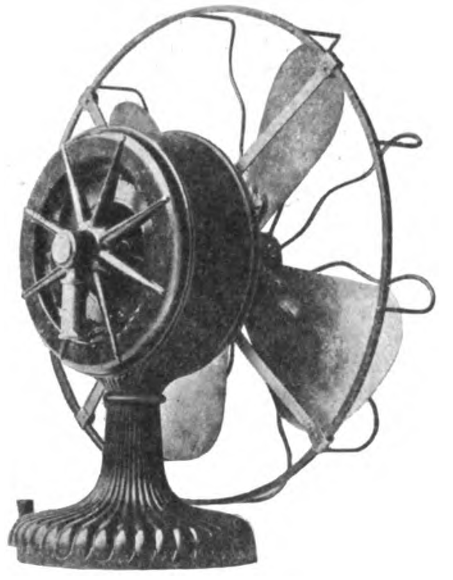

FIG. 1.—WESTINGHOUSE ALTERNATING-CURRENT FAN MOTORS.

The Westinghouse Company has retained the induction type of motor for alternating-current circuits which was built last year, only a few improvements applied to minor details having been practicable. The machine is illustrated by Fig. 1, and the rotor is shown by Fig. 2. The field magnet is of course laminated, the field ring being provided with inwardly projecting teeth to which the field winding is applied. The rotor is of the usual squirrel-cage type, the conductors being bare copper rods threaded through holes in the core without insulation. The bearings are self-oiling and self-aligning, and the oil chambers hold sufficient oil to run through an entire season. The fan is 13 ins. in diameter with four blades. A two-speed switch is provided in the base of the motor. The motors are built for either 60 or 133 cycles.

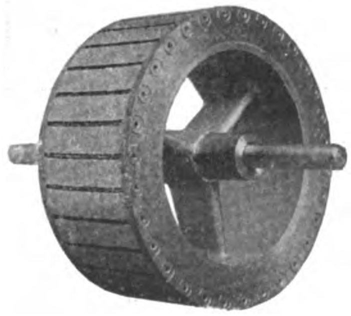

FIG. 2.—ROTOR OF WESTINGHOUSE ALTERNATING-CURRENT FAN MOTOR.

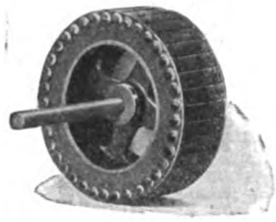

FIG. 3.—G. E. SQUIRREL CAGE ARMATURE.

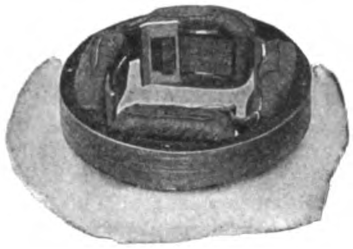

FIG. 4.—G. E. ALTERNATING-CURRENT FIELD.

The General Electric alternating-current desk fan motor, shown by Figs. 5-7, is also an induction machine with a squirrel-cage armature, and the rotor conductors, like those of the Westinghouse motor, are put in without any insulation whatever. The rotor is illustrated by Fig. 3, and Fig. 4 shows the field magnet used in this machine. The field structure is laminated, as usual, and provided with four physical poles, each pole carrying an exciting coil and a short-circuited shading coil, the function of the latter being to split the magnetic flux into two phases, and give the necessary starting torque.

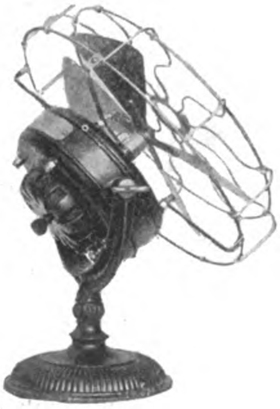

FIG. 5.—G. E. ALTERNATING-CURRENT DESK-FAN MOTOR; REGULATING COIL IN THE BACK OF THE CASE.

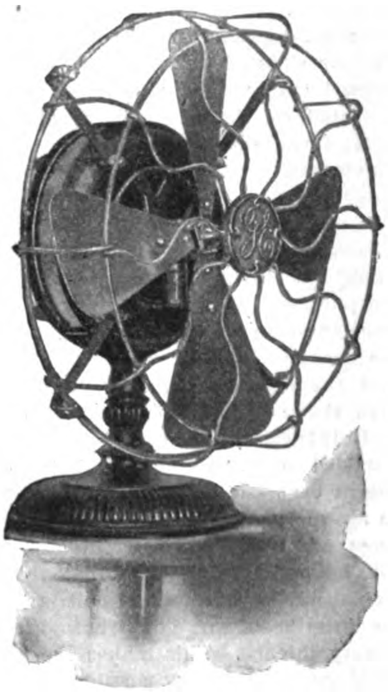

FIG. 6.—G. E. ALTERNATING-CURRENT FAN MOTOR.

The field magnet structure is usually built up complete, as shown in Fig. 4, before insertion in the casing of the motor. Speed regulation is obtained by means of a reactive coil mounted in the back of the motor casing, as shown in Fig. 5, which also illustrates the trunnion style of mounting. There are two running speeds, namely, 1150 and 1550 r.p.m. The 12-in. fans require 68 watts at full speed and 51 watts at slow speed. These machines are built for 60, 125 and 133 to 140 cycles, and for 52, 100 to 108, and 108 to 115 volts; special motors are also built on demand for 220 volts. Fig. 7 represents the bracket form of mounting, in which the reactive coil is contained in the base of the bracket.

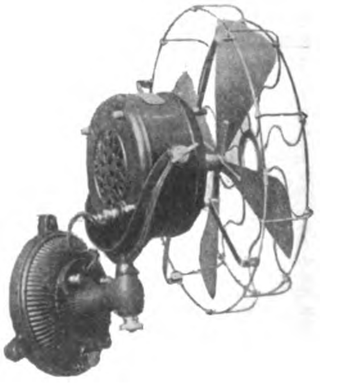

FIG. 7.—G. E. ALTERNATING BRACKET MOTOR; REGULATING COIL IN WALL BRACKET.

Fig. 8 represents a compensator which is provided whenever necessary for the purpose of using a motor built for one voltage on a circuit of different voltage. The compensator consists of an auto-transformer with two pairs of binding posts, one pair for 52 volts and the other pair for 104 volts. Its use obviously enables a 52-volt motor to operate on a 104-volt circuit, or a 104-volt motor to operate on a 52-volt circuit. When the fans are to be attached to thin partitions the flexible mounting shown by Fig. 10 is supplied. This consists merely of an ornamental bracket from which the motor is hung by springs in order that the humming of the machine may not be transmitted to the partition. The motor is provided with a 10-in. fan and a strap switch is mounted on the wall plate of the bracket.

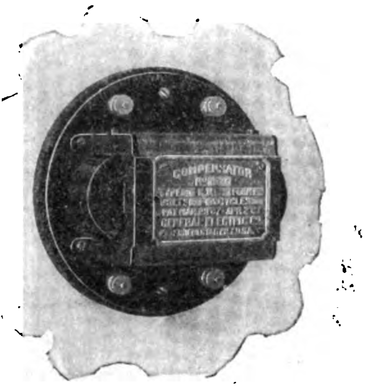

FIG. 8.—G. E. FAN MOTOR COMPENSATOR.

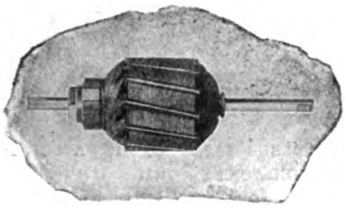

FIG. 9.—G. E. DIRECT-CURRENT ARMATURE.

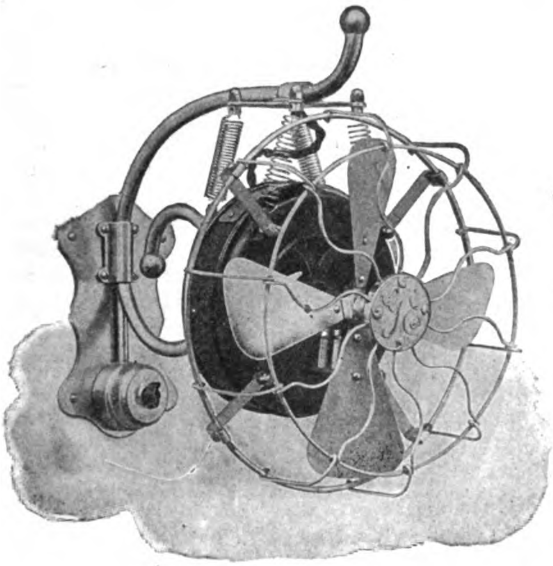

FIG. 10.—G. E. SUSPENSION FOR SMALL FAN MOTORS.

The field magnet of the General Electric direct-current fan motor is a laminated structure built up and having its coils mounted on the poles before insertion in the case of the machine, the same as in the alternating-current motor; Fig. 12 shows this construction. The armature, which is shown by Fig. 9, is of the ordinary drum-wound type with the core discs twisted so as to give a sort of spiral or diagonal direction to the slots, the object of which construction is to eliminate the humming due to the abrupt entrance and exit of the teeth into and from the magnetic field. The brushes are carbon pencils of rectangular cross-section and are fed to the commutator in the usual manner by brass spring-actuated pressure equalizing fingers. The general external appearance of the direct-current fan is shown by Fig. 11. The body of the fan is elliptical in outline and entirely enclosed, removable shields serving to shut in the commutator and brushes. These fans have three speeds, 900, 1200 and 1600 r.p.m., respectively. The power required at full speed by the 12-in. fan is 53 watts, at medium speed 38 watts, and at slow speed 30 watts. The motors are built for the usual direct-current voltages.

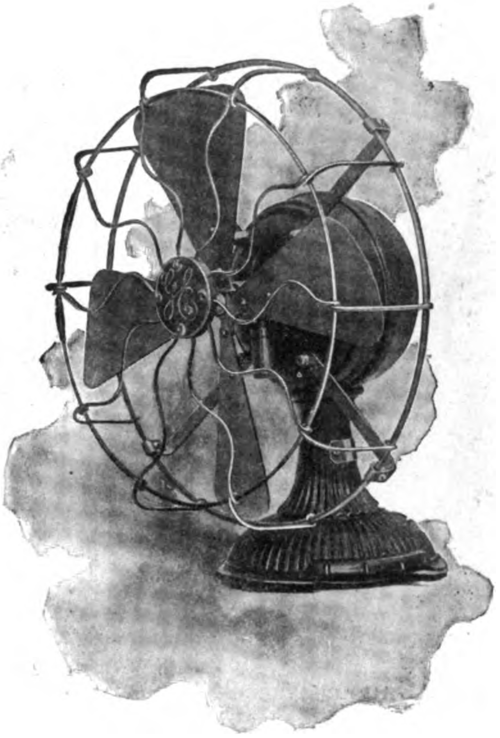

FIG. 11.—G. E. DIRECT-CURRENT FAN MOTOR.

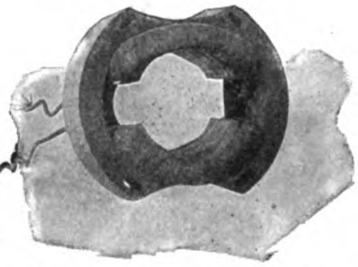

FIG. 12.—G. E. DIRECT-CURRENT FIELD MAGNET AND COILS.

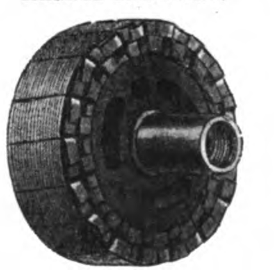

FIG. 13.—ARMATURE OF EMERSON DESK MOTOR.

Another efficient induction type of fan motor is that built by the Emerson Electric Manufacturing Company. Fig. 14 represents the standard Emerson model for 60-cycle circuits, and Figs. 13 and 15 show the construction of this machine. The field magnet has four poles, and each pole carries two windings, one of the ordinary form embracing the entire pole and the other a "shading" winding which is wound on only half of the pole, a slot in the center of the magnet pole piece being provided for this purpose. The function of the shading winding is the same as that of the short-circuited shading coils in the General Electric alternating-current fan motor previously described. The rotor is of the squirrel-cage type, but the conductors are flat copper strips instead of the usual round bars, this construction

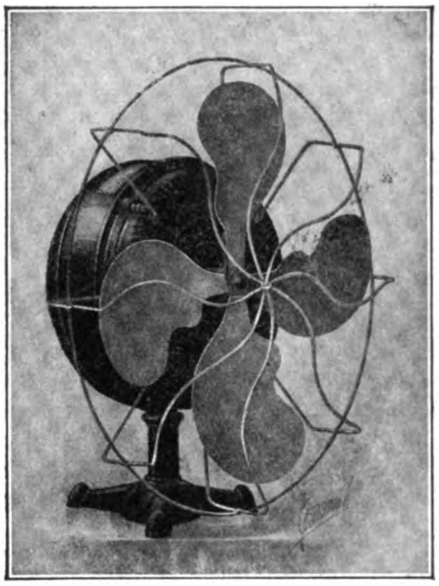

FIG. 14.—EMERSON DESK FAN MOTOR.

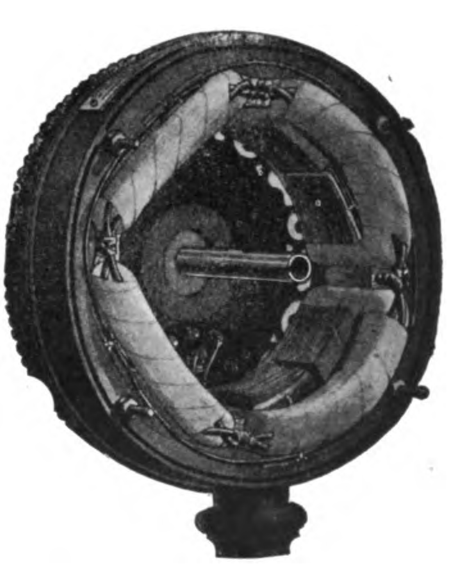

FIG. 15.—INTERIOR OF EMERSON DESK FAN MOTOR.

being necessary in order to obtain the requisite number of conductors and at the same time give the rotor core sufficient cross-section without making its diameter abnormally large. This type of fan is built for either 60 or 133 cycles. In the 133-cycle motors the armature conductors are round rods instead of the type shown in Fig. 13.

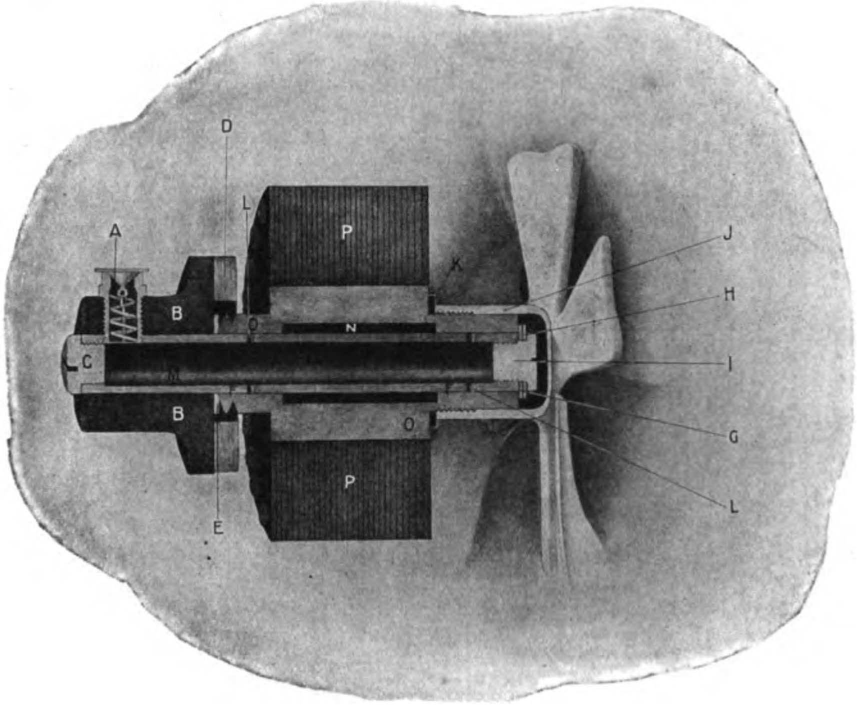

FIG. 16—SECTION OF EMERSON DESK FAN ARMATURE.

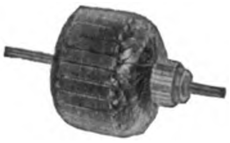

FIG. 17.—ARMATURE OF LUNDELL ALTERNATING-CURRENT MOTOR.

Fig. 20 illustrates the Emerson "Special" model fan motor in bracket form, which is new this year. Its mechanical construction is identical with that of the standard model. The rotor conductors, however, consist of round copper rods like those in the rotor of the 133-cycle standard model. The type of field winding employed is new, however, and is said to give the machine a higher degree of efficiency than that previously obtained. Fig. 16 shows a cross-section of the armature and bearing of the special model for 60 cyles. The armature spindle, M, is hollow and stationary, being permanently secured to the hub, B, which forms a part of the back cover of the machine. The armature core, P, is mounted on a central hub, O, which revolves about the stationary shaft, M. Oil is supplied to the hollow spindle through the cup or well, A, and delivered to the bearing surfaces through the oil holes, L. In addition to the oil, a supply of lubricant is provided in the chamber, N, between the two bearings, which is sufficient to last throughout the season. The throwing of oil is prevented by the felt washer, D, at one end, and the cap, J, which constitutes the hub of the fan at the other end. The hollow spindle is closed by the plugs, C and I. The bearing for the standard model is precisely like that just described, except as to the manner of applying the fan hub. In the standard model the fan hub screws into the armature hub instead of on the outside of it. The 12-in. special fan motor requires something less than 55 watts at full speed and gives a stronger breeze than the motor previously built, which used 65 watts. The weight of the machine has also been reduced, its net weight being 17 lbs. The power factor of the new motor is very high, the machine driving a 12-in. fan at 104 volts requiring less than ¾ ampere. The special model fans are built for 60-cycle circuits only.

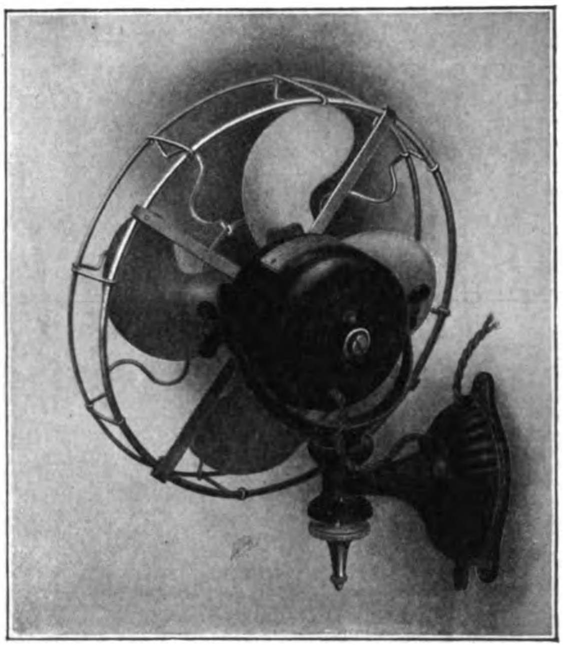

FIG. 20.—EMERSON "SPECIAL" MODEL FAN MOTOR, BRACKET FORM.

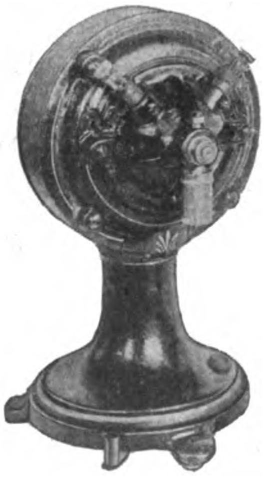

FIG. 18.—LUNDELL ALTERNATING-CURRENT DESK FAN MOTOR.

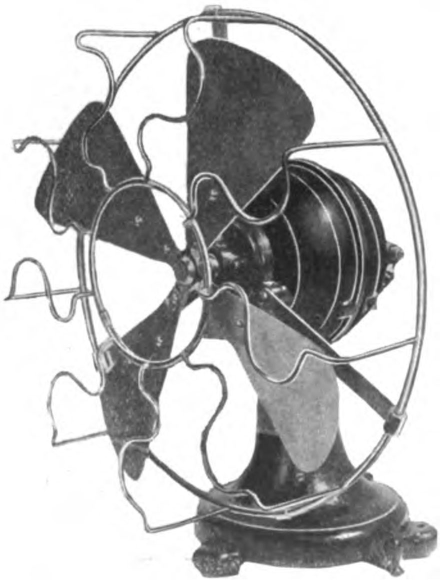

FIG. 19.—LUNDELL DIRECT-CURRENT FAN MOTOR.

The Lundell alternating-current desk fan, built by the Sprague Electric Company, is shown by Fig. 18. It has an eight-pole field and a composite-wound armature, one winding consisting of eight coils close-circuited on themselves, and the other of an ordinary drum winding connected to a commutator. The field magnet is an ordinary simple winding of eight coils connected in series with the commutator brushes. The motor starts up as an ordinary series-wound machine, and as it approaches synchronism the short-circuited armature windings convert it into a single-phase induction motor. The impetus given to the armature by this winding carries it up to synchronous speed, at

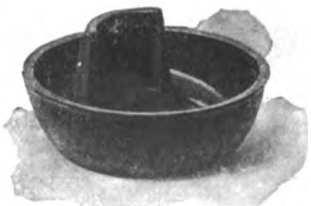

FIG. 21.—LUNDELL FIELD-MAGNET FORGING.

which point the current in the drum winding is rectified, turning the armature core into a revolving field magnet excited by a pulsated direct current. The relation between the revolving and stationary members then becomes that of a synchronous motor. The stationary member, which was originally the field magnet, being energized by alternating current, now fulfills the function of a synchronous motor armature, while the revolving part constitutes the field magnet. Fig. 17 illustrates the armature of the machine.

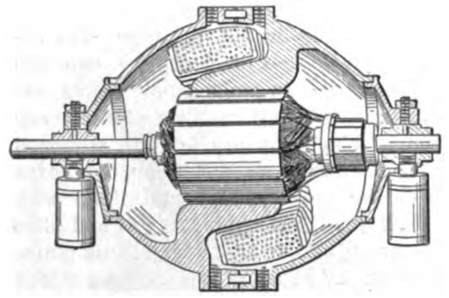

FIG. 22.—SECTION OF LUNDELL DIRECT-CURRENT MOTOR.

The Lundell direct-current fan motor, illustrated by Fig. 19, is of the familiar concentric field-coil type characteristic of the well-known Lundell power motors. A cross-section of the machine is shown by Fig. 22, from which it will be clear that the field coil, while concentric with the armature, is tilted, so that its transverse plane is not parallel with that of the armature. The object of the tilting will be evident from an inspection of the engraving. The field magnet is made in two halves, each half being drop-forged to the shape shown by Fig. 21. The two halves when assembled form the complete field magnet, and are held in alignment by a circular feather, shown at the top and bottom of the structure in Fig. 22. The field magnet is held together axially by a circular plate and two screws fitted to a boss on the top of the shell and a similar arrangement at the bottom. The construction of the magnet allows the armature to be inserted and withdrawn without dismantling the main structure at all. It is only necessary for this purpose to remove one of the end caps which carry the bearings. The oiling arrangement is of the wick type invented by Mr. Lundell. A slight change has been made in the arrangement of the wick so that it will feed the last drop of oil in the cup.

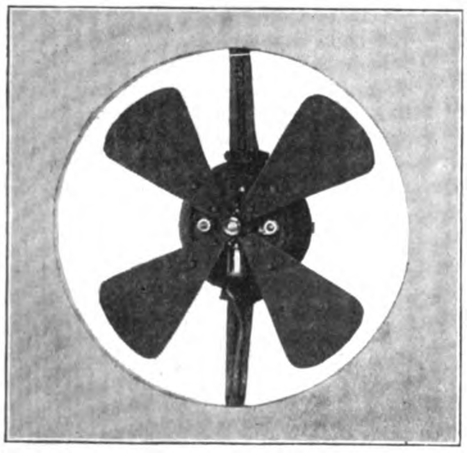

FIG. 23.—LUNDELL MOTOR FOR VENTILATING SERVICE.

In the base of the motor is the regulating rheostat, which gives the motor three speeds. At the maximum speed a 12-in. fan requires .45 ampere at 115 volts. The brush-holders and brushes are of the plunger type, comprising carbon pencils housed in metal cylinders and pressed against the commutator by small coiled springs. The metal cylinders are mounted in insulating bushings located in lugs on the end cap. Fig. 23 shows a Lundell motor adapted for ventilating service. The machine illustrated is an ordinary fan motor mounted in an opening on two brackets. The opening in which the fan blade revolves is cut in a board which is of such size as to fit in an ordinary window casement, rendering any special fitting unnecessary.

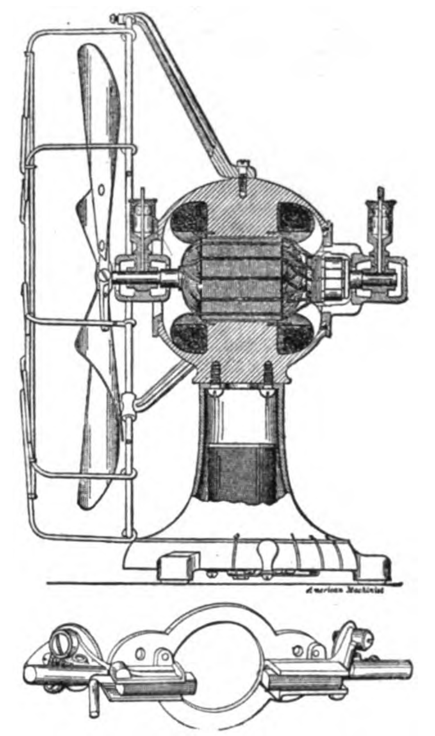

FIG. 24.—SECTION OF HURRICANE MOTOR AND THE BRUSH HOLDERS.

Fig. 25 illustrates the Hurricane direct-current desk fan motor, which, like the Lundell machine, has a spherical contour. The internal construction, however, is very different, as the cross-sectional view given by Fig. 24 will show. The field magnet is cast in a single piece; it is bipolar and has circular openings diametrically opposite each other, through which the field coils and the armature may be inserted and removed. Fig. 24 shows the brush-holder arrangement; flat carbon brushes are used and these slide in slots in the metal portion of the brush-holders. The brush-holders proper are screwed to a piece of fiber which has the shape of a discoidal ring with diametrically-opposite wings. The hole through the center of the fiber ring is just large enough to permit the commutator to project through. The brushes are pressed toward the commutator by coil springs and plungers in tubular housings, the plungers having pins projecting at right angles which impinge against the rear ends of the brushes. The object in using this arrangement instead of allowing the ends of the plungers to press directly against the ends of the brushes is to enable one to withdraw the pressure of the springs from the brushes and leave the brushes free for removal without removing the tubes containing the plungers and springs.

Though the brush-holders are screwed to the wings of the fiber piece above mentioned, they are not mechanically supported by it when in position on the motor but are bolted to the frame of the motor and serve to support the fiber plate between them. The opening in that side of the motor frame toward the commutator is not strictly circular, but has an outline corresponding precisely with the outline of the fiber piece attached to the brush-holders. This is necessary in order to permit the insertion of the field coils; slots on each side of the circular aperture being provided for this purpose.

The cross-sectional view, while illustrating the motor construction, does not illustrate the adjustable feature of the base. Referring again to Fig. 25, a short lever will be seen projecting at right angles to the pedestal. By raising this lever a ball and socket joint at the top of the pedestal is loosened, allowing the adjustment of the motor in a horizontal plane to any angle within a range of 180°, and the tipping of the motor upward or downward to any angle within a range of 30°. Pressing the lever downward tightens the ball and socket joint. Goldmark & Wallace are the general agents.

The Holtzer-Cabot desk fan, Fig. 26, belongs in the same constructional class as the Hurricane machine. The field magnet is spherical, except for the flattened surfaces where the end caps are fastened on, and is a single casting of soft steel. The magnet is bipolar, as the illustration

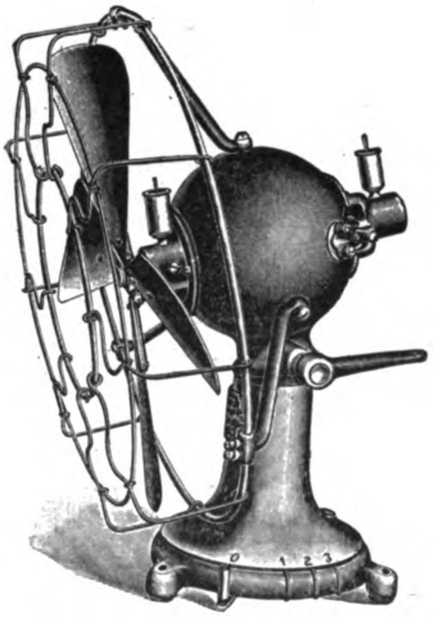

FIG. 25.—HURRICANE DIRECT-CURRENT DESK FAN MOTOR.

plainly shows, and the field coils are inserted through the round openings and held in place by a brass ring which presses against both the upper and lower coils and prevents their accidental displacement. The armature is of the usual construction, having a laminated core and drum winding. The end caps are simple discs of iron in which are cast the grease cups, so that no separate parts are required and there are consequently no joints to render leakage possible. The journal caps can be rotated into any one of four positions so as to bring the grease cup above the bearing, no matter whether the motor be used on a desk, screwed to a wall, or mounted on a ceiling. The bearings proper are of phosphor bronze, self-aligning.

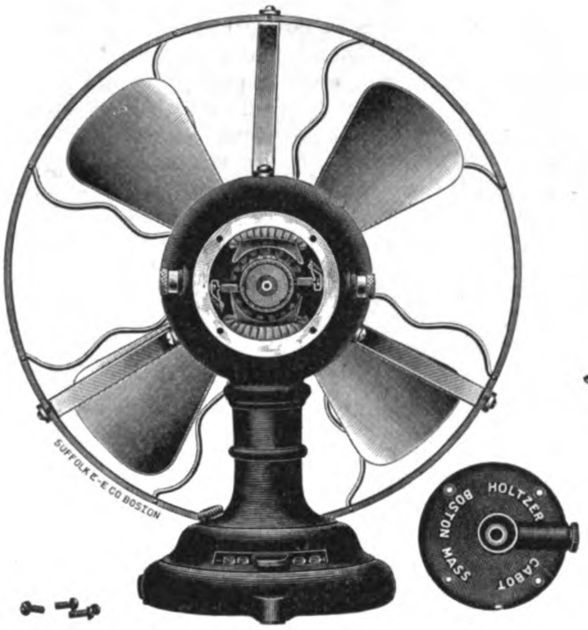

FIG. 26.—HOLZER-CABOT DESK FAN.

The brush-holders are unusually efficient without being at all complicated. Fig. 27 shows a brush and brush-holder full size and the construction will be obvious at a glance. The tension of the spring gives practically uniform pressure throughout the life of the brush; the slot through which the tension finger moves is closed at the front end of the brush-holder so that the finger cannot come in contact with the commutator in case the machine should be used without attention until the brush is worn down sufficiently to drop out. The brush-holder may be readily removed from the case by merely loosening the nut and turning the button (which holds the brush-holder to the end of the insulating plug) at right angles to its normal position. A four-speed rheostat is mounted in the base and the connecting cord is fastened to terminals on the inside of the base, so that there is no danger of their becoming short-circuited or of the user receiving a shock. Fig. 28 shows a Holtzer-Cabot fan with a special mounting for suspension from the ceiling. This machine is provided with a worm adjustment for tilting it to any desired angle.

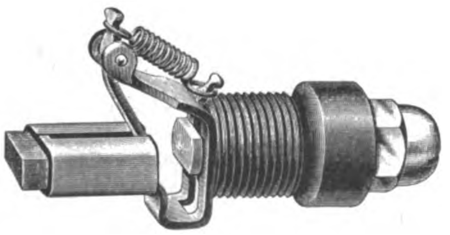

FIG. 27.—HOLZER-CABOT BRUSH HOLDER.

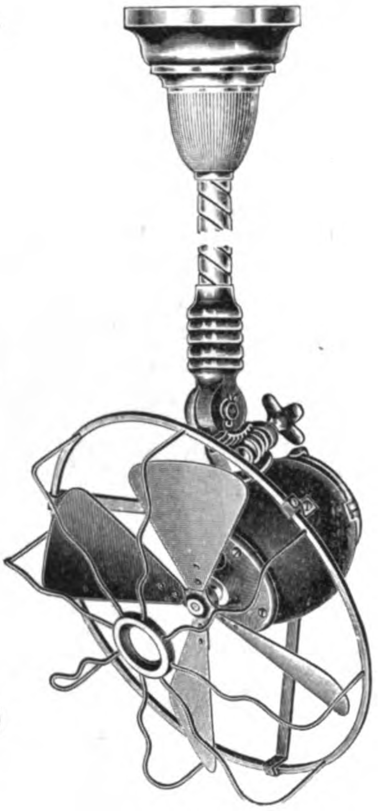

FIG. 28.—HOLZER-CABOT CEILING SUSPENSION FAN.

The Western Electric Company has retained the horseshoe form of field magnet which has characterized its desk fans for the past few years and has given excellent results in practice. Fig. 29 is a view of the 12-in. desk fan, and Fig. 30 is a cross-section of the machine. The field magnet is of wrought-iron drop forged, and is secured to the pedestal by means of the single bolt, E. The armature is of the usual drum-wound construction, the wires being wound in slots. The armature is entirely enclosed by two end caps bolted to the magnet pole-pieces, except for two small openings in one cap through which the brushes are admitted to the commutator. The journal boxes are of the self-aligning type, lined with the best quality of babbitt metal and oiled by means of wicks, as the engraving plainly shows. A detail of the bearing which is of considerable importance is the arrangement of the tube through which the lubricating wick passes up to the shaft. This tube screws into the under side of the journal sleeve, so that the wick does not come in contact with the seat of the sleeve and oil cannot leak out at that point. The wick tube also serves to keep the sleeve in position both angularly and laterally, while allowing it to align itself with perfect freedom. The brushes are of specially-prepared graphite fed to the commutator by means of coiled springs.

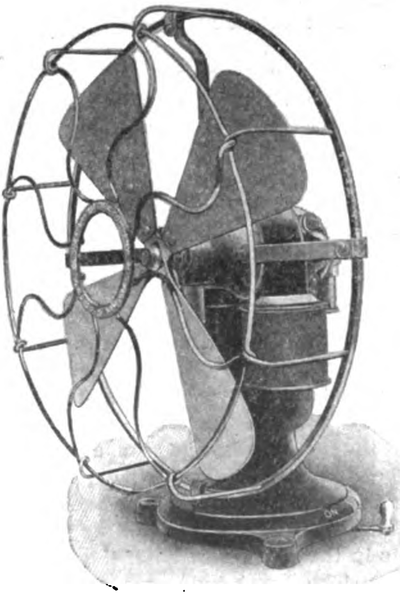

FIG. 29.—WESTERN ELECTRIC DESK FAN.

A three-speed rheostat is put in the pedestal with the switch handle projecting beyond the base. The rheostat consists of German silver wire wound upon a porcelain spool, insulated with asbestos and mica, and mounted on a porcelain base. These machines are wound for the usual direct-current voltages, and the 220-volt and 500-volt motors are designed to be

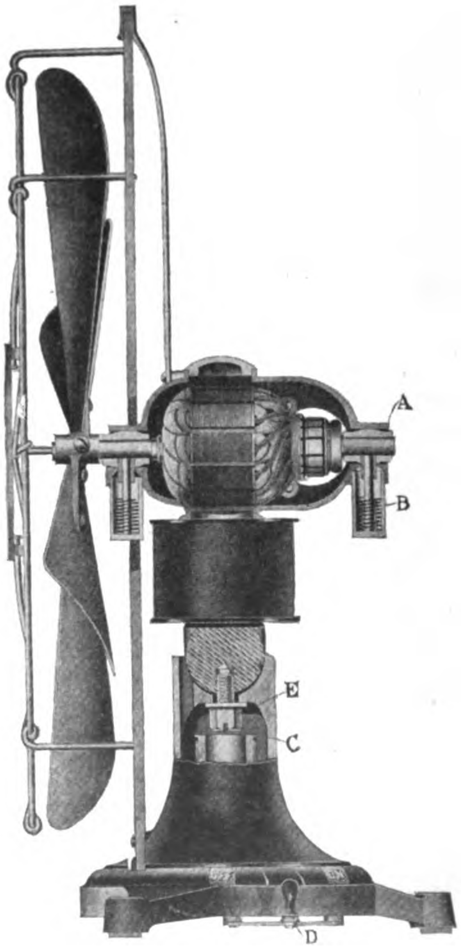

FIG. 30.—CROSS SECTION OF WESTERN ELECTRIC DESK FAN.

connected directly to the service wires without the use of any dead resistance to cut down the voltage. The 500-volt machines, in addition to the regulating switch, are provided with a double-pole quick-break switch. The current consumption of these machines at full speed is 0.36 ampere at 110 volts, 0.2 ampere at 220 volts, and 0.11 ampere at 500 volts. The speed is 1800 r.p.m., with the exception of the 110-volt motor, which runs at 1875 r.p.m.

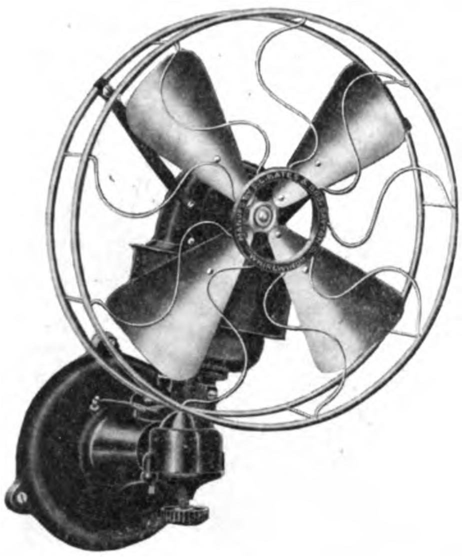

FIG. 31.—BATES DIRECT-CURRENT DESK FAN.

The Bates direct-current desk fan, illustrated by Fig. 31 is similar in general construction with the fan motor just described, the field magnet being of the bipolar inverted horseshoe type, provided with end caps screwed to the pole-pieces so as to enclose and protect the armature and commutator. The magnet core is forged steel. The engraving shows the bracket form of motor with universal adjustment, but the machine is, of course, built also in the usual pedestal form for desk service. The current consumption of the 12-in. 110-volt fan is 31 watts, and the maximum speed is 1900 r.p.m. The 16-in. size requires 60 watts and runs at 1600 r.p.m.

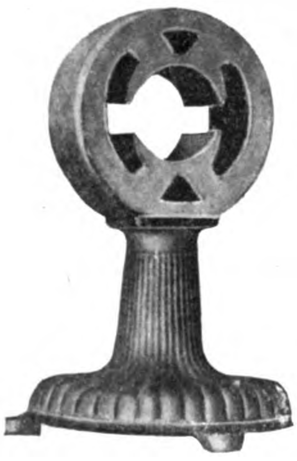

FIG. 32.—"ECLIPSE" FIELD MAGNET.

Still another fan motor having a bipolar horse-shoe field magnet is the Peerless, illustrated by Fig. 34, and built by the Warren Electric & Specialty Company. The field magnet is a steel drop-forging of high magnetic permeability; the field coils are wound on fiber spools, protected by a heavy layer of insulating material and enclosed in brass jackets. The armature of this motor is wound with double silk-covered wire, and the commutator segments are cut from hard-drawn copper bar. The bearings are of the usual self-aligning type made from a high grade of gun metal, and lubricated by means of a wick oil cup of the usual form. The brushes are of the carbon pencil plunger type mounted in brass tubes. The Warren Company also builds a fan motor of the enclosed field type in two forms, one of which is illustrated by Fig. 36. The machine illustrated is not adjustable on the pedestal, and runs at only one speed. The 12-in. 110-volt fan runs at 1650 r.p.m., and requires ½ ampere. This fan is known as Type G. The same type of field magnet is used in an adjustable fan known as Type E, in which form the motor is mounted on trunnions, for vertical adjustment, and has also a horizontal swivel adjustment. The Type E fan moreover has a rheostat and switch in the base, which give it three running speeds, while the Type G machine has no speed adjustment.

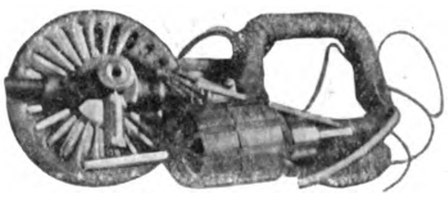

FIG. 33.—PARTS OF "ECLIPSE" MOTOR.

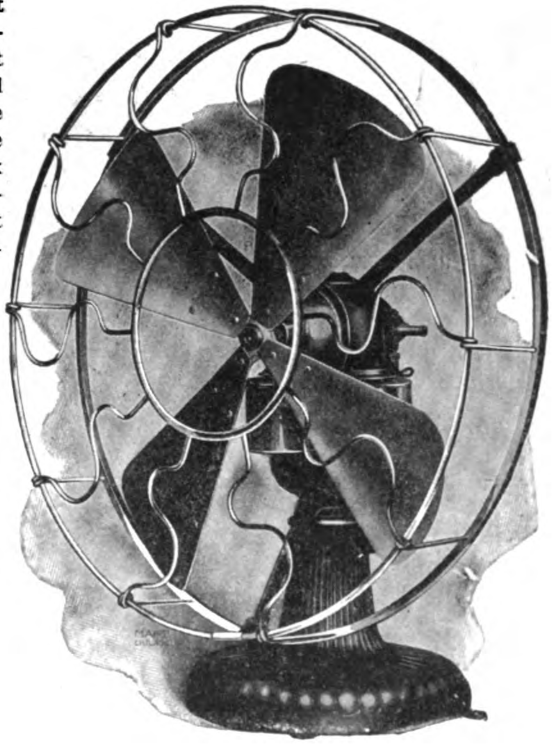

FIG. 34.—PEERLESS DESK FAN MOTOR.

An attractive form of enclosed motor, known as the "Eclipse," has been brought out this year by the Geo. C. Towle Manufacturing Company. Fig. 35 represents this fan with trunnion adjustment, and Fig. 32 illustrates the field magnet construction of the same motor but mounted solidly on the pedestal. The other parts of the machine are shown in Fig. 33. The illustrations show the electrical and magnetic features of construction so clearly as to render a description unnecessary. The machine has self-oiling and self-aligning bearings with wick feed, and is provided with a rheostat which gives it three running speeds, namely, 1000, 1600 and 2000 r.p.m. These motors are built for 110, 170, 220 and 250 volts, and are made in both the pedestal and bracket forms. The motor may be entirely dismantled by removing two bolts which hold both of the end caps in position.

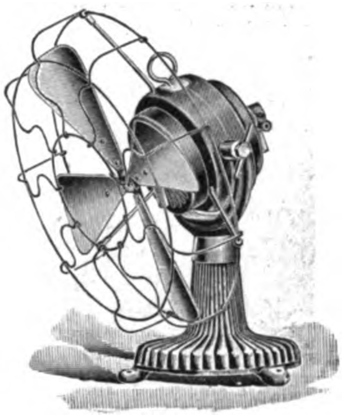

FIG. 35.—"ECLIPSE" DESK FAN MOTOR.

The Paragon desk fan motor for direct-current circuits is illustrated by Fig. 37. The characteristic Paragon form of field magnet has been retained, but the general appearance has been made more graceful by a slight change in the outline. It is of the bipolar type cast in a single piece. The armature and commutator are as-

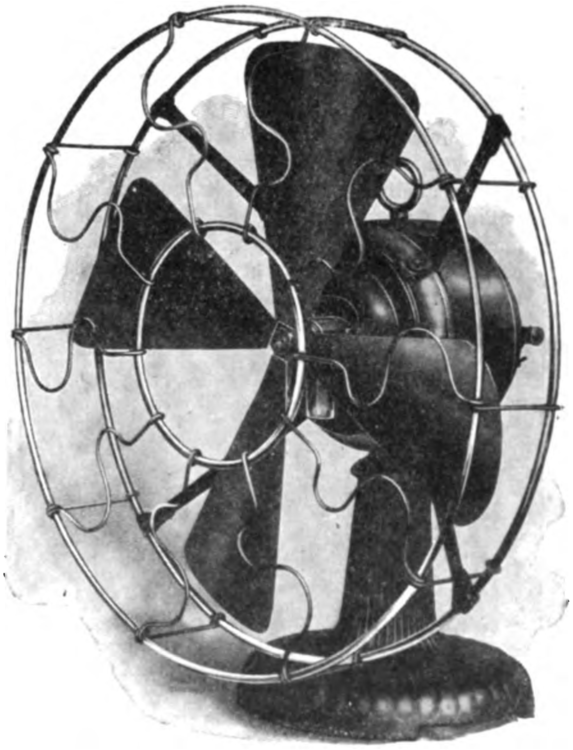

FIG. 36.—PEERLESS ENCLOSED-FIELD FAN MOTOR.

sembled under high pressure on brass tubes, which are headed over at each end, riveting the parts permanently in position. The brushes are of the pencil plunger type, but are made of rectangular cross-section so that they cannot turn in the holders and thus alter the area of the commutator contact. The brushes are mounted in insulating plugs in one of the end caps. The bearings are self-aligning, and of the wick-feed type. The wick is mounted, however, in a slightly different manner from that usually employed, being provided with a retaining tube which prevents it from buckling and insures its being always pressed firmly against the shaft by its spring. Fig. 38 illustrates the bracket form of mounting, which is of the searchlight trunnion type. The pedestal fans are also provided with this style of mounting when desired. The fans take 35 watts at 110 volts and 44 watts at 220 volts.

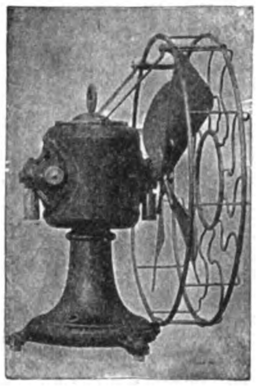

FIG. 37.—PARAGON DESK FAN MOTOR.

The Diehl direct-current desk fan motor is illustrated by Fig. 40; it will be noticed that the Paragon desk motor previously described is very similar to this one in external appearance. The chief difference in construction lies in the method of providing access to the interior of the field magnet case. Instead of using end caps of the ordinary type, the field magnet shell is divided vertically just beyond the magnet poles, and the smaller portion of the shell takes the place of the ordinary end cap. The brush-holders are mounted in this part of the machine, and the rear bearing is made integral with the field magnet shell, there being no opening at the back end, except the hole in the journal for the reception of the shaft. The field magnet is bipolar and the coils are, of course, form wound. The armature is wound with double silk-covered wire. The bearings have self-aligning bronze sleeves and self-feeding wick oil cups. The illustration shows a universal joint between the pedestal and the motor, which provides for adjustment of the air current. This machine is also built in bracket form.

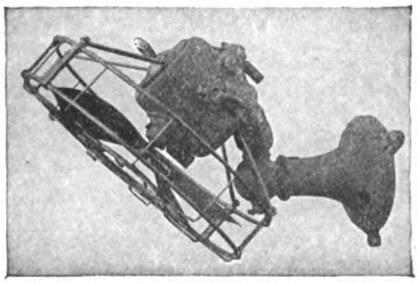

FIG. 38.—BRACKET MOUNTING OF PARAGON MOTOR.

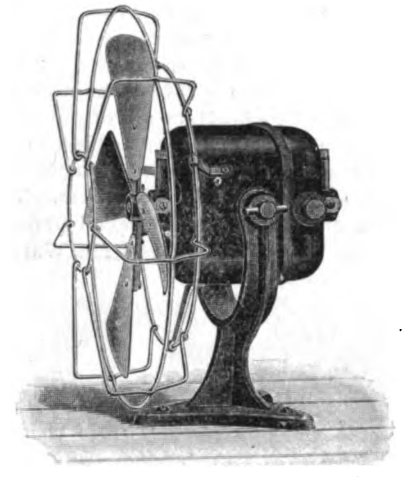

FIG. 39.—TRUNNION MOUNTING OF A DIEHL DIRECT-CURRENT MOTOR.

A later type of Diehl motor is shown by Fig. 39. In this machine the field magnet shell is split at the side distant from the fan, and the commutator and brushes are located at that side of the machine. The engraving shows the trunnion or searchlight mounting, but the machine is supplied with either ball and socket joint or a rigid pedestal. The trunnion mounting has the advantage that one machine may be used either for desk service or as a bracket motor; turning the fork through an angle of 90° serves to convert it into a bracket machine. In this type of motor also the oil cups are placed on top of the bearing, instead of beneath it, as in the type shown by Fig. 40.

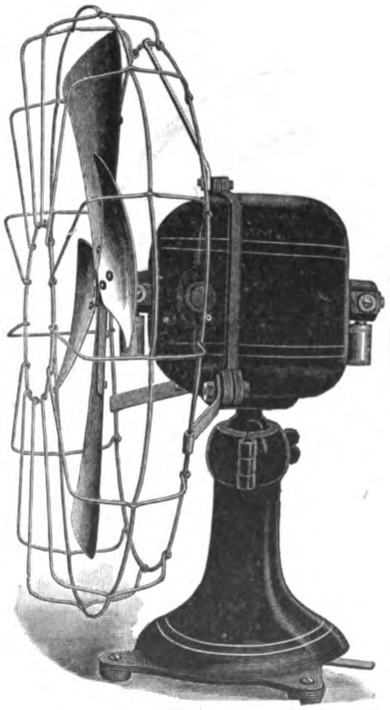

FIG. 40.—DIEHL DIRECT-CURRENT FAN MOTOR.

Fig. 42 illustrates the Falcon desk fan motor for direct-current circuits. This motor is of the familiar enclosed bipolar type with a ball and socket universal joint between the motor and the pedestal. The pedestal is provided with screw holes so that the machine may be converted into a bracket motor by simply turning the pedestal up at right angles with the vertical plane of the motor, and screwing the base to the wall. The motor case entirely encloses the armature, except for a small opening in each of the end caps. The case is split horizontally and held together with screws, the heads of which are sunk in slots in the side of the case. The armature may be removed, however, by taking off one of the end caps. The brushes are of the self-feeding carbon-pencil type, and the bearings are self-oiling with wick feed. The speed-regulating rheostat in the pedestal gives the machine three running speeds. The 12-in. fan requires 0.45 ampere at 115 volts, and 0.25 ampere at 220 volts. Three sizes of this fan motor are built, namely, 12-in., 15-in. and 18-in. fans.

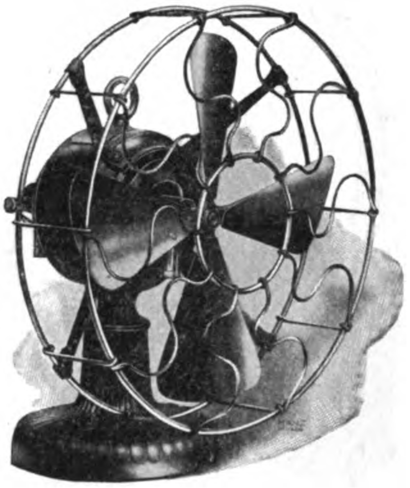

FIG. 41.—COLONIAL DIRECT-CURRENT FAN MOTOR.

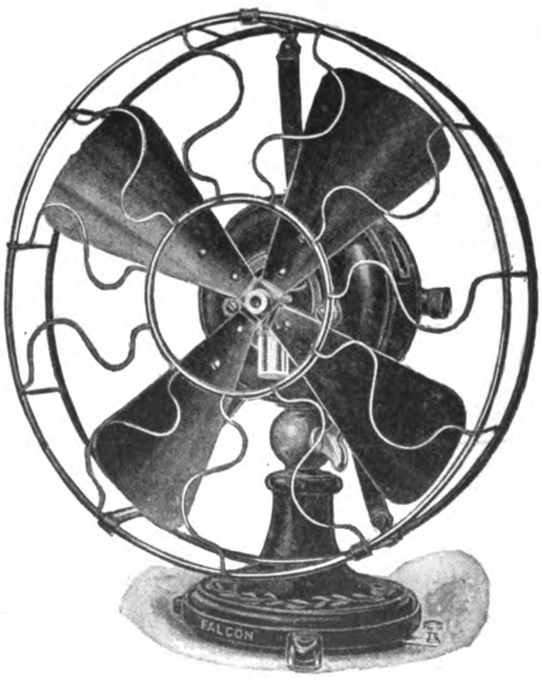

FIG. 42.—FALCON DESK FAN MOTOR.

The Colonial direct-current desk fan (J. Jones & Son), shown by Fig. 41, is of somewhat similar design, but the field magnet shell is cast in a single piece, the end cap being made large enough to permit the insertion and removal of the field coils, as well as the armature. It is a bipolar machine with the familiar form of carbon-pencil brushes and wick-oiling bearings. The bearings are of composition brass and self-aligning. The removal of two screws is sufficient to take the fan apart and give free access to the interior of the field magnet. This machine is also built in bracket form and is wound for 110-volt and 220-volt circuits.

Fig. 48 illustrates the Dayton Standard ceiling fan for direct-current circuits, and Fig. 45 is a cross-section of the motor which is a bipolar machine with peculiarly-constructed pole-pieces. The armature is a Gramme ring, supported from one side only, so that the pole-pieces may embrace three sides of the armature core. This arrangement obviously reduces the magnetic reluctance in the air-gap to an extremely low figure, and makes the field in which the armature rotates a very powerful one. The magnet coil is divided into two sections, this arrangement being necessary on account of the passage of the spindle through the center of the magnet. The armature is mounted directly on the ornamental cup which forms the lower part of the motor casing, and has a single bearing of the revolving shell type. The portion of the case marked B serves as an oil reservoir, and the cup, H, in the fan-blade hub catches the lubricant, and prevents its being thrown out by the blades.

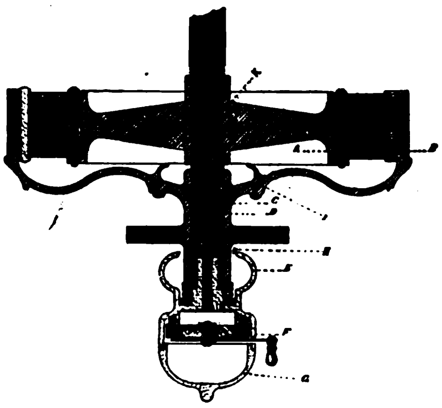

FIG. 43.—SECTION OF DAYTON ALTERNATING-CURRENT FAN MOTOR.

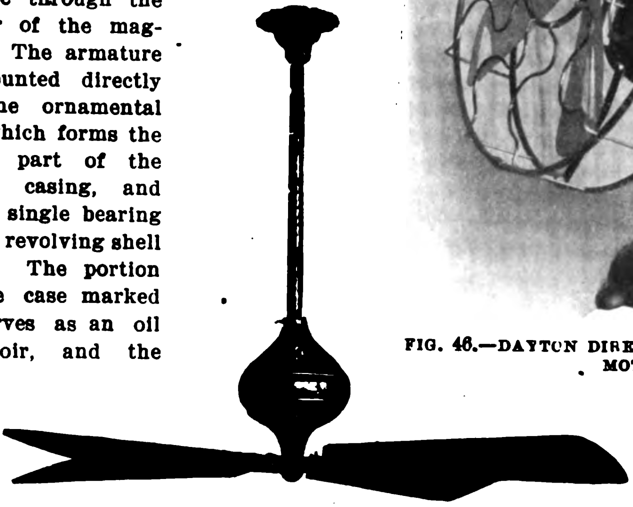

FIG. 44.—DAYTON, "JUNIOR" CEILING FAN MOTOR.

The Dayton Junior ceiling fan is illustrated by Fig. 44, and a cross-section of this machine is shown by Fig. 47. The field magnet is of the ordinary bipolar type and the armature is drum wound in slots. In this machine the armature shaft rotates within its bearing in the usual manner, and the lower part of the casing, B, serves as an oil reservoir, from which oil is fed to the lower end of the shaft and caught by the cup in the fan-blade hub. The upper end of the shaft is lubricated from the oil chamber, J, the drip from the bearing being caught by the cup, I, mounted on the armature shaft. The brushes are of the carbon-pencil or cartridge type, and the holders are mounted in the upper casing, as the engraving plainly shows.

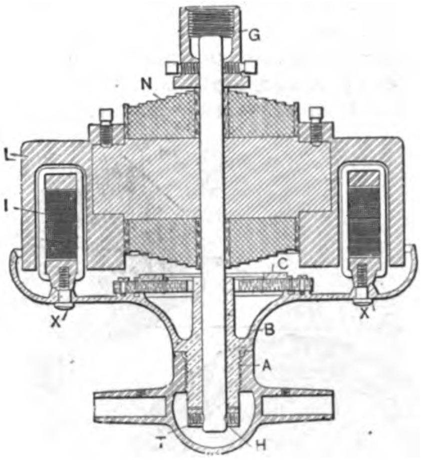

FIG. 45.—DAYTON CEILING FAN MOTOR.

The Dayton alternating-current fan, a cross-section of which is shown by Fig. 43, is a very simple machine. It has an internal field magnet or stator, A, into the center of which is fitted the stationary spindle, D. The rotor, B, is mounted on the lower casing, J, and this is provided with a bearing somewhat similar to that of the standard Dayton machine. It is also equipped with a ball bearing to take the downward thrust due to the weight of the revolving part. Fig. 46 illustrates the Dayton direct-current desk motor, which is similar in construction to the Junior ceiling fan motor, the only difference being that the machine is made shorter along the shaft, and the bearings are of the usual type employed in desk machines. The motor is provided with a trunnion or searchlight mounting, and is supplied for 110-volt, 220-volt or 250-volt circuits. The 12-in. machine consumes 44 watts on a 110-volt circuit.

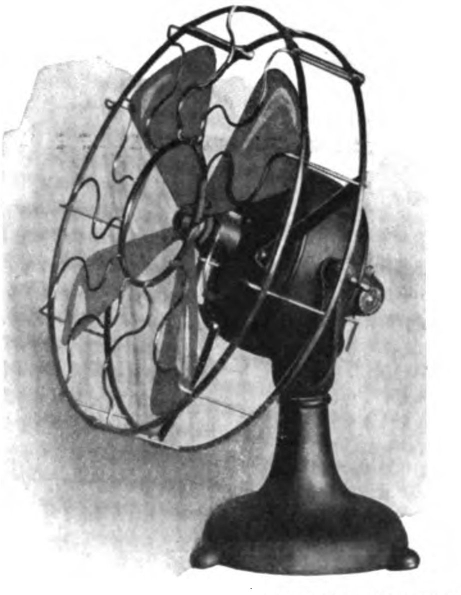

FIG. 46.—DAYTON DIRECT-CURRENT DESK FAN MOTOR.

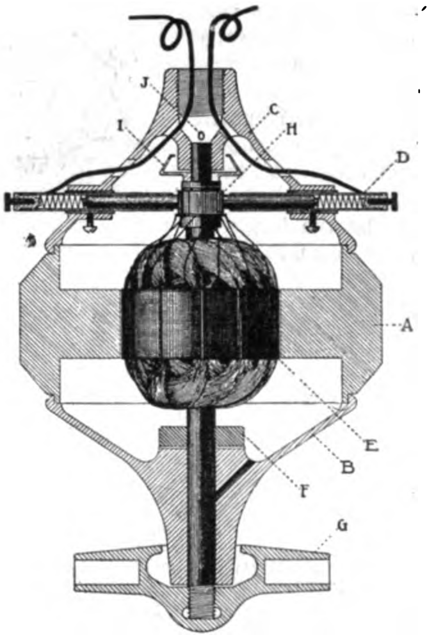

FIG. 47.—DAYTON, "JUNIOR" CEILING FAN MOTOR.

A cross-sectional view of the Western Electric Standard ceiling fan for direct-current circuits is given by Fig. 49. The motor is a bipolar machine, and the cross-section shown is taken at right angles to the vertical plane of the magnet poles. The armature is drum wound in slots, with the commutator located below it. The bearings are of a somewhat unusual type for a ceiling machine. The upper bearing is oiled by means of a wick from the side in the same way as the bearing of a horizontal motor, a cup or pan on the shaft serving to prevent the leakage of oil onto the armature. Immediately above this oil pan there is a small hole through the side of the shaft, which is hollow. The oil passes, therefore, from the upper bearing through the shaft to the lower bearing, H, and after lubricating this bearing it is caught by the cup formed in the upper part of the fan-blade hub, L. A heavy oil is used for lubricating the motor in

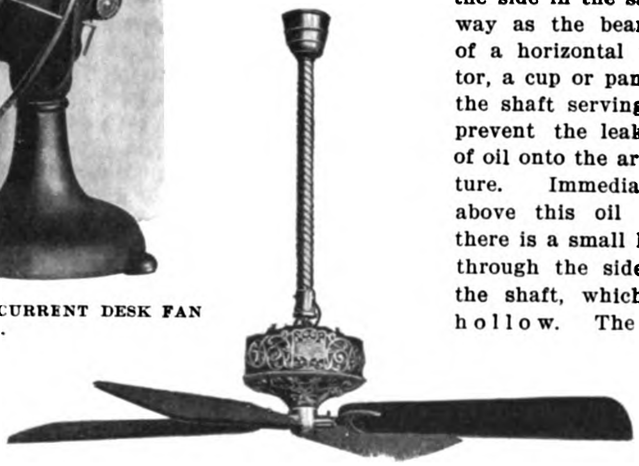

FIG. 48.- DAYTON DIRECT-CURRENT CEILING FAN MOTOR.

order to prevent it from running through too rapidly.

The armature shaft bearings are fastened directly to the magnet structure, so that any magnetic pull on the armature is transmitted directly to the magnet frame. This arrangement enables the air-gap to be made extremely small, as there is no liability to lateral displacement of the armature. The upper bearing is independent of the casing, so that the motor may be set up and handled conveniently with the stem and cover removed. The rheostat is mounted within the magnet structure, as indicated in the engraving by the letter D. The regulating switch, R, is at the extreme lower end of the fan shaft, and is made unusually substantial in order to avoid liability to damage by resting the fan upon the thumb-piece in handling it preparatory to installation. These fans are made for 110, 170, 220 and 500 volts. Fig. 51 is an exterior view of the Western Electric "Arctic" ceiling fan motor, which differs from the standard machine in that no switch or regulating rheostat is incorporated in its structure. As the illustration plainly indicates, the fan is controlled by a separate switch either hung from the ceiling or mounted on a nearby wall. The Arctic fan is wound for the same voltage as the standard motor.

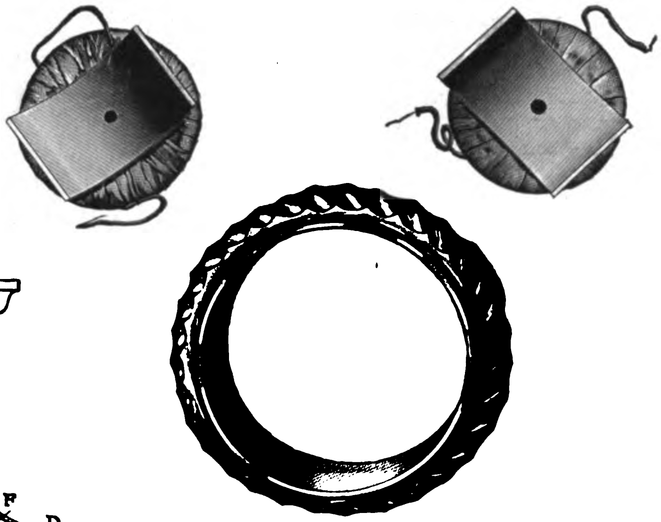

FIG. 50.—PARTS OF ROBBINS & MYERS STYLE A MOTOR.

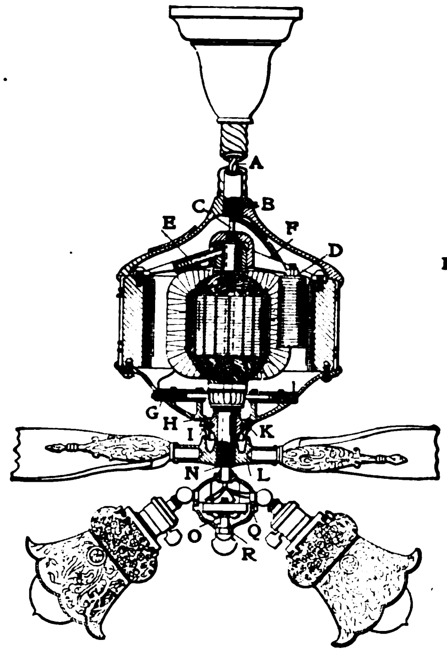

FIG. 49.—WESTERN ELECTRIC DIRECT-CURRENT CEILING FAN.

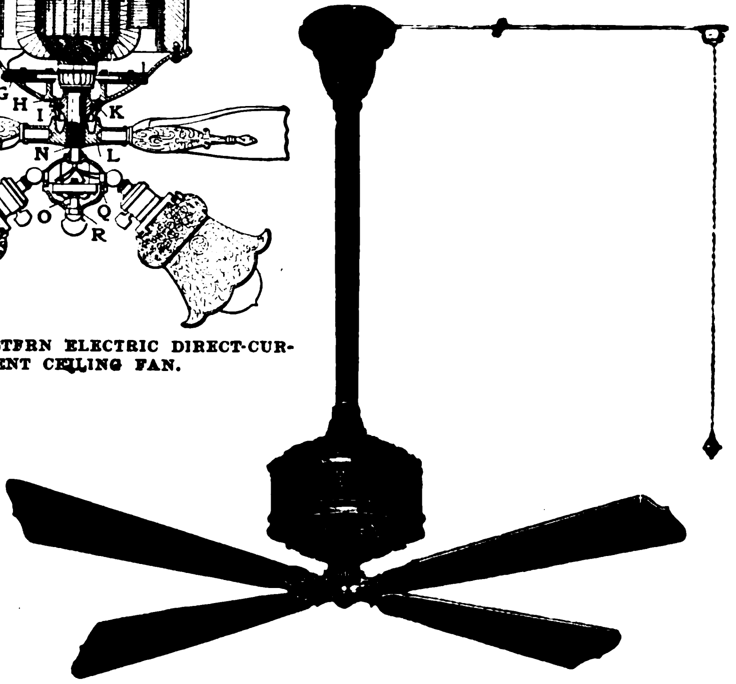

FIG. 51.—WESTERN ELECTRIC "ARCTIC" CEILING FAN.

Fig. 52 gives a sectional view of the 1901 model Standard direct-current ceiling fan motor built by the Robbins & Myers Company, Springfield, Ohio, and now in its fifth season. This fan is made in two general styles, designated by the company as Style A and Style B; the two styles differ from each other only in the construction of the field magnet and in external appearance. The pole-pieces and cores in the Style B fan motors are cast integral with the yoke ring; the pole-pieces have each one long and one short horn, as shown by Fig. 53, which is a view of the field magnet without the coils. The object of extending one pole-tip of each pole-piece is to obtain a greater area of air-gap, thereby decreasing its magnetic reluctance, without involving the provision of a removable pole-piece in order to put the field coil on or take it off. The field coils are rectangular, form-wound, thoroughly taped and finished with a baked insulating varnish; each coil is slipped on over the long pole horn, drawn to place, and then pressed over the short pole horn, which serves to hold it in position without any other mechanical fastening.

The field coils in the Style A motor are circular in form and are mounted on drop-forged magnet cores, which have each a pole-piece on one end and a curved face at the other; the magnet cores are bolted on to machined seats in the yoke ring, which is of cast iron. Fig. 50 illustrates this construction. The use of drop-forged magnet cores gives the Style A fan motor a higher efficiency than that of the Style B machine.

A novel feature common to both fans, and said to be found in no other fan motors, is an arrangement of a switch and resistance coil in fans operated in series, whereby any one fan of the series may be stopped without interfering with the operation of the other fans. A patent has been issued to the company covering this device.

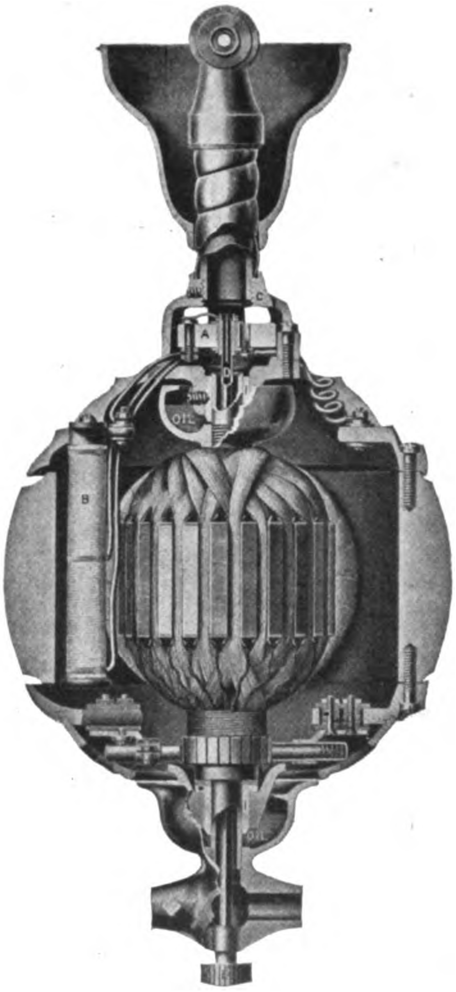

FIG. 52.—SECTION OF ROBBINS & MYERS DIRECT-CURRENT CEILING FAN MOTOR.

Reference to Fig. 52 will show that the bearings are supported and centered in end plates which together with the yoke ring form a spherical case enclosing the armature and field magnet structure. The company has adopted a new system of fitting these plates which secures absolute alignment of the bearings without resorting to swivel sleeves; the use of these sleeves has therefore been discontinued, with the result that the motor has greater rigidity and freedom from noise. The oiling system is too clearly shown by the engraving to require a detailed description. A marked bottle of oil is sent with each fan and the purchaser has only to empty half of the oil into each of the journal cups in order to prepare the fan for a season's run. The disposition of the regulating resistance and the porcelain switch are also clearly shown. These parts are connected up independently and may be placed in position or removed without disturbing any of the mechanism of the motor as there are no wires leading through the shaft as in previous models.

The direct-current desk and bracket fans made by the Robbins & Myers Company are illustrated by Figs. 54 and 55; these fans are now in their fourth season. The motors are designed on the same general plan as the Style B ceiling fan motor, having the peculiar arrangement of magnet poles shown in Fig. 53. The lubrication is accomplished in the usual manner with wick oilers, except that a special semi-solid lubricant is used which, it is claimed, cannot be thrown out by the fan after it works through the bearings. The guard is of familiar design and made entirely of brass. The motors are all mounted in swivel trunnion frames, which allow universal adjustment of the direction of the air current. These motors are also provided with the patent switch arrangement for series operation, which allows any one fan to be stopped independently of the others.

Fig. 56 illustrates the desk fan motor built by the B. B. Electric Company. The motor is of the bipolar type, having a cast-iron field magnet cast in a single piece, with openings large enough to admit the field coils and armature. The armature is of the usual drum type, wound in slots. The brushes are of carbon, rectangular in shape, sliding in brass holders and pressed against the commutator by helical springs. A ball-and-socket joint enables the motor to be used on a desk or mounted on a wall, and a resistance coil and switch in the base provide three speeds. Lubrication is effected by wick-feed oil cups. When assembled, the working parts are entirely enclosed. The motor is built for 115 volts, and the 12-in. fan is driven at 1800 r.p.m., with a current consumption of 0.35 ampere.

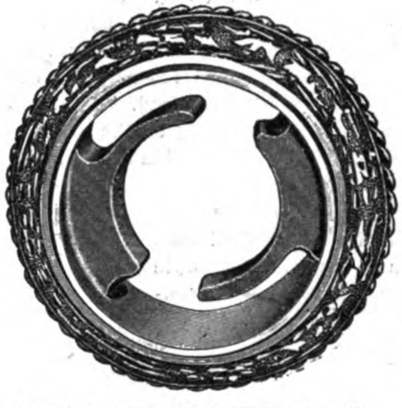

FIG. 53.—ROBBINS & MYERS FIELD MAGNET.

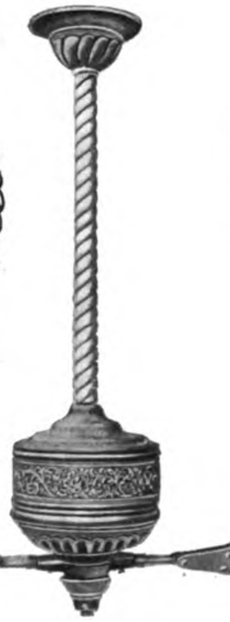

FIG. 57.—PARAGON DIRECT-CURRENT CEILING FAN MOTOR.

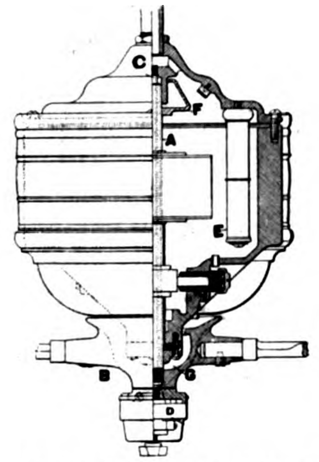

FIG. 58.—SECTION OF PARAGON CEILING FAN.

Fig. 57 illustrates the Type D Paragon ceiling fan motor built for direct-current circuits, and Fig. 58 is a semi-sectional view of the same machine. The motor is a bipolar machine with a drum armature wound in slots. The motor shaft is supported in bearings top and bottom, and the bearings are provided with grease retaining cups, F and G. The brushes are of the carbon-pencil or cartridge type, mounted in the lower framework of the field magnet. They are entirely enclosed in the Type D fan by the lower part of the ornamental casing. These machines are wound for 100, 120, 220, 250 and 500 volts; the current consumption is 0.82 ampere at the lowest voltage, 0.43 ampere at the intermediate voltage, and 0.24 ampere at 500 volts.

Another efficient ceiling fan of the same general type as the one just described is the "Peerless" Type H machine built by the Warren Electric & Specialty Company, and illustrated by Fig. 61. The general design is precisely the same as that of the Paragon machine. The shaft carries an oil cup at the top and bottom, so that the bearings are constantly submerged in oil. The bearing shells have curved seats, making them self-aligning. A noticeable detail of this machine is the manner in which the fan-blade hub is put on. The lower oil cup, instead of being cast integral with the fan-blade hub, making it necessary to remove the oil cup in the event that the fan-blade hub needs to be removed, is entirely separate and mounted permanently on the shaft. The oil cup is provided at the bottom with wings corresponding to the arms of the fan-blade hub, and the two are bolted to-

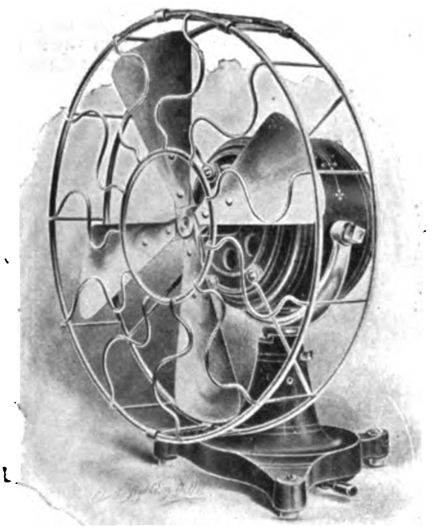

FIG. 54.—ROBBINS & MYERS DESK FAN MOTOR.

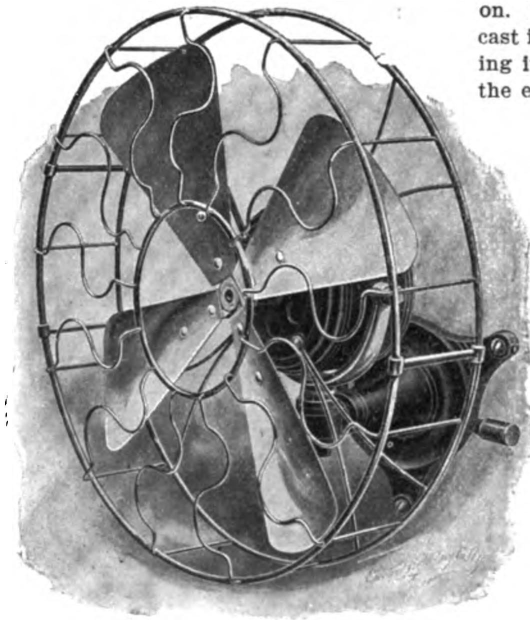

FIG. 55.—ROBBINS & MYERS BRACKET FAN MOTOR.

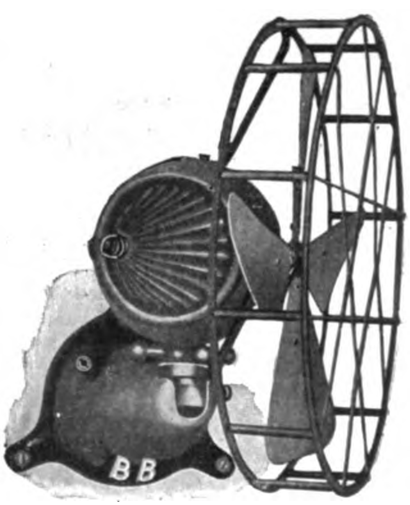

FIG. 56.—B. B. FAN MOTOR.

gether, as indicated in the engraving. The shaft is hollow in order to allow the switch spindle to extend upward to the switch, which is located at the top of the canopy. Two speeds are available, the rheostat controlled by the switch being located in the upper part of the fan structure. The commutator and brushes are of the familiar type, the latter being graphite-carbon pencils mounted in tubular shells, which are enclosed in insulating sleeves through the lower part of the casing. This fan is wound for 110, 170, 220, 250 and 500 volts. The current consumption at these voltages is 1 ampere, 0.7 ampere, 0.55 ampere, 0.45 ampere and 0.23 ampere, respectively. This fan is furnished with either two blades or four; with two blades the speed is 130 r.p.m., and with four it is 110 r.p.m. The Warren Company has also brought out a new fan this season known as the Midget, which has a sweep of 24 ins., instead of the 60-in. sweep of the Peerless fan, and has a speed of 500 r.p.m. This fan is wound for all the voltages just mentioned except 500. It is not provided with a **regulating switch, but is intended to be used in connection with a wall controlling switch.**

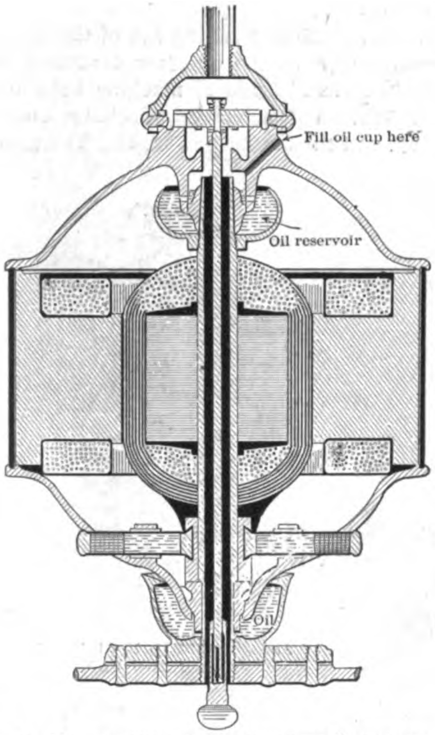

FIG. 59.—SECTION OF "PEERLESS" CEILING FAN MOTOR.

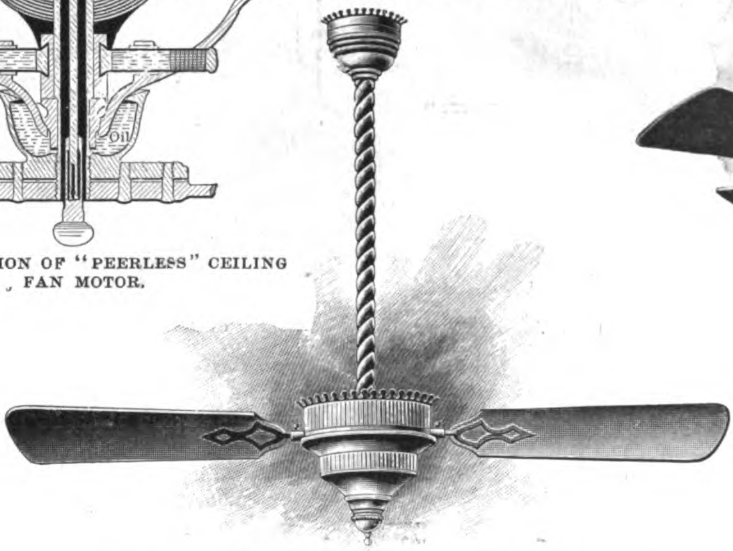

FIG. 60.—DIEHL STANDARD DIRECT-CURRENT CEILING FAN.

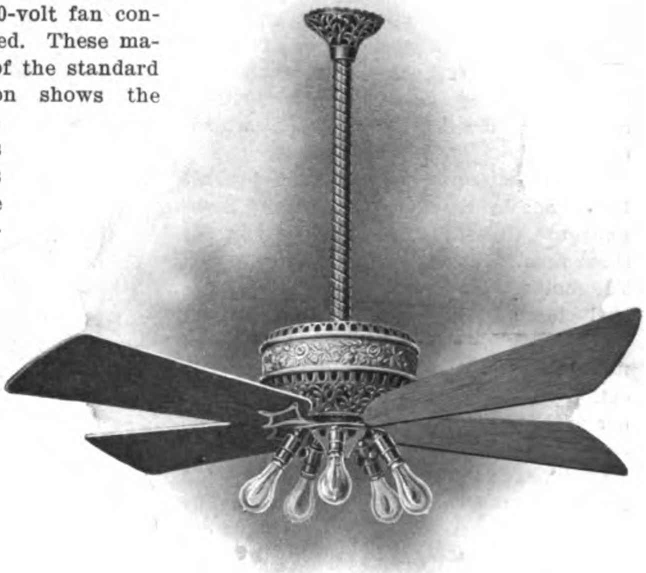

FIG. 62.—BATES DIRECT-CURRENT CEILING FAN.

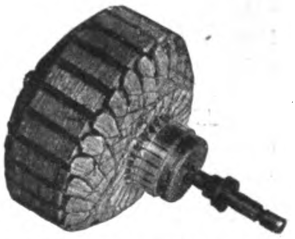

FIG. 63.—BATES DIRECT-CURRENT MOTOR ARMATURE.

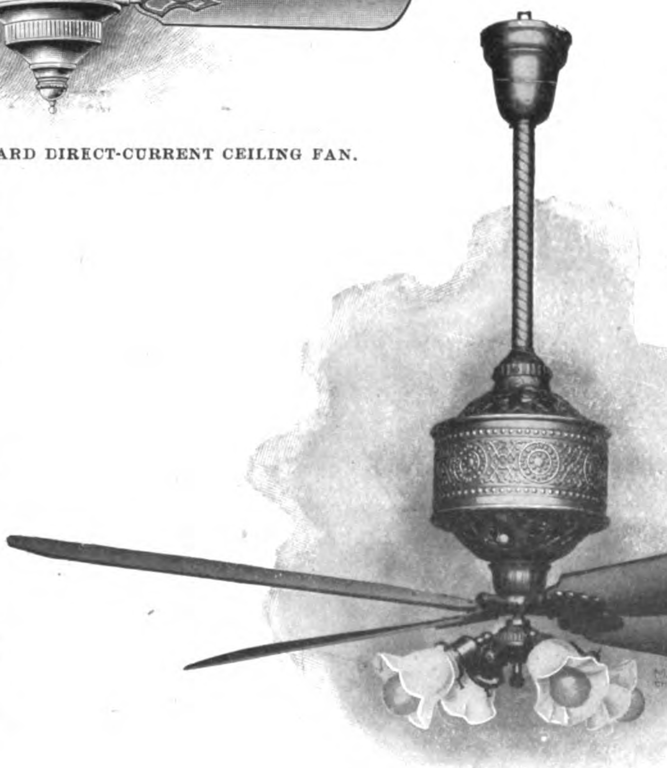

FIG. 61.—"PEERLESS" CEILING FAN.

The Bates Style A direct-current ceiling fan is illustrated by Fig. 62. It is a 6-pole machine with inwardly projecting (radial) pole-pieces, and form-wound interchangeable field coils individually insulated and securely wedged into place. The armature, which is illustrated by Fig. 63, is of the drum type, of large diameter, and has an unusual area of radiating surface; only two brushes are employed. The armature coils are form-wound and individually insulated before being placed in the slots. After the armature is completed it is dipped into an insulating varnish and baked in an oven until it is thoroughly dried out. The commutator and brushes are of the usual type, the latter being round carbon pencils in cartridge holders. The 110-volt fan consumes 85 watts at full speed. These machines are wound for all of the standard voltages. The illustration shows the revolving electrolier type of fan, but of course it is supplied without the lamps when so desired. The style A fan has no speed regu**lation. Messrs. Bates & Bro. built a similar fan, however, known as the Imperial, which is equipped with a three-speed switch.**

Fig. 60 illustrates the Diehl standard direct-current ceiling fan. This machine is provided with a bipolar field magnet of laminated sheet-iron, and a Gramme ring armature of the external type. This arrangement obviously gives a very short magnetic circuit, resulting in corresponding economy in field excitation and current consumption. A radial commutator is located below the armature, and carbon brushes of a modern type are employed. **This machine is built for all of the standard direct-current voltages and for 170 and 250 volts also. The sweep of the fan blades is 60 ins. The fan is provided**

with a three-speed regulator when desired. The Diehl Company also builds a ceiling fan, the motor of which is of a design similar to the desk fan motor previously described.

The Eclipse ceiling fan (Geo. C. Towle Manufacturing Company) is illustrated by Fig. 64. The motor has a multipolar field magnet cast in a single piece and provided with form-wound coils. The armature is of large diameter and has 29 coils. The motor is encased in a polished brass cover which may be removed by simply unscrewing the switch button at the bottom of the motor. The fan is ordinarily furnished with four blades, and runs at 150 r.p.m. The machine is wound for 110, 170, 220, 250 and 500 volts.

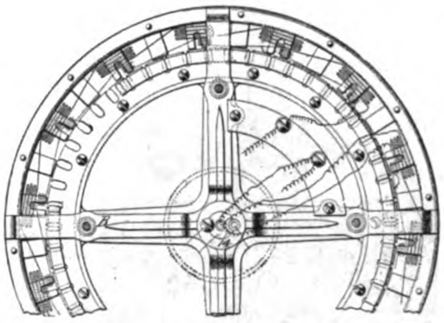

FIG. 65.—DIAGRAM OF EMERSON "SPECIAL" MOTOR WINDING.

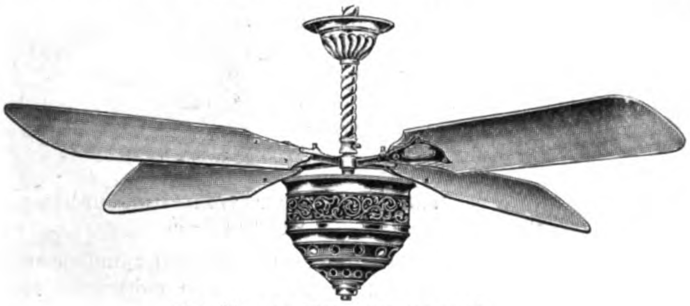

FIG. 64.—ECLIPSE CEILING FAN.

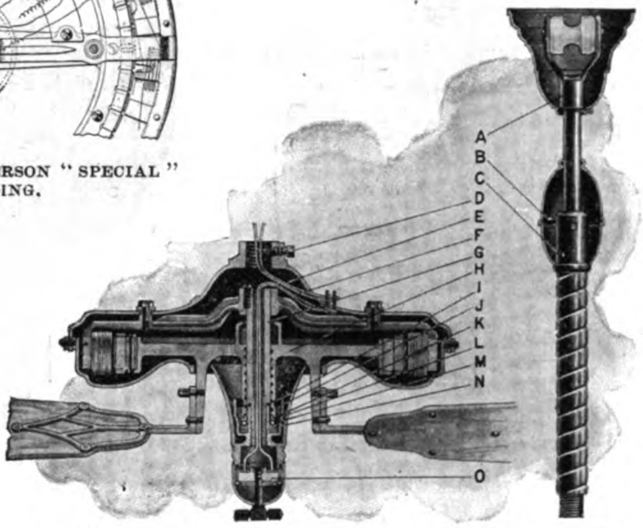

FIG. 67.—SECTIONAL VIEW, EMERSON CEILING FAN MOTOR.

One of the very few alternating-current ceiling fan motors is the Emerson machine, which is represented by Fig. 68. This is an induction motor, and its general construction is clearly indicated by Fig. 67. The field magnet has 28 poles, each divided into two parts by a slot in the center. The object of this construction is to allow the use of shading coils, each wound on half a magnet pole, as described in connection with the desk fan motor of this company. The coils are form-wound and individually insulated before being put in place. The armature is of the squirrel-cage type, and the conductors are flat copper strips similar to those on the Emerson desk fan rotor illustrated by Fig. 13, and previously described. The accuracy of the stampings is not relied upon, but the armature core is turned to size after the discs are assembled in order to reduce the air-gap to the smallest possible clearance allowable by mechanical conditions. The armature, like that of the desk fan motor, is provided with a hollow shaft, and revolves about a stationary spindle. The weight of the armature or rotor is taken by a thrust ball bearing, shown at N. The oiling arrangement is unique. The oil reservoir, K, is located at the bottom of the bearing, and the bore of the shaft is provided with a spiral groove, similar to a screw-thread, which raises the oil to the top of the bearing, whence it trickles down again, keeping the bearing thoroughly lubricated. This machine is built for 52, 104 and 110 volts, and for use on 60-cycle circuits. It has two speeds, namely, 210 r.p.m. and 160 r.p.m. The switch is arranged so that the shading coils may be cut out after the machine has been started, and this gives the lower speed. This motor is also supplied for 133-cycle circuits, but the high-frequency type has only one speed, which is about 500 r.p.m., and is equipped with five fan blades, the sweep being 30 ins. instead of the usual 56-in. sweep.

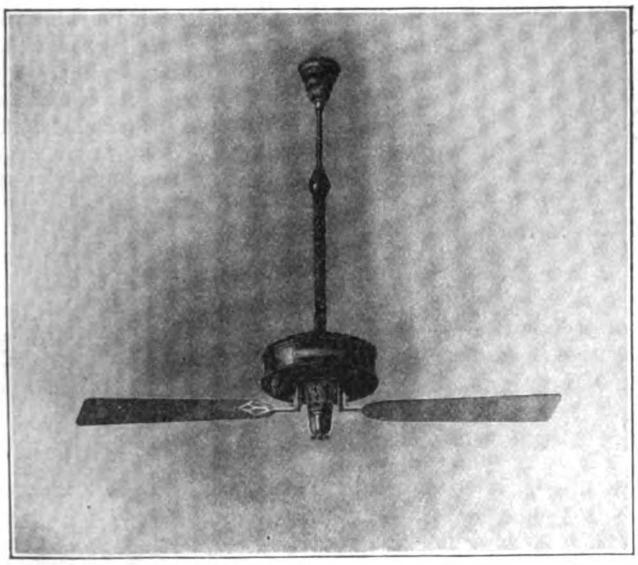

FIG. 66.—EMERSON "SPECIAL" MODEL CEILING FAN.

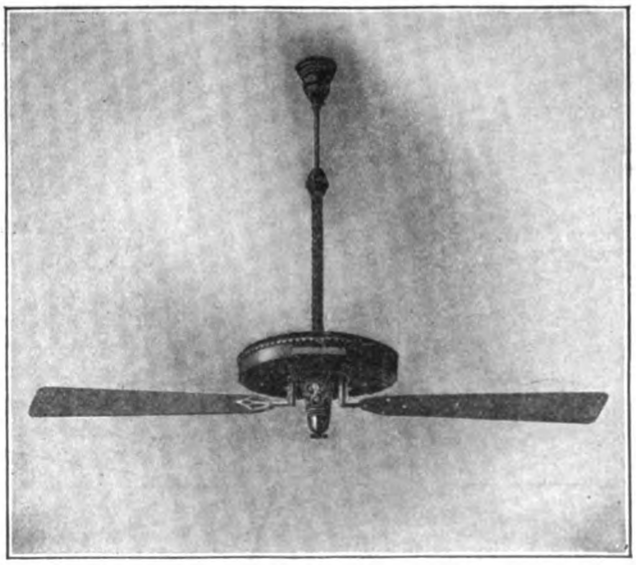

FIG. 68.—EMERSON STANDARD CEILING FAN.

Fig. 66 illustrates the Emerson "special", model ceiling fan, which is of almost exactly the same construction as the standard model. There is a difference, however, in the field construction, as an inspection of Fig. 65 will show. Instead of splitting every magnet pole and providing coils for all of the poles, only the alternate poles are split and wound, the intermediate poles being consequent. This winding makes the fan more compact, as the wireless poles are not so wide angularly as those which carry coils. The blades have a 50-in. sweep as compared with 56 ins. in the standard model, and the speeds are the same. This machine is only built for 60-cycle circuits, and for 104 and 110 volts.

The Empire ceiling fan motor of the Sprague Electric Company is illustrated by Fig. 75. As will be seen in the engraving, it is of the four-pole radial magnet type and has but two brushes, set 90° apart. A cross-sectional view through two of the magnet cores is given by Fig. 69, which also shows the deep oil cup that surrounds the hub of the armature—a notable feature in the construction. The armature is a slot-wound drum and is illustrated by Fig. 70. The speed is 135 r.p.m., and the voltages and current consumption are as follows: 110 volts, 0.95 ampere; 165 volts, 0.64 ampere; 220 volts, 0.57 ampere; 250 volts, 0.53 ampere.

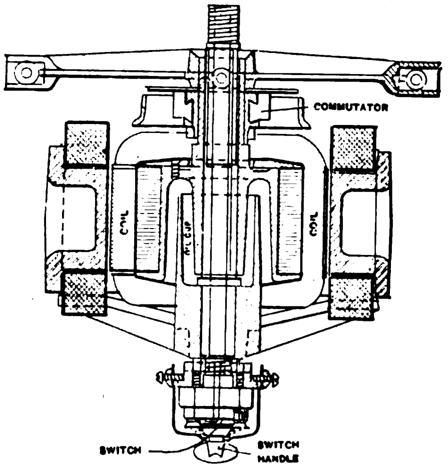

FIG. 69.—SECTION OF EMPIRE CEILING MOTOR.

The Backus direct-current ceiling fan is illustrated by Fig. 71. The motor has a bipolar field magnet and a Gramme ring armature, as indicated by the sectional view, Fig. 72. The field is of the Vanderpoele type with the armature shaft bearing passing through the center of the field magnet core, and a form-wound exciting coil located on each side of the bearing. The upturned pole-pieces embrace a high percentage of the armature core, giving an air-gap of large area and consequently small reluctance. The brushes are carbon pencils disposed parallel with the shaft, a commutator of the radial type being used. The main bearing is located immediately beneath the armature, a grease cup being formed in the field magnet frame at that point. An auxiliary bearing is located at the lower extremity of the structure where another grease cup is formed in the casting. These fans are built for 110-115 volts, 170 volts, 220-250 volts and 500 volts. The 110-115-volt and 220-250-volt fans are provided with variable-speed switches; the thumb piece of the switch extends below the center of the fan-blade hub. The normal speed of the fan is 170 r.p.m., and the power consumption is about 100 watts with fan blades having 57½ ins. sweep.

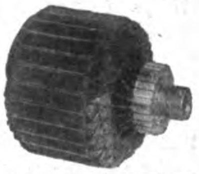

FIG. 70.—ARMATURE OF EMPIRE CEILING FAN MOTOR.

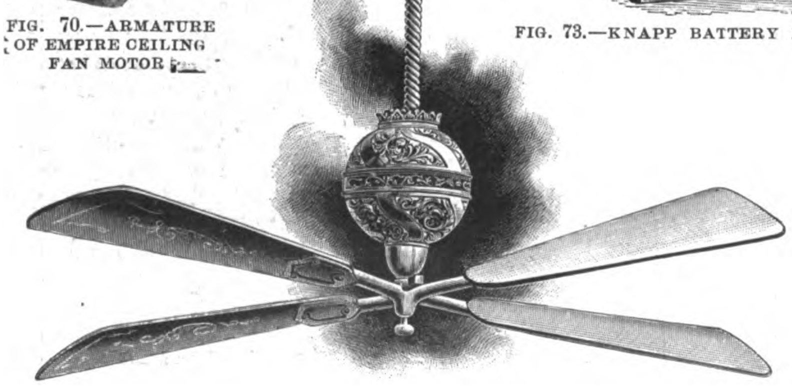

FIG. 71.—BACKUS DIRECT-CURRENT CEILING FAN.

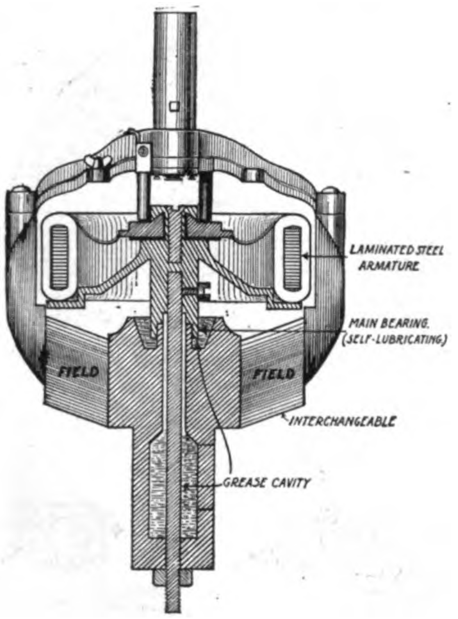

FIG. 72.—SECTION OF BACKUS FAN MOTOR.

The only other alternating-current ceiling fan which has not been described is the Tuerk machine, built by the Hunter Fan & Motor Company. A special feature of this machine is the use of a high-speed motor with a speed-reducing gear between the motor spindle and the fan blades. The fan blades are attached to the lower part of the casing of the machine, and this casing consequently revolves. Its motion is received from two leather-faced friction wheels which are mounted on short individual spindles and arranged to transmit the motion of the armature spindle to the casing. The result is the same as though a pinion of the diameter of the armature spindle were used to drive a gear on the casing of the diameter of the friction surface upon which the intermediate wheels bear, and of course the difference in speed is correspondingly great. The speed of the fan blades has been increased since last year, and is now 175 r.p.m., with a consumption of about 110 watts. The machines are built for the usual frequencies, and for 52, 104-110 and 208-220 volts.

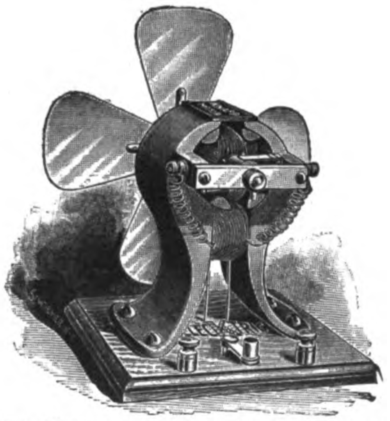

FIG. 73.—KNAPP BATTERY FAN MOTOR.

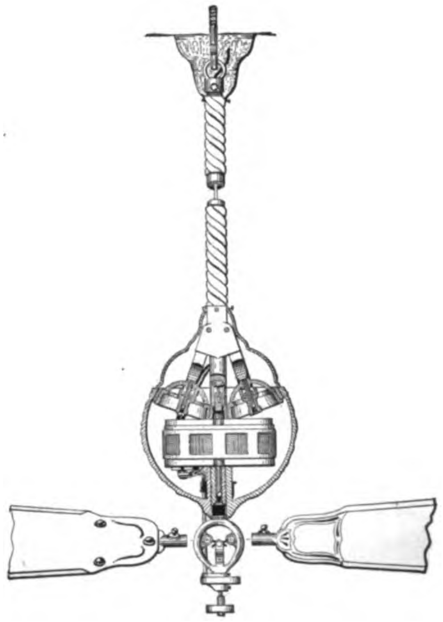

FIG. 74.—TUERK ALTERNATING-CURRENT CEILING FAN.

Among the little fan motors built to operate on battery current, one of the most familiar is the Knapp machine, illustrated by Fig. 73. This is known as the type C motor of the Knapp line. The armature has six projections or teeth, and is provided with a six-coil Siemens winding. The motor drives an 8-in. four-blade fan at 1800 r.p.m. when it is supplied with current from three cells of battery. The battery is a carbon-zinc primary cell and is usually enclosed in a wooden case.

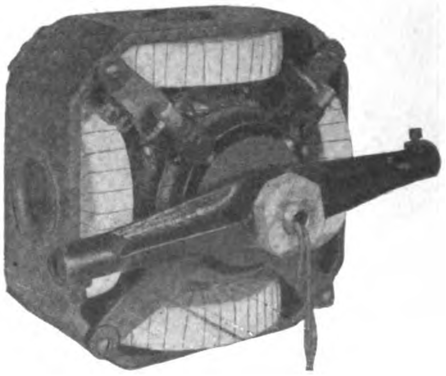

FIG. 75.—EMPIRE CEILING MOTOR.

Fig. 76 shows a little battery motor

known as the "Oddo Wilfan," built by Jas. H. Mason. The armature of this little machine has a three-pole core with three coils, and drives a six-inch fan at 2200 r.p.m. The engraving shows the fan resting on top of a box which is intended to be filled with gravel, a ballasted foundation, so to speak. The battery used with the motor is a bichromate-of-potash cell, being a modification of the Grenet electropoion type. The electrolyte consists of nine pints of water in which are dissolved ⅛ lb. of saltpeter and 1 lb. of bichromate of potash, to which is added 1½ lbs. of commercial sulphuric acid.

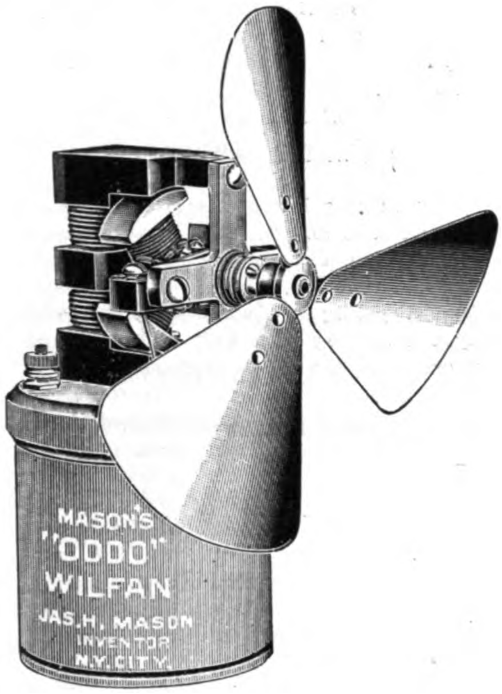

FIG. 76.—"ODDO WILFAN" BATTERY FAN.

Another interesting little machine is the Arctic battery fan motor, shown by Fig. 77. This motor is of the familiar bipolar type and built by the American Electric Company. It is made in several sizes; the one illustrated is known as No. 3, and is designed to run a 9-in. four-blade fan at 1600 r.p.m. when supplied with current from three cells of a modified form of Fuller battery.

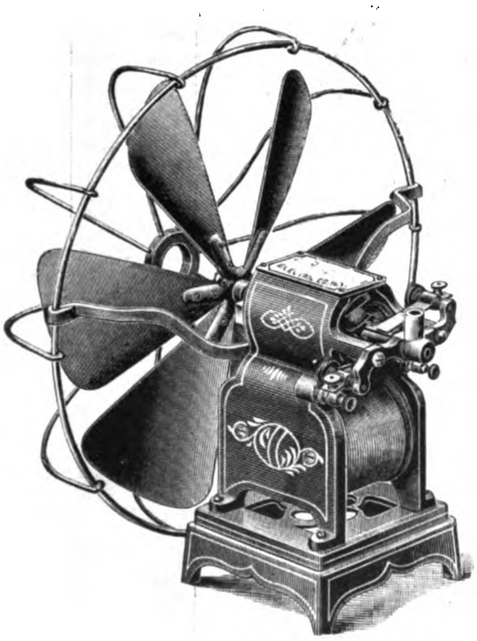

FIG. 77.—ARCTIC BATTERY FAN MOTOR.

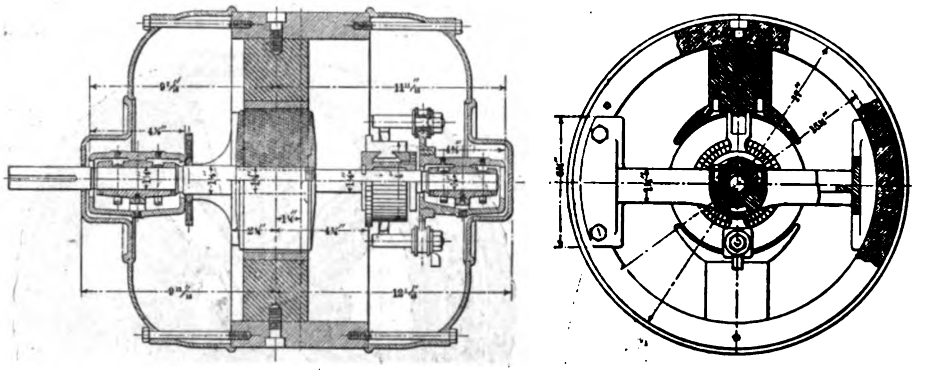

FIG. 78.—LATEST TYPE OF STURTEVANT 4-POLE VENTILATING FAN MOTOR.—FIG. 79.

The brushes are of copper leaf but are mounted in pivoted spring brush holders, like those of large machines.

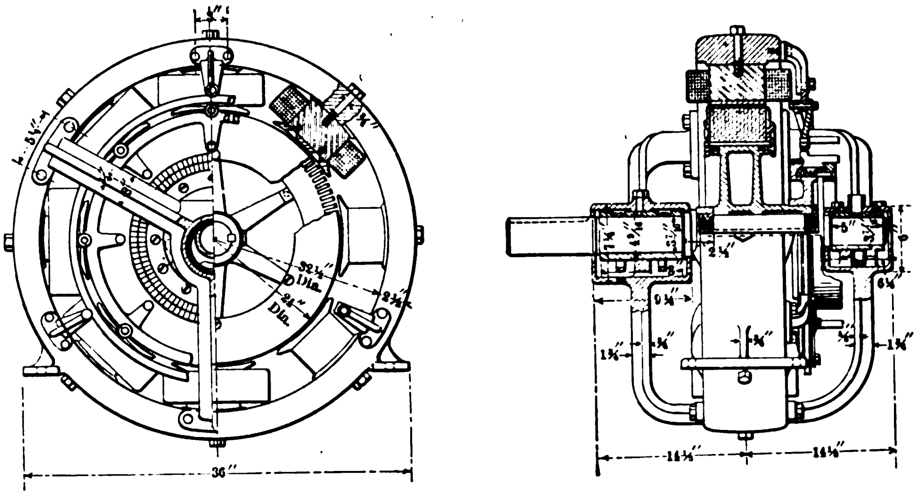

FIG. 80.—LATEST TYPE OF 8-POLE STURTEVANT VENTILATING FAN MOTOR.—FIG. 81.

The binding posts have rubber bushings in the wire holes, so that there is no connection with the battery until the binding post screws are set up. The object of this is to avoid cumbering the little machine with a switch; it is cut in and out by simply setting or unsetting one binding post screw.

Fig. 82 illustrates the latest form of Sturtevant ventilating fan and motor outfit. The motor is of the bipolar type and entirely enclosed, as the illustration indicates. Fig. 78 is an axial cross-section of the motor, and Fig. 79 is partly a transverse section and partly an end view with the cap removed. The armature bearings are contained in journal yokes of the ordinary type, bolted to and extending outward from the field ring. The magnet cores are wrought iron, bolted to the ring, and the pole-pieces are cast-iron and bolted in turn to the cores. The end caps are entirely independent of the remainder of the machine, and can be removed while the machine is running without interfering in the least with its operation. This type of motor is built for use with fans ranging from 18 ins. to 54 ins. diameter. For fans larger than 54 ins. four-pole and eight-pole motors are employed. The eight-pole motor construction is clearly indicated by the sectional views, Figs. 80 and 81. The field ring is of cast steel in the medium-size machines, and of cast iron in the large sizes. The field cores are of wrought iron and the pole-shoes of cast iron. The field coils of both the bipolar and multipolar types are machine wound.

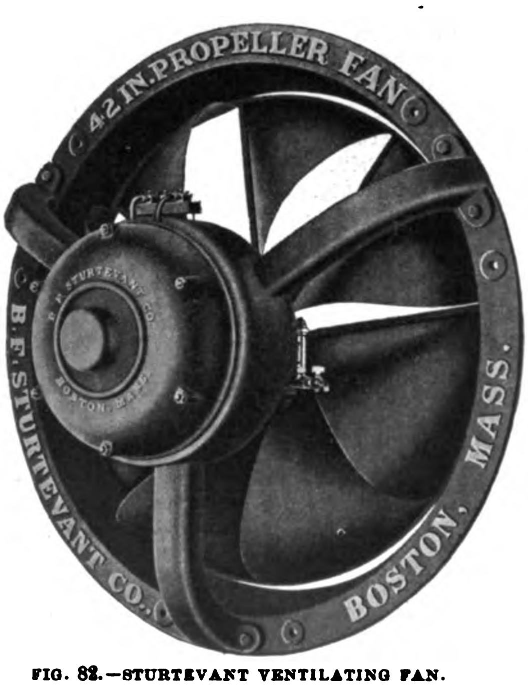

FIG. 82.—STURTEVANT VENTILATING FAN.

The armature core discs are clamped between end plates of a diameter equal to the extreme diameter of the core discs and slotted correspondingly, this construction being used in order to clamp the teeth as well as the body of the discs. The armature coils are form-wound, the armature being of the drum type. A modified form of reactive carbon brush is employed on all of the machines. The fan blades are of propeller design, gradually assuming a helical shape toward the outer edges. The object of this construction is to pick up the air at low velocity and accelerate it during its passage from the inner to the outer edges of the fan blades.

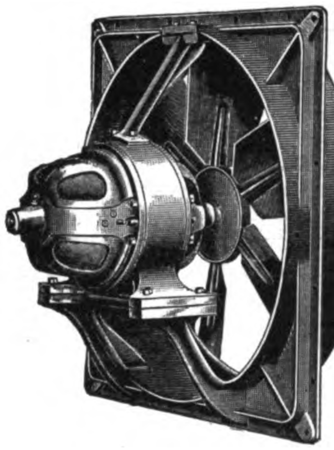

FIG. 83.—TRIUMPH VENTILATING FAN.

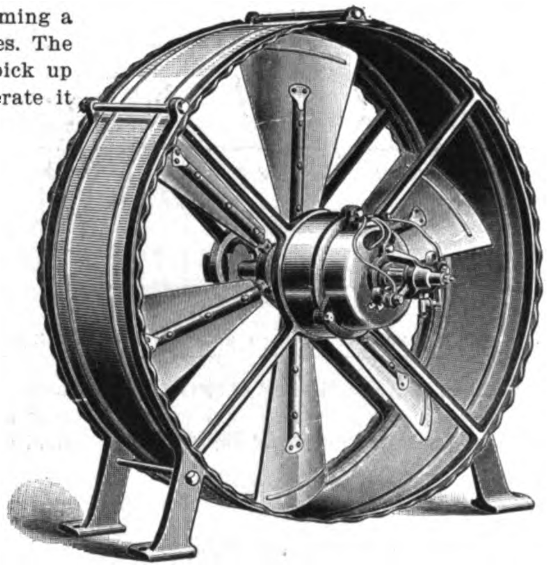

FIG. 84.—WING VENTILATING FAN.

The Fuller ventilating fan, illustrated by Fig. 85, has blades shaped like segments of a screw-thread; that is to say, if each blade were continued around until it completed a circle it would be a perfect screw-thread of one turn. The motor, as the engraving plainly shows, is a four-pole machine with four radial arms cast integral with the field ring, by means of which the motor is fastened to the fan casing. The armature has a drum winding and the coils are form-wound and insulated before going on the core. The brushes are of the reaction type, modified in order to allow the motor to run in either direction without changing their adjustment. The bearings are lubricated in the usual manner by an oil ring on the shaft. The outer periphery of the oil ring is notched in order to increase its capacity for carrying oil.

The Triumph ventilating outfit, illustrated by Fig. 83, is built by the Specialty Manufacturing Company, and comprises an enclosed multipolar motor mounted on a bracket which is cast integral with the fan frame. This method of mounting has been adopted in order that the motor might be available for other purposes when the service of the fan is not desired, in which case the motor can be readily removed from its bracket and a pulley substituted for the fan on the end of its shaft. The motor is of the latest modern design, provided with self-feeding carbon brushes, self-oiling bearings, and a starting rheostat with automatic release. A feature of the fan casing is the square frame which is cast on the periphery of the circular ring surrounding the fan blades. This allows the apparatus to be installed in an ordinary rectangular opening without making special provision for it.

Fig. 84 illustrates the ventilating fan and motor combination of the L. J. Wing Manufacturing Company. The motor is a four-pole machine with laminated magnet cores and pole-pieces bolted to a soft-steel yoke ring. The armature is drum-wound and provided with form-wound coils of the barrel type, insulated, of course, previously to being placed on the core. The armature discs are insulated from each other by japanning, and air ducts are provided for ventilating the core and winding. The motor is secured to the fan frame, as the engraving shows, by four radial arms, and the fan is mounted directly on the motor shaft.

The method of lubricating fan motors by means of wick-feed oil cups has grown to be almost universal practice, most of the machines being provided with oil cups of the type illustrated by Figs. 86 and 87. These cups are substantially made of brass, and the wick is stiffened by being mounted in a long sleeve turned solid with the enclosing cap of the cup. The lower end of the wick is embraced by the upper end of a conical spring, which provides a simple means of adjusting the pressure of the spring. The upper convolutions of the spring clasp the wick so tightly that the maximum pressure of the spring cannot cause it to slip on the wick. At the same time the wick may be twisted through the spring by hand so as to increase the compression of the latter. This cup is made by the Bowen Manufacturing Company, and is known as Style H.

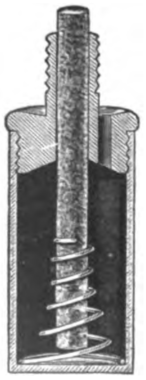

FIG. 87.

WATER HAMMER.

Sometimes a line of steam piping sags because it is insufficiently supported and its own weight causes it to bend between adjacent supports; again, very accurately leveled piping is occasionally distorted by the settling of a wall or foundation upon which one of the supports rests. In either case there is liable to be formed a gathering or "pocket" of condensed water by drainage to the "sag" from both directions, while the plant is temporarily idle or after it is shut down at night. Then when steam is again turned on and reaches the pocket of water it will tend to evaporate the water; but, owing to the conditions of temperature being usually unfavorable for complete evaporation of the mass of water at once, it will, it is generally believed, be partially evaporated and again condensed, alternating rapidly between the two conditions, and producing the familiar pounding or hammering that we are so well acquainted with in steam pipes. If, unfortunately, the conditions of temperature happen to be favorable, the whole mass of pocketed water may be temporarily evaporated and carried along the pipe as steam and at steam's velocity, only to be condensed back into water further along the pipe, in which event the recondensed mass of water will be moving at the high rate of several thousand feet per minute. If it encounters an elbow or other fitting, the fitting is almost sure to be wrecked. Such an accident took place in Detroit, Mich., a few years ago, when an elbow in an 8-in. pipe was smashed and much damage done to the building. In order to avoid this contingency it is essential that care be taken not only to turn on steam slowly and to warm up the pipes carefully at starting, but also to locate all possible sags and depressions in the steam pipe for the purpose of releveling, or of tapping for drain-cocks. Furthermore, in view of the destructive possibilities of this water-hammer or explosive boiling, steam drums and headers which are connected up so that all inlets and outlets are on the side or top, leaving no opportunity for condensation to drain out, should be tapped for drain cocks at their lowest points.

Besides the troubles already mentioned, water of condensation in pipes has the serious disadvantage of causing pitting and cutting grooves when running along a pipe in a stream. Instances have been known where this grooving action has been so great at elbows as to cut entirely through the metal. An effort has been made in modern practice to eliminate this trouble by running a small pipe immediately beneath the main pipe, the two being connected at frequent intervals by short vertical pipes. The small pipe drains all the water out of the steam pipe, and may be so connected as to return the drain water back to the boiler directly.

Abstracts from Foreign Contemporaries

Modification of the Hughes Telegraph Keyboard.—In a recent issue of the London "Electrical Review" C. H. Garland describes Signor Paolo Fauret's modified Hughes keyboard now being used between Milan Bourse and Rome. It consists in a rearrangement of the figure keys as shown by Fig. 1. Ordinarily the figures form a consecutive series running from left to right without interruption, and the modification was devised with a view to obviating certain inconveniences found with this arrangement in practice. It is said to be favored in commercial and stock exchange work, where many figures are employed, and also in all the figure codes, being easier of manipulation.

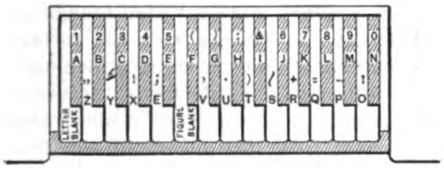

FIG. 1.—HUGHES KEYBOARD.

Bolt for Connecting Storage Battery Lugs.—In a recent number of the London "Electrical Engineer" is described a bolt devised by W. O. Rooper, for connecting storage battery lugs, by means of which any plate in any cell can be quickly removed and replaced. Fig. 2 shows its construction. Each plate has a jaw formed on its lug, and through these jaws is passed a lead-coated pin; spacing washers keep the jaws in position, and the whole is tightened by means of patent nuts which are not affected by acid. The joints, it is said, may be left in strong acid without harm, and no trace of corrosion is found on removal.

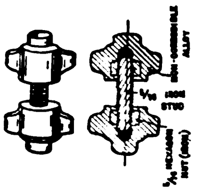

FIG. 2.

A New Electrolytic Interrupter.—The "Physikalische Zeitschrift" in a recent issue describes a new interrupter devised by W. A. Hirschmann, which is illustrated herewith. A hollow piece of ebonite, H, Fig. 4 revolves with the shaft, A, and is provided with two copper contacts, M, with inlets into the interior of the ebonite as shown at T and U, Fig. 4. The other contact, C, is pressed against the contact, M, by the spring, F. The opening, B, in the ebonite block is so arranged that it scoops up the mercury in the bottom of the apparatus into the interior of the block and forces it out through the apertures at T and U. The contact P serves to spread the issuing mercury over the contacts, M, thus keeping them amalgamated. The apparatus works noiselessly in an accumulator circuit or a 110 or 220-volt supply circuit.

A New Steam Stop Valve.—In a recent issue of "Engineering" is described an interesting steam stop valve, the construction of which is such as to leave the spindle and seat free to expand and contract under changes of temperature without affecting the seating of the valve disc. The construction is shown in the sectional view herewith (Fig. 3), which is almost self-explanatory. The valve disc is provided with an auxiliary seat which is fitted to the body seat by means of a flat ground joint. The yoke into which the spindle is threaded, instead of being bolted solidly to the cap of the valve, is held down by heavy coil springs, as shown. These springs are adjusted to exert a pressure of 50 lbs. above the maximum boiler pressure, so that the valve may be mounted with the boiler pressure against the under side of the disc without incurring liability to leakage. A distance ring is provided on the valve spindle to prevent jamming the valve beyond the amount necessary to render it steam-tight. The auxiliary seat is provided with a guide slot to take the guiding lug on the bottom of the valve disc.

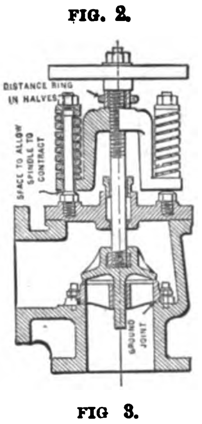

FIG 3.

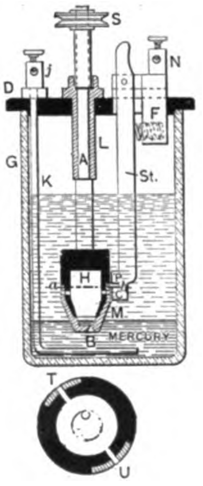

FIG. 4.

Three-Phase Motors for the London Metropolitan Underground Railway.—Complete particulars concerning the London Metropolitan Underground Railway being as yet unobtainable from Ganz & Co., the contracting engineers for the electrical equipments, the London "Engineer" publishes a description of the Valtellina Railway in the Lake Como district of Italy installed by the same concern, and which the London railway will closely resemble, differing only in some minor details. Thus, on the Italian line each motor truck carries two motors, whereas in London each front and rear motor car will carry four motors, or eight for each train. In both schemes two trolley wires and the rails carry three-phase currents. The line current in Italy is carried at 20,000 volts; but it is proposed to use 3000 volts in London. Contact with the rails is formed by the driving wheels, as in ordinary trolley practice. Every conductor from the trolley wires is incased in metal as a safeguard against accident. The motors are three-phase induction motors and are arranged in pairs for high and low tension. Each consists of a high-tension stator and a low-tension rotor. Current at 3000 volts enters the stator of the high-tension motor from the trolleys and the rails, and induces in the rotor lower voltage three-phase currents which, during starting and up to half speed, are taken to the stator of the low-tension motor. The currents induced in the rotor of the latter are passed through a non-inductive liquid rheostat the resistance of which is automatically reduced from maximum to zero. At half speed the low-tension motor is cut out of the circuit, thereafter running idle, while at the same instant the full rheostat resistance is switched out of its rotor circuit into the rotor circuit of the high-tension motor, where it is once more automatically reduced from maximum to zero during the acceleration from half to full speed. In slowing down this series of operations is reversed. To half speed the retardation is entirely electrical, and during this period three-quarters of the kinetic energy of the train is said to be absorbed and pumped back into the line as three-phase currents by the dynamo action of the motors, while the other one-fourth is dissipated by the brakes.

The mechanical mounting of the motor and the method of driving the wheels are features of the system. The wheels are keyed in the ordinary way upon an axle which passes through the core of the rotor; the latter being connected to each driving wheel by five tangential links through which the motion of the rotor is transmitted to the wheels.

High Voltage Arc Lamp Trouble.—In a recent issue of the London "Electrical Review" J. G. Griffin describes a method of dealing with the high voltage arc lamp trouble with which Burnley and other British towns were suffering after the voltage at the customers' terminals had been raised from 105 to 220. It was found that the 220-volt arc gave more heat, the carbons lasted but half the time, the light was unsteady, and the lamp gave but one-fifth of the light, and that fifth was of such an inferior quality that it was impossible to distinguish the different shades of colored materials. Failing to remedy the evil they finally returned to the old 105-volt lamps, supplying them from a five-wire system, as shown in Fig. 5. Here A is the main generator, B, B, two machines forming the three-wire balancers. Two small balancers, CC, DD, are connected across both sides of the three-wire system, as shown, and from the middle wires of these small balancers cables, E and F, are run to the afflicted arc lamp district. The lamp is then connected to this new service wire and one of the mains already on the premises. The balancers were coupled together, having their fields cross-connected, which made them nearly self-regulating. Ordinarily the balancers were run only five afternoons and evenings per week. Should a customer desire to use his lamps at any other time, he signalled to the station by an arrangement shown in Fig. 6. Two 32-c.p. lamps, I and J, are connected in series on each side of the main neutral wire, and the center wire from these lamps is connected through a bell to the arc lamp balancing wire on that side of the system. Throwing in the arc short-circuits one of the incandescent lamps permitting current to pass through the bell, causing it to ring, and making the other incandescent lamp glow brightly. The switchboard attendant starts up the proper balancer as soon as the bell rings.

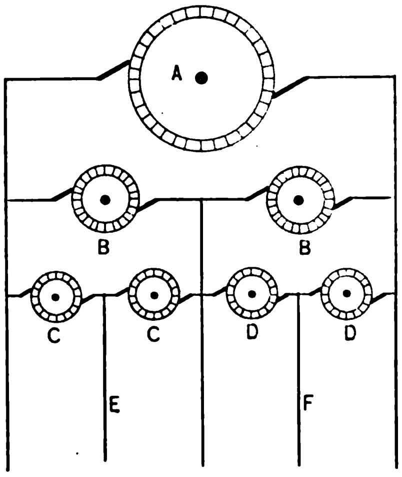

FIG. 5.—FIVE-WIRE SYSTEM.

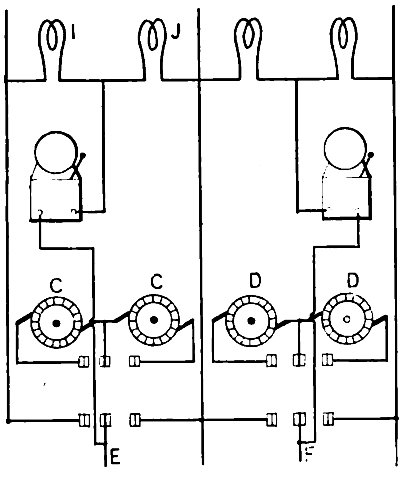

FIG. 6.—SIGNALING ARRANGEMENT.

A Frequency Meter.—J. Harden contributes to a recent issue of the "Elektrotechnischer Anzeiger" a description of a new frequency meter exhibited at Paris by Hartmann & Braun. The instrument will measure the frequency of any periodic current, whether alternating current or pulsating direct current, or the current from an induction coil. Its operation is independent of the wave form, and in outward appearance it resembles an ammeter or voltmeter. It has a scale for frequencies from 80 to 115, and tuned to the intervals of these numbers are 36 steel springs. A broad arm, on the axis of which is an alternating current magnet system, is turned around the scale by means of a button. When it comes opposite to the steel spring tuned to the frequency of the current under investigation the spring vibrates, emitting a tone which is readily detected. The frequency is read directly from the scale.

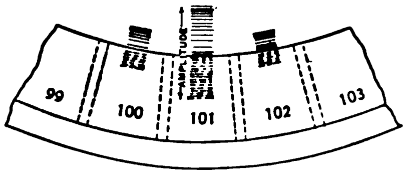

FIG. 7.—FREQUENCY METER SCALE.

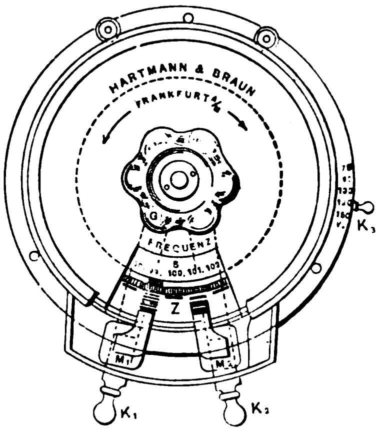

FIG. 8.—FREQUENCY METER.

Current Intensity of Lightning Flashes.— Some time ago, F. Pockels succeeded in showing that the remanent magnetism produced in basalt by a magnetic field depends only upon the maximum intensity of the latter, regardless of the length of time during which that maximum intensity might prevail. This fact, according to the "Physikalische Zeitschrift," he uses to determine the current intensity of lightning flashes. A rod of basalt is placed near a lightning conductor in such a position that the circular lines of magnetic force produced by a discharge would approximately pass through the length of the rod. The maximum intensity of the discharge current is then calculated. Some experiments made by Chistoni in the Monte Cimone observatory in the Apennines yielded magnetizations indicating currents of 10,000 to 20,000 amperes. Another rod showed a feeble magnetization which the author attributes to the prevalent "St. Elmo's Fire."

Feed Water Heater.-A very effective type of feed-water heater lately put upon the market is described in a recent issue of the London "Mechanical Engineer." The apparatus is built under the patent of G. G. Green, and is known as the "Airedale" feed-water heater. The construction is clearly shown by Fig. 9. The special feature consists of a spiral deflector placed inside each tube, as shown in the illustration. By the aid of this deflector the steam passing through the tube is given a rotary motion which breaks up the current and sweeps from the surface the drops of condensed water which naturally collect on the interior of the tubes. This permits a much more rapid transfer of heat from the steam to the feed water, and it is claimed by the makers that a tube thus fitted shows an increase of efficiency of 25 per cent as compared with the plain tube. A test was made upon an actual heater designed with suffi-

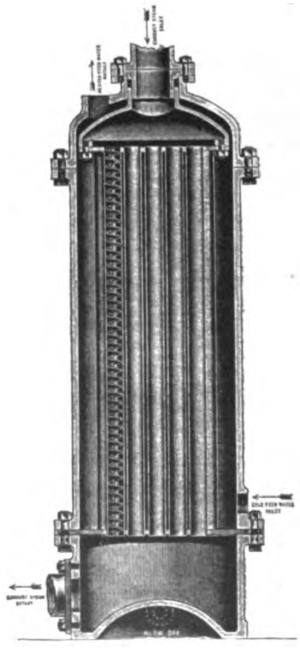

FIG. 9.—FEED WATER HEATER.

cient heating surface to heat 200 gallons per hour to about 200° Fahrenheit when working with ordinary tubes. The heater shell in both cases was filled with water at 70° Fahrenheit, and steam supplied through a ½-in. pipe. The temperature of the water in each case was as follows:

Without Deflectors.

Temperature at start	70° Fahr.
Temperature in 18½ minutes	180° Fahr.
Temperature in 21¼ minutes	190° Fahr.
Temperature in 23½ minutes	200° Fahr.

With Deflectors.

Temperature at start	70° Fahr.
Temperature in 2¼ minutes	180° Fahr.
Temperature in 3 minutes	190° Fahr.
Temperature in 5 minutes	200° Fahr.

The temperature was taken at the surface of the water in the shell, and all the steam was condensed in the tubes when the deflectors were used; whereas without deflectors a great portion of the steam passed through the tubes without in any way heating the water. Nothing is said concerning the extent to which the back pressure on the engine is increased.

Insulation Test.—A method for determining the relative insulation resistance of conductors is contributed by Dr. J. Rabinowicz to a recent issue of the "Elektrotechnische Zeitschrift." The connections are shown in Fig. 10, where G is a galvanometer; U, a switch; *x*, an insulated trough of water; K, a sample of the cable to be tested; E, a submerged copper plate; B, a battery having an e.m.f. of 20 volts; C, a condenser with a capacity of 1 microfarad, and M, a binding post. The current passing through the insulation of the cable is used to charge the condenser, C, the connection being as shown in the diagram. After a certain length of time the switch is thrown from 1 to 2, so that the condenser is discharged through the galvanometer. The insulation resistance of various cables may be compared by charging the condensers, as stated, for the same length of time for each cable and noting the deflection of the galvanometer on discharge. The cable giving the smallest deflection has the best insulation.

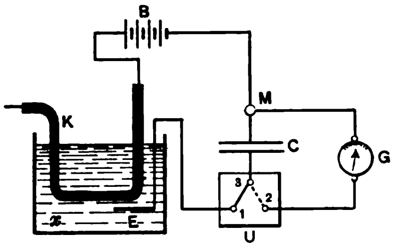

FIG. 10.—DIAGRAM OF CONNECTIONS.

Electric Arc Lamp Using Highly Refractory Electrodes.—Ewald Rasch contributes to the "Elektrotechnische Zeitschrift" an illustrated article in which he gives the principles of a new electric arc light using such highly refractory electrolytes as magnesia, oxides of thorium, zirconium, calcium, etc. In order to strike the arc the electrodes require to be heated as in the Nernst lamp; but the author claims the technical difficulties are not so great. The density at the ends of the electrodes is from 30 to 40 watts per square millimeter (0.00155 sq. in.), resulting in a very high temperature. Electrodes of magnesia, or oxide of zirconium give an arc of exceedingly white light, the gases formed also enhancing the luminosity. Electrodes of magnesia, calcium fluoride, oxide of chromium and oxide of nickel give a yellow light. Electrodes of 0.1 to 0.2 in. in diameter, yielding 600 to 1000 candle-power, give 3 to 4 candles per watt. When the arc is kept constant the ratio of candles per watt increases with increasing watts. The author found that at a pressure of 200 volts the specific luminosity in candles per watt, with constant arc length, increased up to 5.21 candles per watt and then decreases, the electrodes at that point becoming liquid; and Turmlirz, in his investigation of the mechanical equivalent of light, has shown that an ideal efficiency of 100 per cent corresponds to 5.21 candles per watt. The author claims that this light is considerably cheaper than the Welsbach incandescent gas light. In the accompanying diagram (Fig. 11) is given a comparison of the specific luminosity in candles per watt for different lamps.

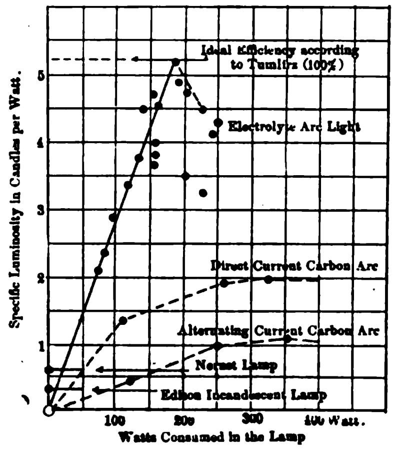

FIG. 11.—COMPARATIVE CURVES.

Alternating Frequency Indicator.—What is probably the simplest method yet devised for determining the periodicity of an alternating current is that of R. Wachsmuth, described in a recent number of the "Annalen der Physik." Clamped in a vise (Fig. 12) is a piece of watch spring, to which is fastened, by means of a bit of wax, a small square piece of white paper. When this is illuminated by a source of light fed by an alternating current, and caused to vibrate, it will appear to remain still when the frequency of the current equals the frequency of vibration of the spring. The latter may be calculated by the formula, N = 7.92 × the thickness in millimeters ÷ the square of the length in centimeters; but in practice a graduation may be easily marked on the spring itself. A small correction must be added for the paper in case of light springs. The method is applicable for frequencies as high as 150 per second, beyond which the springs become too stiff.

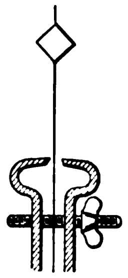

FIG. 12.

New Railway Conduit.—A recent issue of the London "Electrical Review" contains a description of a new slotted conduit for electric railways, the claims for which are that it can be rapidly laid, easily drained and cleaned, and a high insulation maintained, while the initial cost is comparatively low. Fig. 13 is a section through the conduit showing the mounting of the conductors. The sides of the conduit and slot are formed by pairs of specially-designed rolled steel Z-shaped sections of suitable length, separated at the ends, and bolted every 6 ft. to iron sleepers set in a concrete bed. The rails rest on the raised portion of the bed and are securely bolted to the iron sleepers and fastened to the sides of the conduit by tie bars. Interposed between and bolted to the ends of each pair of Z-shaped sections are iron frames which form the sides of the conduit between the sections. Iron doors are hinged to these frames, the opening of which gives free access to the conduit for cleaning, repairing, etc. The insulator holders are bolted to the Z-shaped sections within reach of the access doors, and are provided with grooves lined with suitable packing to carry and protect the insulators, which extend above and below the conductors and on both sides of the holders, to protect the back from dust and moisture and thereby maintain a high insulation. The feeder cables may be connected to the conductors under the access doors. The conduit only requires a maximum excavation of 18 ins.

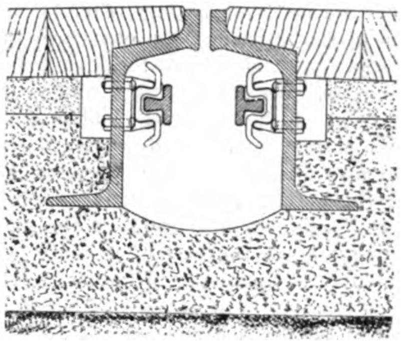

FIG. 13.—RAILWAY CONDUIT.

Testing Cells and Batteries in the Royal Navy.—According to the London "Electrical Review," two classes of cells are used in the British Navy, one having very high internal resistance, used for testing, and another used for performing ordinary work. The single-test cell is a Minotto, or modified form of Daniell, consisting of a cylindrical vulcanite container, in the bottom of which is placed a copper cup containing crystals of sulphate of copper. A piece of thick flannel or "fearnought" is placed on top of this, then a thick layer of fine sawdust, another disc of fearnought, and on this a zinc slab. An insulated wire passes up from the copper cup and forms the positive pole. The negative pole is formed by a wire leading from the zinc. The battery as supplied may be stowed away until required for use. The "fearnought"

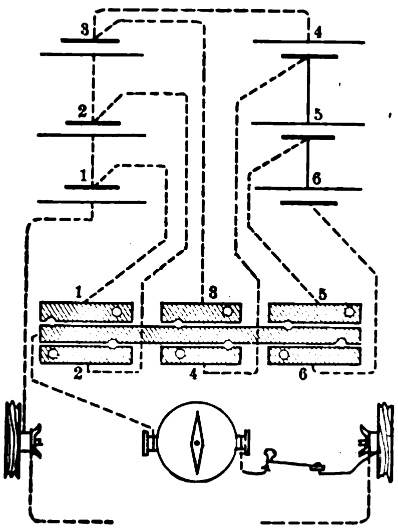

FIG. 14.—TESTING OUTFIT.

and sawdust are then soaked in fresh water, and the battery is put on short circuit for half an hour, after which it is ready for use.

The six-cell test battery, Fig. 14, consists of six Minotto cells, contained in a wooden box, and is used for high insulation tests. Besides having a hinged top, the front of the box opens outward and forms a tray, upon which is fixed a 1000-ohm astatic galvanometer, a spring key, and the main terminals. The system of brass blocks, which is fixed on the partition that keeps the battery in place, consists of one long strip of brass, having on either side of it three smaller strips, each of which is connected to the negative pole of its own cell. The long strip is connected with the galvanometer, and the negative pole of any cell can be brought into connection with it by means of a brass plug, thus putting from one to six cells into the circuit.

Mica Lagging for Steam Boilers and Pipes.—An illustrated article on the use of mica as a lagging for steam boilers and pipes, embodying excerpts from the experiments of Prof. Capper and R. Atkinson, is printed in a recent number of London "Engineering." In his experiments with four different kinds of well-known non-conducting compositions, Prof. Capper found that the steam condensed per square foot of cooling surface per hour for the different compositions was as follows:

	Thickness, inches.	Lbs.	Per Cent.
Bare pipe	....	1.516	100
A	1.6	.420	27.7
B	1.25	.399	26.3
C	1.4	.208	13.7
Mica	1.6	.177	11.67

The mica lagging is made up in flat and curved mattresses, enclosed between covers of wire netting sewn with wire. For small pipes it is molded to form and enclosed with textile covers. Minute flakes of mica are laid in parallel planes, transversely to the direction of flow of the heat, without any cement or adhesive to connect them together. The heat, therefore, on emerging from one flake has to cross an air space to enter the next flake. Here it encounters the surface resistance which is always found when heat travels from a gas to a solid, and then passes through the mica, which is a very poor conductor, to find a second surface resistance at its posterior face. The flow of heat is consequently very slow. The following table gives the results of a series of tests by R. Atkinson of the Canadian Pacific Railway. In these, tanks about 14 ins. cube were filled with water, which was then boiled and afterward allowed to cool down, the rate of cooling being noted. In one case the tank was bare, and in the other cases lagged with (1) asbestos compound, (2) magnesia blocks, (3) wood lagging and air space, (4) asbestos and wood, and (5) mica.

	Loss in Five Hours.	Temperature at end of Fifth Hour.	Mean Temp. during Fifth Hour.	Difference between Tank and Atmosphere.	Loss in Fifth Hour.	Loss in Fifth Hour per Deg. of Difference of Temp.
Bare tank	84	128	183½	55½	11	.198
Asbestos compound	53	159	163½	85½	9	.105
Magnesia bl'ks	33¾	178¼	181¾	103¾	7	.0674
Wood lagging and air space	33¾	178¼	181¾	103¾	7	.0674
Asbestos and wood	30	181	185	107	6	.056
Mica	20	192	194½	116½	5	.0428

Some Recent Electrical Patents

Revolving-Field Magnet Structure.—With a view to providing a field magnet for generators of the revolving-field type which shall be adapted for rotation at high speeds and simple in construction, B. G. Lamme has patented the structure shown by Fig. 1. The body portion of the field magnet is built up of a plurality of sections, five of these being shown in the lower drawing and numbers from 1 to 5. These sections have progressively smaller bores, the shaft having a series of shoulders at intervals a trifle less than the axial width of the magnet sections so as to allow the sections to be tightly compressed. All of the sections, of course, have the same number of polar projections, and a common polar cap or pole-piece, 12, is bolted to all of the sections. Ventilating apertures, 8, are provided through the sections, which communicate with radial ventilating slots, 7. The field magnet poles are provided with ventilating grooves, 9, allowing a circulation of air within the field coils. Patent No. 668,194.

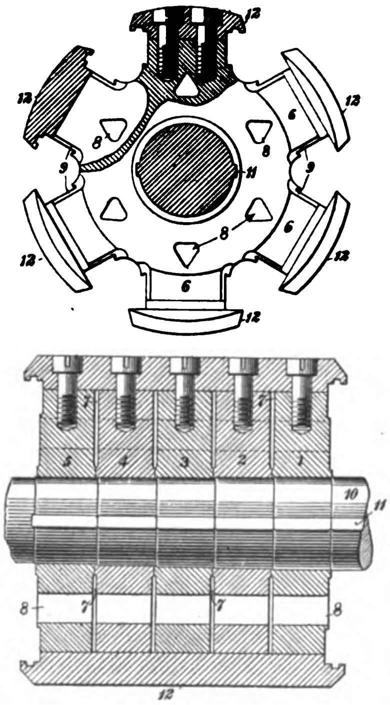

FIG. 1.—REVOLVING FIELD MAGNET STRUCTURE.

Variable-Speed Motor.—The appreciation of the utility of the electric motor for driving machine tools has developed a demand for an economical method of varying the speed of such motors, which has led to the production of various devices for this purpose. One of these, which controls the speed by varying the cross-section, and consequently the strength, of the field magnet, has been patented by Frederic A. Johnson. Mr. Johnson's method is illustrated by Fig. 2. The upper field magnet core is hollow and contains a plug, F, of magnetic material which may be drawn upward by means of the screw bolt, G, and a hand wheel, H, the hub of which is threaded to fit the screw-thread on the bolt. The plug, F, is prevented from turning by any suitable means, such as a groove in its side and a pin in the stationary part of the field magnet. The hollow cap, E, merely serves to hold the stationary portion of the field magnet core in position and has nothing to do with the regulation of speed. As the plug, F, is drawn up-

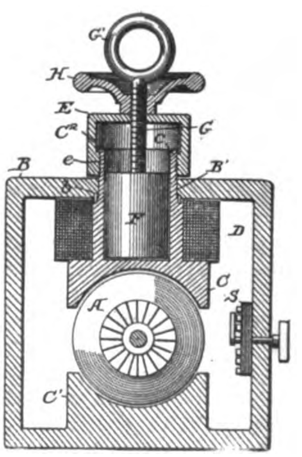

FIG. 2.—VARIABLE-SPEED MOTOR.

ward the magnetic reluctance of the circuit is increased and the flux is therefore decreased, resulting in an increase in the speed of the armature. Patent No. 666,315.

Protector for Incandescent Sign Lamps.—A well-known difficulty in the use of incandescent lamps for out-door signs is that of protecting the socket and base of the lamp from the weather. So important is this difficulty that special weather-proof lamp sockets and bases have been devised for this class of service. A method by which the ordinary wall socket and lamp may be used for sign work has been patented by E. Eckl, and is illustrated by Fig. 3. It consists of mounting the socket, B, on a base board, and providing an enclosing face plate, D, secured to the board by means of cleats, C, and having holes, E, into the mouth of each of which a socket projects; an annular cap or mantle, G, is screwed to the face plate and encloses the joint between the lamp base and the socket. The mouth of the mantle is flared outward so as to provide a channel, F, which prevents moisture from trickling down the inclined surface of the upper side on to the lamp. Patent No. 668,630.

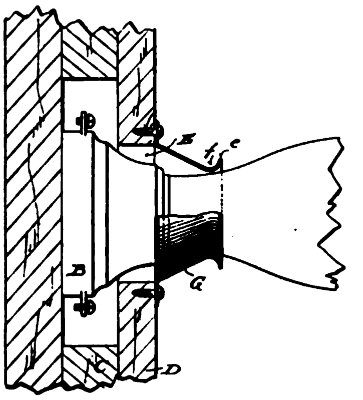

FIG. 3.—INCANDESCENT LAMP PROTECTOR.

Reserve-Fuse Box.—Fig. 4 shows a reserve-fuse box which has been patented by J. F. Lyons. The circuit terminals are attached to the plates, 2 and 3, and the circuit is completed normally by means of the fuse, 8. An auxiliary fuse, 18, is mounted on a pivoted non-conducting arm between two conducting plates, 13 and 16. This arm is normally held up in the position shown by the prop, 22, resting on the fuse, 8. When the latter blows, it is obvious that the prop, 22, will fall, allowing the arm, 11, to be thrown downward by means of the retractile spring at its rear end. The bifurcated clip, 13, straddles a pin, 20, on one of the main terminal plates, and puts the fuse, 18, in circuit between the two plates. Patent No. 668,293.

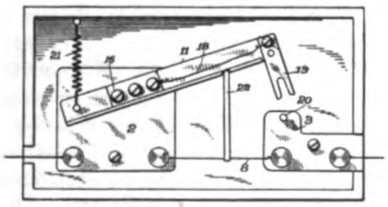

FIG. 4.—RESERVE FUSE BOX.

Wireless Telegraph Receiver.—Mr. Guglielmo Marconi, whose work is now too well known to require any detailed mention, has patented the form of wireless telegraph receiver illustrated diagrammatically by Fig. 5. In the drawing, A is the vertical conductor which is connected to one end of the primary, j^1, of an induction coil, the other end of the primary being grounded in the usual manner. The feature of the patent is in the arrangement of the secondary, j^2, winding of the induction coil. This winding is divided into two sections, one end of each section being connected to the coherer, T, and the other end being connected to the plates of a condenser, j^3. The layers of each of the secondary windings are tapered from the core out; that is to say, the first layer consists of 77 turns of wire, the second layer of 49 turns, the third of 46 turns, the fourth of 43 turns, the fifth of 40 turns, and so on until the last layer contains only three turns. A longitudinal cross-section of the coils, therefore, would show a triangular outline for each division of the secondary winding. C^1 and C^2 are choke coils, the function of which is to prevent the oscillations generated in the secondary winding of the induction coil from entering the battery circuit and weakening their effect on the coherer, T. Patent No. 668,315.

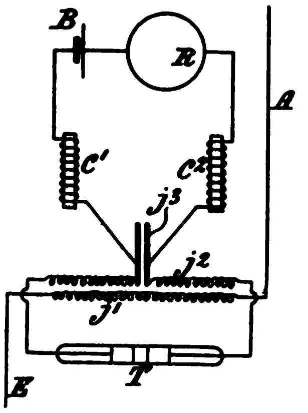

FIG. 5.—WIRELESS TELEGRAPH RECEIVER.

Controller.—It is frequently the case in street railway practice that the motors driving the car are heavily overloaded and the progress of the car made spasmodic by moving the controller handle too rapidly from the "off" position to one of the running positions. Fig. 6 illustrates a simple locking mechanism devised by Emmett W. Stull for the purpose of preventing the motorman from moving the controller too rapidly in a forward direction. On the controller spindle, B, is mounted a ratchet wheel, and on the backboard of the controller is pivoted a lever, F, carrying at its outer end a pawl, *f*, which is adapted to engage with the ratchet wheel when drawn inward toward the controller spindle. Beneath the ratchet wheel is provided a magnet coil around the controller spindle and connected in series with the motor circuit. This coil obviously magnetizes the controller spindle, the degree of magnetization varying with the amount of current flowing. The arrangement is such that when the current exceeds a predetermined limit the ratchet wheel, which is of iron, attracts the lever, F, which is also of iron, and thus draws the pawl, *f*, which is of non-magnetic material, into engagement with one of the ratchet teeth. A spring, K, is provided to oppose the magnetic attraction referred to. This spring is adjustable in order to predetermine the current flow at which the pawl will be drawn into engagement with the ratchet. The object in making the pawl, *f*, of non-magnetic material is to prevent it from being held in contact with the ratchet by residual magnetism. The inventor states that the coil used to magnetize the controller spindle would preferably be identical with the coil of the blow-out magnet. Patent No. 662,038.

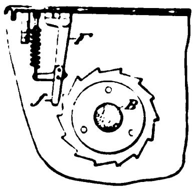

FIG. 6.

System of Electrical Distribution.—In electric railway systems where storage batteries are employed to smooth out violent fluctuations in the load, and in which the batteries are kept "floating" on the system, being charged during light-load periods and discharged during the heavy-load periods, it has been ordinarily the custom to connect the battery directly across the bus-bars in series with a booster; the function of the booster being to automatically regulate the charging and discharging of the battery. It is also customary in some other classes of service where plain shunt-wound dynamos are used, to connect a storage battery across the bus-bars for the purpose of taking care of load peaks, and permitting the use of generators the maximum output of which is determined by the average load instead of the maximum. In the latter case it has frequently been found that during the period of excessive load the dynamos would fail to take their share of the total load, and thereby cause the battery to be seriously overworked. Fig. 7 herewith illustrates diagrammatically a method proposed by Henry R. Kent for simplifying the general arrangement of storage batteries used for the purposes described and improving their operation. The generators are compound-wound machines connected up in the usual manner,

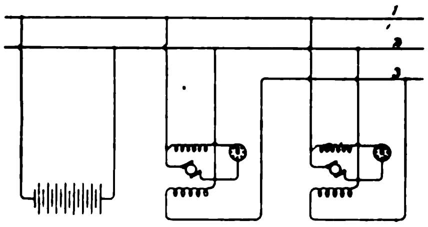

FIG. 7.—STORAGE BATTERY ARRANGEMENT.

but the battery, instead of being connected across the line bus-bars, 1 and 3, is connected between the line bus-bar, 1, and the equalizer bus-bar, 2. The effect of this arrangement is to put the battery in parallel with the armatures only, so that both the current from the battery and that supplied by the armatures pass through the series windings of the generators. It is obvious that any tendency to overload the battery will strengthen the field magnets of the generators and compel them to take a larger share of the load. Patent No. 663,659.

Steam Engine Efficiency.

To the Editor, American Electrician;

Sir:—In my article on "Steam Engine Efficiency," published in the March number of your paper I used the simple and well-known formula of the isothermal, or Mariotte, expansion curve, as the basis of comparison, not because it is simpler and hence more easily used by practical engineers, but because I believe it to be nearer correct than other formulas. On page 742 of Kent's "Mechanical Engineers' Pocket-Book" you will find the subject briefly alluded to and different authorities quoted, and perhaps I can justify my practice by the authorities there given.

Quoting the previous formula for better reference, the work in foot-pounds that should be done by 12 lbs. of steam of 150 lbs. boiler pressure, expanding 30 times, and exhausting into a condenser of 1 lb. pressure is

$$W = 144 \left[\frac{P\ (1 + \text{hyp. log } R)}{R} - p \right] R\,C\,S$$

when

$P =$ absolute initial pressure $= 165$ lbs.
$p =$ absolute condenser pressure $= 1$ lb.
$R =$ number of expansions $= 30$.
$C =$ cubic feet per pound of steam $= 2.72$.
$S =$ pounds of steam used per I. H. P. per hour $= 12$ lbs.

Making the substitutions, the result is 3,271,312 foot-pounds. As a horse-power = 1,980,000 foot-pounds per hour, the efficiency of the engine as a converter of available energy would be:

$$\frac{1{,}980{,}000 \times 100}{3{,}271{,}312} = 60.5 \text{ per cent.}$$

It is suggested by you that the adiabatic expansion curve should be used, but let us see what that would give us. Quoting the formula for this curve as given by you we have:

$$W = 144 \left[\frac{10\ P}{R} - \frac{9\ P}{R^{1.111}} - p \right] R\,C\,S,$$

and making the proper substitutions the result is 2,829,400 foot-pounds, and the efficiency is $\frac{1{,}980{,}000 \times 100}{2{,}829{,}400} = 70$ per cent.

The formula, $\frac{254{,}500\ (461 + T)}{H\ S\ (T - t)} = \text{Eff.},$ which was proposed by you is a purely theoretical one; it ignores the number of expansions entirely, and yet the engine designer is constantly compelled to limit cylinder proportions by practical considerations. In your formula,

$T =$ temperature of admitted steam $= 365.6$.
$t =$ temperature of condenser $= 102$.
$H =$ total heat of steam of 165 lbs. abs. pressure above $32° = 1193.5$.
$S =$ actual steam used per I. H. P. per hour $= 12$ lbs.

The value of H, however, should be the total heat of the steam minus the heat of the water at condenser temperature. Giving it this value and substituting the other values in your formula gives an efficiency of 59.2 per cent, instead of 55.7 per cent, as found by you. It is a mere accidental coincidence of figures that your result agrees so nearly with mine.

An engineer should be able to ascertain the efficiency of his engine under existing circumstances. He has found from the indicator cards the horse-power, and the same cards show the point of cut-off. Assuming a compound engine with cylinder proportions of 1 to 4.25, and a cut-off in the first cylinder of .25 or 4 expansions in the first cylinder, there is a total of 17 expansions, with an initial boiler pressure of say 150 lbs. Assume further that the condenser pressure = 2.20 lbs. absolute, and that careful measurements of feed water and calculations of power had shown that he was using 15 lbs. of steam per I. H. P. per hour. This is as much definite data as is generally available to a busy stationary engineer. He would like to know the efficiency of this engine. Applying the formula I have given and making proper substitutions we have:

$$W = 144 \left[\frac{165\,(1 + 2.8332)}{17} - 2.20 \right] \times 17 \times 2.72 \times 15 = 3{,}495{,}746 \text{ foot-pounds,}$$

and the efficiency would be $\frac{1{,}980{,}000 \times 100}{3{,}495{,}746} = 57$ per cent nearly.

This teaches him that 43 per cent of the steam supplied to the engine does no useful work. The larger part is condensed in the cylinder, considerable leaks through the piston or valves into the condenser, a small part is condensed by radiating its heat into the atmosphere, and some is wasted by the clearance spaces in the cylinders and receiver connections. Were all of these losses eliminated an efficiency of 100 per cent would be realized. It is true that this is impossible in practice, and it is also impossible to realize 100 per cent mechanical efficiency, but if we find the latter to be only 75 per cent or 80 per cent we search for the cause and apply a remedy, for a well-constructed steam engine ought to have a mechanical efficiency of 88 per cent to 93 per cent. It is in order to give the practical engineer a clear conception of the losses in his engine which come within the domain of man to reduce or to bring by skill to nearly a 100 per cent standard of efficiency that I make use of the formula I have given.

A. F. Nagle.

Montclair, N. J.

NEW BOOKS.

The Copper Handbook. By Horace J. Stevens. Houghton, Michigan: Horace J. Stevens. Paper; 328 pages, 5¾ x 8¾ ins. Price, $1.

This is a very comprehensive discussion of the copper industry generally, and begins with a historical review of the Lake Superior copper region, including a political history of the Upper Peninsula, and the discovery of copper. The second section of the book is devoted to miscellaneous information, including a sketch of the Michigan College of Mines. This is followed by a section outlining the geological characteristics of the country, after which is given a vast amount of statistical information, mostly tabular, relating to copper production, dividends paid by various mines, capitalization of mining companies, American copper production and exports, English copper statistics, the world's copper production, etc., etc. The final section of the book is descriptive of defunct and active copper mining companies. The book should be of great value to anyone interested in the copper mining industry.

The Progress of Invention in the Nineteenth Century. By Edward W. Byrn, A. M. New York: Munn & Co. Buckram; 476 pages, 6½ x 9½ ins.; 306 illustrations. Price, $3. Half red morocco, with gilt top, $4.

As its title would indicate, the scope of this book is unusually extensive; consequently it could not be made thorough within the limits of a single volume. As the author states in the preface, "it is simply a cursory view of the century in the field of invention, intended to present the broader bird's-eye view of progress achieved." The "bird's-eye view" is a very interesting one for the most part, but it is marred by inaccuracies and important omissions in spots. The description of the dynamo credits the commutator and brushes with "gathering up all the impulses of the same polarity and conducting them away by one brush and gathering those of opposite polarity and conducting them away by another brush," which is a crude way of stating it. Polyphase work is dismissed with the slovenly statement that "an important development * * * is to be found in what is known as the polyphase multiphase, or rotating current, pioneer patents for which were granted to Tesla May 1, 1888." A most ridiculous statement is found on page 71, to-wit: "Although the alternating current is used for arc light, only continuous current can be used for the incandescent lights." In the chapter relating to steam engineering the author falls into the common error of crediting Stephenson with the invention of the reversing link valve motion and Seguin with the multitubular boiler, when it is well known that one of Stephenson's pattern-makers devised the link and Nathan Read the tubular boiler. Aside from inaccuracies of the kind enumerated, however, the book makes very interesting reading.

NOTES.

The Milwaukee Industrial Exposition.—The Board of Directors of the Milwaukee Industrial Exposition are seriously considering a suggestion to make this year's exposition almost entirely electrical.

A Correction.—In the description of a 75-light dynamo which was published in the January number it was stated that the armature core should have 40 slots. This was a misprint; the correct number of slots is 41.

Summer School for Apprentices and Artisans. — The University of Wisconsin, Madison, Wis., has made quite a departure in educational work in the shape of a summer school for machinists, carpenters, engine tenders, shop foremen, superintendents and other practical workers. The session begins July 1 and ends August 9. Complete information concerning this course may be obtained from Mr. J. B. Johnson, Dean of the College of Engineering, at the University.

United Electrical Contractors' Association.—At the annual meeting of the United Electrical Contractors' Association of New York State, held in January of the present year, it was decided to issue a call for a meeting at Buffalo on July 17 for the purpose of forming a National Electrical Contractors' Association. This meeting will be held at the Builders' Exchange Building, Buffalo, at 10 A. M., on the date mentioned. Further information may be had from the secretary of the association, W. H. Morton, 31 Catharine Street, Utica, N. Y.

Southwestern Gas, Electric & Street Railway Association.—The third annual meeting of this association will be held at Houston, Tex., on April 19-22. The headquarters will be at the Rice Hotel. The papers scheduled for this meeting are as follows: "Municipal Ownership vs. Private Corporations," by T. B. Miller; "Association Between Meetings," by C. A. Newning; "Station Work," by Geo. Cushman; "Street Railways of Texas," by F. E. Scovill; "Inspection," by W. S. Rathell; "Cheap Fuel and How to Use it Economically," by L. T. Fuller; and "Water Power for Small Plants," by F. R. Starr.

Water Power Development in Nebraska.—A company has been organized for the purpose of developing an extensive water-power plant on the Niobrara River, Nebraska. A dam about 2000 ft. long and a canal about 7 miles long will be built. It is expected to realize 1500 to 2000 horse-power, which will be distributed electrically throughout the adjacent territory. A 35-mile electric railway in Knox and Boyd Counties is contemplated, which will be supplied with power from the proposed hydraulic plant. Mr. Arnold C. Koenig, of Grand Island, Neb., has been appointed chief engineer for the undertaking.

Electrical Development in the West Indies.—The British Colonial Office on the island of Trinidad has granted a charter to the Trinidad Electric Company, which is composed of Montreal capitalists, for the construction of an electric railway line and lighting plant in the city of Port of Spain, the capital of the island. The Trinidad Electric Company obtained control of the existing mule railway lines and lighting plant in Port of Spain some months ago, and the present charter enables it to convert the railway lines into electric trolley lines, and to extend the electric lighting plant to all parts of the city and its suburbs.

The Reflection of Light.—Incandescent lamps and other sources of illumination are frequently used under great disadvantage by reason of unfavorable wall surfaces, the colors of which are such as to absorb the light instead of reflecting it. In a recent issue of a German paper there was given a table showing the percentage of light reflected by surfaces of various colors. It will be advantageous for central station men to use this table as an aid in making installations of incandescent lamps; the table is reprinted below:

Surface.	Per cent.
Black velvet	0.4
Black cloth	1.2
Black paper	4.5
Dark blue	6.5
Dark green	10.1
Bright red	16.2
Deep yellow	20.0
Pale blue	30.0
Pale yellow	40.0
Pale green	46.5
Pale orange	54.8
White	70.0
Mirror surface	92.3

These figures do not take into consideration actinic or chemical effects, but only the optic effect.

A Short But Heavy Duty Transmission Line.—The line which conducts current to the electrolytic plant of the Boston & Montana Smelter at Great Falls, Mont., from the power-house (hydraulic) is probably the only one of its kind in the world. Each conductor of the circuit consists of bars of copper 2 ins. by 12 ins., with the ends lapped and bolted together. The cross-sectional area of each conductor is therefore 24 sq. ins. The bars rest on glass blocks on top of a wooden trestle work built for this line. It is found that 10,000 amperes heats the conductor comfortably warm in cool weather. As the dynamos that supply this line are run by water wheels which have no governors on account of the load being constant, it is necessary to provide against a runaway in case the circuit should accidentally be broken. For this purpose there is an electro-magnetic relay connected in the main circuit, and so arranged that if the current falls off, a switch is instantly closed, putting on an artificial load in place of that accidentally cut out. The artificial load consists of common iron steam pipe filled with circulating water from the river and used as dead resistance.

The National Standardization Bureau.—The bill to establish a National Bureau of Standards passed the U. S. House of Representatives on March 2 and the Senate on March 3. Several amendments were made, the effect of which will reduce the items of appropriations, but these will not materially affect the establishment or the work of the bureau.

A Railway Consolidation in California.—The Oakland Railway Company, which operates 24 miles of railway, has been sold to the Oakland Transit Company, formerly operating 81¼ miles of railway, so that the latter company now operates 105¼ miles of railway. With one exception, the Oakland Transit Company controls all the street railway lines in Alameda, Berkeley and Oakland.

The Steam Engine and its Competitors.—In an extremely interesting paper read at the February meeting of the American Institute of Electrical Engineers, Mr. W. J. Hammer devoted considerable space to a discussion of the steam engine and rival prime movers. This section of Mr. Hammer's paper included a letter from Dr. R. H. Thurston which contained the statement that the best work so far done by steam and gas engines is practically on a par; each has delivered a net horse-power with a consumption equivalent to about 1 lb. of good coal. Dr. Thurston also expressed the opinion that the steam engine has attained so nearly its limit that further progress under commercial conditions would seem likely to be very slow and to be dependent mainly upon the possibility of extending the thermodynamic range of working temperatures. Improvements in the direction of higher pressures and superheated steam should, he said, permit an increase in efficiency by something like 50 per cent, which would mean a decrease in fuel consumption of about 25 per cent. On the other hand, there is much larger opportunity to reduce the wastes which now characterize the gas engine than to extinguish those affecting the steam engine. The gas engine, he said, had come to be a formidable rival of the steam engine and is gaining upon it rapidly. Mr. Hammer described several large gas engines of European manufacture, among them the Cockerill engine for utilizing blast-furnace gases, which was described in our issue of August, 1900. Mr. Hammer also described an electrical plant in Upper Silesia driven by Otto-Deutz gas engines of 200 and 300 horse-power, the smaller engines being direct-coupled to direct-current dynamos, and the larger ones to alternating-current dynamos. The circuit load consisted of several thousand incandescent lamps and a number of motors. The experimental sulphur-dioxide engine at the Charlottenburg High School, which was referred to in this department of the April, 1900, number, was also described by Mr. Hammer, as well as the Parsons turbines at the Elberfeld three-phase alternating-current plant.

Electrical Equipment in Industrial Plants.

The plants described in our leading article this month exemplify strongly both the advantages obtained by the electrical distribution of power in industrial plants and the flexibility of alternating currents as applied to a composite service. A number of small, inefficient and troublesome steam plants have been displaced by a single power generating plant easily attended and of high economy. Three separate classes of service are supplied from a single source, so that there is only the one class of generator to handle. This, of course, is not new practice, several isolated plants and many central stations being operated in this way; and judging from the rate of increase in the number of these plants, the convenience of operation would appear to overbalance the well-known disadvantages inherent in the use of induction motors.

One of the features of the St. Joseph plant is an elevator motor which is thrown on and off with the elevator, as in direct-current practice. In this case, however, the motor is thrown on, apparently, without any auxiliary resistance in circuit, the impressed e.m.f. being reduced from 220 volts to 140 volts by an ordinary transformer. The effect of this upon the busbar e.m.f. must be highly interesting, and a contemplation of this procedure naturally arouses doubts as to the advisability of saving the expense necessary for wound rotors with inserted resistances, when the saving entails such objectionable results as must follow from the practice described.

◆

The Heat Waste of a Gas Engine.

It is, of course, well known that the work indicated in a gas engine cylinder accounts for only about 20 per cent of the heat energy due to the combustion of the gas, and the utilization of some of the rejected heat units forms an interesting problem. Some designers have attempted to extend the range of expansion, with varying degrees of success; the Atkinson two-cycle engine is a notable example of effort in this direction. One of the most attractive plans for raising the economy, and one that would naturally occur to a speculative mind, is to utilize the heat in the jacket water and exhaust gases for some purpose such as supplying a heating system. This is obviously open to the objection that it is difficult to operate satisfactorily two systems different in character when one is entirely dependent upon the other. In due course of progressive reasoning, one reaches the suggestion that the discharged jacket water and exhaust gases be made to operate an auxiliary steam engine, either a totally separate machine or arranged to deliver power to the gas engine shaft and, therefore, regulated along with it. The heat in the exhaust gases would be used to evaporate as much of the jacket water as possible into steam to supply the auxiliary engine.

A rough investigation of a case based on results obtained in gas engine practice, however, seems to show that the saving obtainable, although appreciable, would not be so great as might at first be supposed. For example, a test of an Otto engine indicating 13 horse-power showed that 900 lbs. of jacket water passed through per hour and was raised in temperature from 64 to 110° Fahr. The exhaust gases had a temperature of 1210° Fahr., and the heat contained in them was rejected at the rate of about 66,000 B. T. U. an hour. Assuming that the temperature of these gases could be usefully reduced to 80° Fahr. by transmitting their heat to water through the medium of a vaporizer, there would be about 46,000 B. T. U. an hour available for evaporating water into steam for the auxiliary engine. Supposing that the steam pressure to be carried were 120 lbs. by gauge in order to admit of compounding, then our 46,000 heat units would evaporate about 42 lbs. of water an hour, the supply being taken from the delivered jacket water having a temperature of 110° Fahr. This quantity of steam would enable the auxiliary engine to develop about two horse-power, and increase the mechanical output of the fuel about 15 per cent. It might be that in larger sizes such a combination would figure out to better advantage, but it is doubtful if the gain in net power would justify the complication of the added parts and the expense of providing them, under existing conditions of practice.

◆

Alternations and Cycles.

Several correspondents appear to be confused as to the distinction between an alternation and a cycle. For purposes of application it would suffice to explain that two alternations make one cycle, but for the man who always (and commendably) desires to "know why," this explanation is unsatisfactory, notwithstanding its absolute accuracy. When an alternating current passes from its maximum strength in one direction to the same strength in the opposite direction it accomplishes one "alternation" or reversal;

then it goes back again to maximum strength in the first direction, passing through another alternation. When it has done this a complete "cycle" has been performed, because the current has come back to the condition in which it was at the beginning of the cycle and any further variation will be merely a repetition of what has already occurred. A cycle is a series of events or operations which occur or are performed over and over successively in the same order, hence the application of the name to the two reversals of current. A cycle is also called a "period" by some engineers; this appellation is used to a greater extent in Great Britain than in this country. The frequency of an alternating current when given in cycles is always the number of cycles per second; when stated in alternations, it is always the number of alternations per minute. Thus, the current in a 60-cycle circuit passes through 60 cycles per second, and is also said to make 7200 alternations, meaning 7200 reversals or half-cycles per minute. Similarly, "133 cycles" and "16,000 alternations" are synonymous terms.

Steam Engine Efficiency.

A discussion of steam engine efficiency might be indefinitely prolonged unless the parties to it could agree upon a close definition of the word "efficiency." Last month we gave expression to an opinion concerning Mr. Nagle's method of computing efficiency, published in the same number, and suggested what seemed to us a somewhat more accurate method. That Mr. Nagle does not agree will be evident from a perusal of his very interesting letter, printed elsewhere in the present number; that the real cause of disagreement is a discrepancy between the two conceptions of 100 per cent efficiency will be evident also. If 100 per cent efficiency be taken to mean the performance of the maximum work possible under conditions of isothermal (hyperbolic) expansion, then Mr. Nagle's method is correct. It is difficult to see, however, why hyperbolic expansion should be made the basis of efficiency, because an engine working with no losses in the cylinder could not possibly show hyperbolic expansion. Mr. Nagle himself states in his letter that if all the losses due to cylinder condensation, piston and valve leaks and clearance spaces could be eliminated, an efficiency of 100 per cent would be realized; now, under these very conditions the steam would expand adiabatically and the ideal curve obtained could not be a hyperbola. Consequently the hyperbolic formula is scarcely consistent with his own statement of what 100 per cent efficiency would be.

It was by no means intended to suggest last month that the adiabatic curve should be made the criterion of efficiency. We only stated that if any curve were to be taken it should be the adiabatic for the reason that if the cylinder were a non-conductor of heat the steam would expand adiabatically, and a non-conducting cylinder would certainly be an essential to the no-loss condition. However, no one knows accurately what the formula for adiabatic expansion is. The formula printed last month was based upon the adiabatic formula commonly quoted, but it has never been verified—naturally, since a non-conducting cylinder has yet to be made. As we pointed out before, it seems much simpler and more rational to ignore expansion curves and start from the available energy contained in the steam; then see how much of this is accounted for by work. This is what we suggested, and what we still consider the rational basis of efficiency. The admitted steam contains a certain number of heat units and the fraction $\frac{T - t}{461 + T}$ represents the proportion of these heat units that are available for work. If all of the heat units in the steam be represented by H, then the total heat available is $H \frac{T - t}{461 + T}$, regardless of expansions or anything else. If the exhaust steam does work in heating feed water after leaving the engine, that is a separate operation which raises the plant efficiency but has no effect upon the efficiency of the engine as a converter of energy because it alters neither the heat units delivered to the machine nor those thrown out in the exhaust.

When all is said and done, however, it really remains a matter of the definition of 100 per cent efficiency. The British Institution of Civil Engineers recommends that the performance of an engine be stated as economy in thermal units per minute per indicated horse-power, which is highly practical. The thermal units are taken as the total heat of the admitted steam minus the heat of its weight in water at exhaust temperature. For purposes of comparison, however, an ideal engine is made the standard, the performance of which is assumed to follow the Rankine cycle—feed water at exhaust temperature, admission up to cut-off at constant pressure, adiabatic expansion down to the back pressure, and exhaust at constant pressure corresponding with the lower temperature limit. Rankine's formula for work done by a cubic foot of steam expanding adiabatically against a back pressure, p, and exhausting at a pressure, p_e, modified to apply to a pound of steam, reads

$$W = 778 \left[T - t \left(1 + \text{hyp log} \frac{461 + T}{461 + t}\right) + \frac{T - t}{461 + T} L + R \left(p_e - p\right) \right]$$

in which L is the latent heat per pound of steam at admission and R the number of expansions. This would form a nice subject for study on a rainy Sunday afternoon. No less an authority than Prof. C. H. Peabody gives the efficiency of steam in an engine cylinder as the ratio of work done to the heat energy supplied, figuring the latter above exhaust temperature, and so it goes. As we remarked before, it all depends upon what is meant by efficiency.

A Useful Form of "Dead" Resistance.

Suggestions have been made by several persons to the effect that instead of wasting the energy commonly expended upon resistance coils in series with fan motors, electric bells, etc., it might be turned to account by using incandescent lamps for "dead" resistance. While the practicalness of these suggestions may be to a high degree problematical so far as motors and bells are concerned, there is no doubt that the resistance coils usually put in series with enclosed-arc lamps could in many cases be displaced electrically by incandescent lamps to good advantage. One 6.6-ampere arc lamp on a 110-115 volt circuit, for example, lacks about 35 volts of taking the full circuit e.m.f., and this voltage is therefore available for the incandescent lamp or lamps. A single lamp of about 64 candle-power would just fill the gap, and as this would permit an economy of 3.6 watts per candle the lamp should stand the fluctuations in impressed voltage reasonably well. The unsteadiness would probably unfit the light for reading purposes, but it could be utilized for general illumination. If memory serves, a few sporadic attempts have been made to employ incandescent lamps in this way, putting a parallel group of lamps of low candle-power in series with one arc. Nothing has been heard lately, however, concerning the results of these trials or as to any extension of the plan.

THE CONSTRUCTION OF A DIRECT-CURRENT FAN MOTOR.

The accompanying engravings illustrate a compact form of direct-current fan motor, the construction of which is easily within the ability of anyone at all experienced in the use of machine tools. The motor is of the bipolar ironclad type; the field magnet having the form and dimensions shown by Fig. 5. Fig. 2 is an axial cross-section of the motor frame taken vertically. It is intended that the magnet proper shall be of cast-steel set into a thin cast-iron shell, the front cap of which is integral with the shell, as indicated by Fig. 2; but if the builder should prefer, the entire structure may be made a single casting of steel. The first construction requires somewhat more machining, as it will be necessary to turn up the exterior of the field magnet and bore out the cast-iron shell so that the two will fit snugly together; but the result will be a very much better-looking machine than if the field magnet structure were wholly of cast-steel. There is only a single bearing, the shell of which is cast integral with the motor casing, as indicated in Fig. 2, and this is provided with a grease cup of the ordinary gravity-feeding type. A cross-section of the cup is included in Fig. 2, and a dimensioned drawing of it is given by Fig. 1.

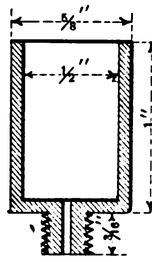

FIG. 1.

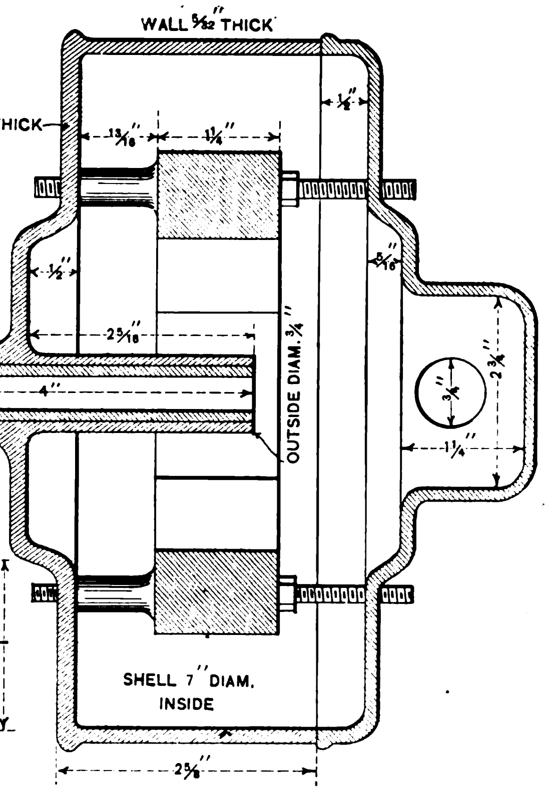

FIG. 2.—CROSS-SECTION OF MAGNET AND SHELL.

The rear cap of the motor case, a vertical cross-section of which is shown in Fig. 2, is detachable, and is provided with a recess extension near the center to accommodate the commutator. The brush-holders, which are of the ordinary tubular type, are mounted in insulating bushings in opposite sides of this extension. This end cap is intended to be of cast-iron no matter which way the field magnet is constructed. It is secured in place by means of nuts which thread on four machine screws that pass completely through the field magnet. These four screws also serve to secure the fan guard to the opposite side of the case, and in the event that the field magnet proper is made of cast-steel and the case of cast-iron, the same screws serve to hold the magnet in the case, as indicated in Fig. 2 and Fig. 3, which show this construction. The photograph shows the field magnet casing mounted on a trunnion pedestal, but of course the builder can use any form of mounting he may prefer. This is about as simple, however, as any that an amateur can construct that will provide both vertical and horizontal adjustment. The trunnion yoke, shown in Fig. 3, is a separate casting with a stem fitting into a hole in the pedestal, which enables the motor to be swung around about a vertical axis, while the trunnions provide for adjustment up and down about a horizontal axis.

The armature core is of the ordinary drum type provided with 12 holes for the winding, the holes being located so that the outer edges are 1/16 in. below the edge

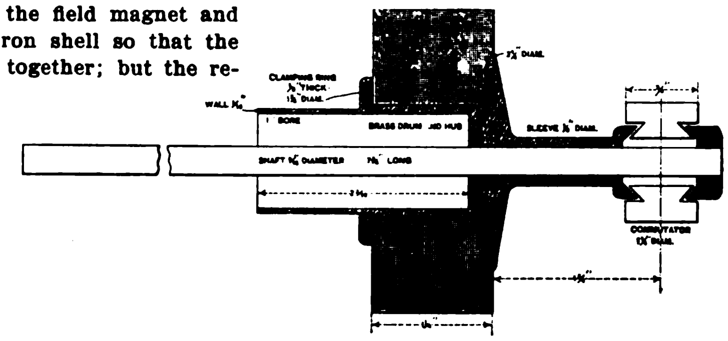

FIG. 4.—CROSS-SECTION OF ARMATURE CORE AND COMMUTATOR WITH SHAFT.

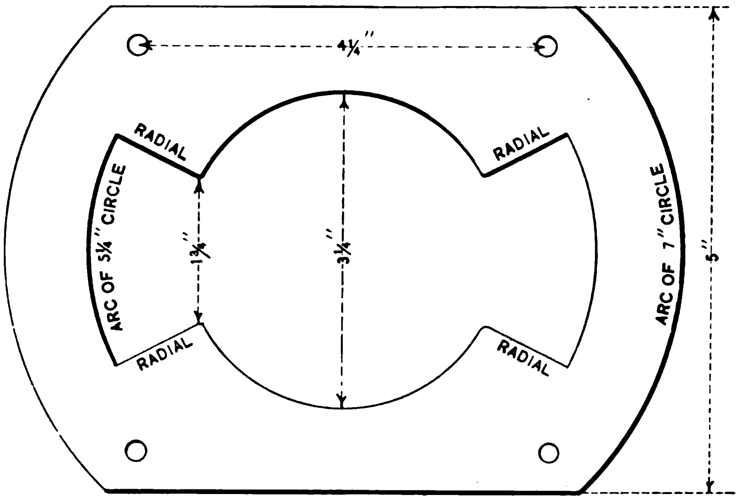

FIG. 5.—FACE VIEW OF FIELD MAGNET.

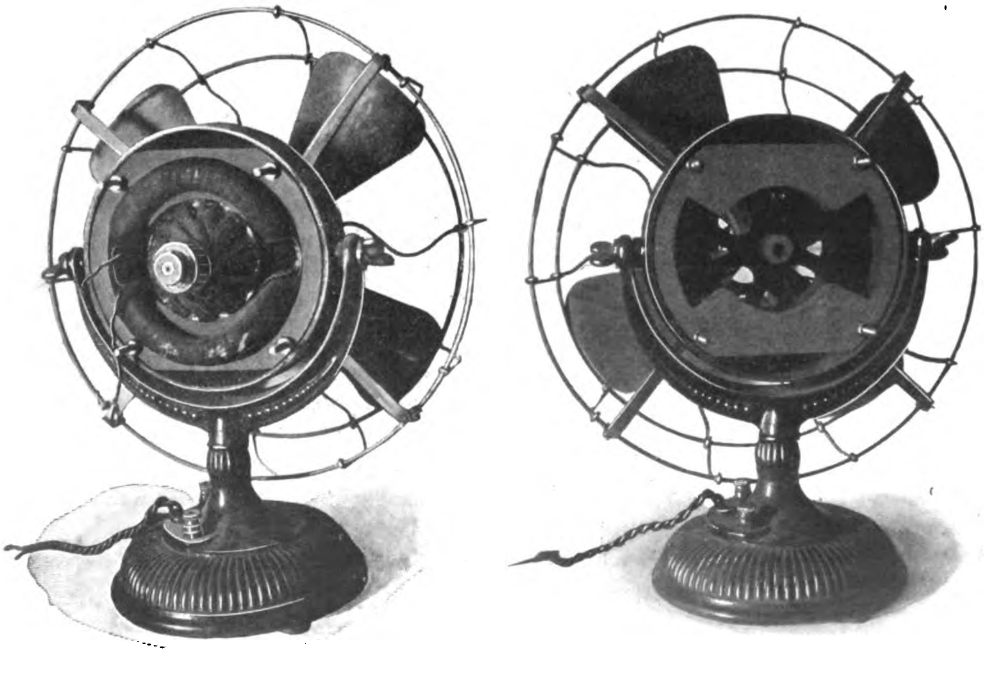

FIG. 3.—VIEW OF MOTOR WITH AND WITHOUT FIELD COILS AND ARMATURE.

of the armature core, as indicated in Fig. 7, which shows the condition of an armature disc before the core is assembled. After assembling the discs on the shaft the thin webs between the winding holes and the periphery of the disc must be cut away, preferably with a milling tool, but allowably with a hack-saw and file, leaving the discs as indicated by Fig. 8. The holes for the winding are ⅝ in. in diameter. Fig. 4 is a cross-section of the complete core with the shaft and commutator. The brass drum on which the core discs are mounted is open at the end opposite from the commutator to allow the bearing shell on the motor frame to project into the core. There is no bearing beyond the commutator. Fig. 6 is a cross-section of the brush-holder with its insulating bushing.

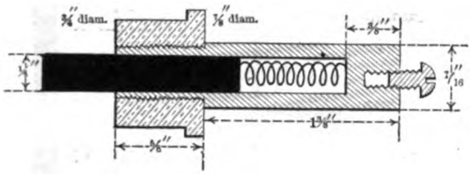

FIG. 6.—CROSS SECTION OF BRUSH HOLDER.

The armature winding consists of 12 coils of No. 33 double silk-covered magnet wire, each coil containing 185 turns. A winding diagram may be made by drawing an armature disc and numbering the slots successively. The winding should proceed as follows: First wind a coil in slots 1 and 6, twisting the terminals together lightly near slot 1. Then turn the armature core through half a revolution and wind a coil in slots 7 and 12, twisting the terminals together near slot 7. The next two coils should preferably come in slots 9 and 2, and 3 and 8; the next two in slots 5 and 10, and 11 and 4. This will complete half the armature winding. The seventh coil goes in slots 10 and 5 on top of the coil previously wound in those slots, but the terminals are twisted together at the opposite side of the coil near slot 10. The eighth coil goes in slots 4 and 11; the ninth coil goes in slots 2 and 9 with the terminals left near slot 2; the tenth coil goes in slots 8 and 3 with the terminals near slot 8; the eleventh coil goes in slots 12 and 7 with the terminals near slot 12; and the twelfth coil goes in slots 6 and 1 with the terminals near slot 6.

In winding the coils, care should be taken to preserve identification of the starting and finishing terminals of each coil. The best plan is to tie a knot in the starting terminals and then leave the finishing terminals straight. When all the coils are in place untwist the 12 pairs of terminals and connect the coils together as follows: Twist the finishing end from slot 1 to the starting end from slot 2; finishing end from slot 2 to starting end from slot 3, and so on all the way around the armature. Then carry the twisted terminals out to the commutator, the pair from slots 1 and 2 going to segment No. 1, and the pair from slots 2 and 3 going to segment No. 2, and the pair from slots 3 and 4 going to segment No. 3, and so on all the way around. The terminals of the coils cannot be pulled through straight out to the commutator but must be laid flat along the head of the armature winding and bound into place by means of strings as illustrated in Fig. 10, which was made from the photograph of the complete armature. This precaution is necessary in order to prevent the edge of the recess in the removable cap from chafing the leads running to the commutator.

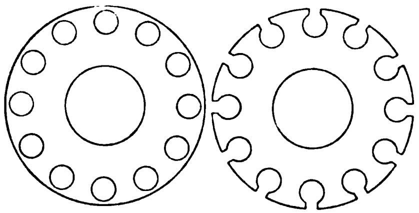

FIG. 7. FIG. 8.
ARMATURE DISCS.

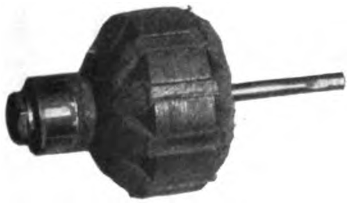

FIG. 10.—VIEW OF ARMATURE.

The commutator has 12 segments, and is preferably of the construction illustrated in Fig. 4, but the reader is strongly advised to purchase a commutator from any one of the various manufacturers rather than to attempt to construct it. The winding of the armature across the heads must be compressed until it measures not more than 2¾ ins. along the shaft. The field magnet winding consists of two coils of No. 25 single cotton-covered magnet wire wound into the ordinary rectangular outline and then taped and bent to the form shown in Fig. 11. Each coil must contain 30 layers of wire and each layer must have 44 turns, making 1320 turns per coil.

The machine is designed for two speeds; with the field magnet coils connected in parallel it will run at the maximum speed, and with the coils connected in series it will run at the lower speed. The magnet coils are connected in series with the armature irrespective of their relation with each other. A switch should be provided in the base of the motor for the purpose of cutting the fan in and out of circuit, and changing the relation between the field coil connections. A diagram of the switch is shown by Fig. 9. The details of its construction may be worked out to suit the individual ideas of the builder, the only essential features being that it shall be mounted on a non-combustible base, preferably of slate or porcelain, with the metal parts so disposed that they cannot possibly come in contact with the pedestal base. The connections between the field magnet coils and the switch in the base are preferably established by means of ordinary lamp cords led through holes in the end cap and in the pedestal base. Each of these holes should be insulated with a substantial fiber bushing. A double-pole snap switch should be inserted between the motor and the supply circuit.

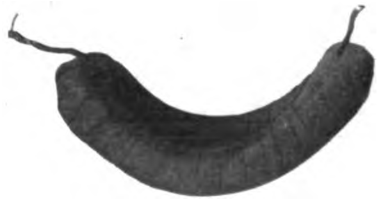

FIG. 11.—FIELD COIL.

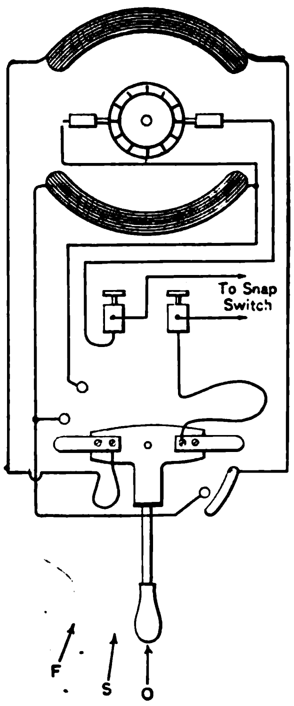

FIG. 9.—DIAGRAM OF SWITCH CONNECTIONS.

Fig. 12 shows the complete motor with the fan and guard, but the reader is advised to purchase both fan and guard from any dealer in electrical supplies; the design of a propeller fan is not a sufficiently simple matter to justify an amateur in attempting it, and the same is true of the fan guard, although to a lesser degree.

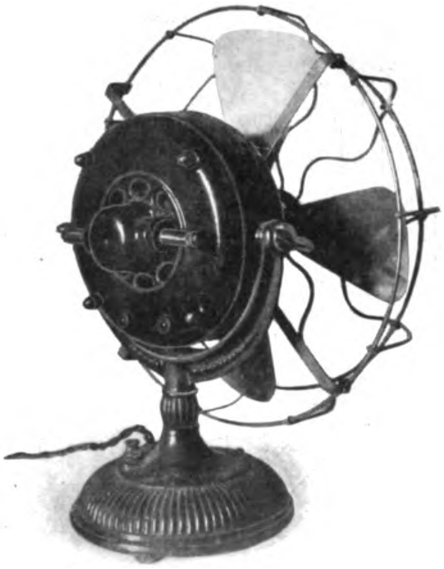

FIG. 12.—COMPLETE MOTOR.

It is only necessary in ordering these two parts to specify the diameter of the fan, size of the shaft, and the distance apart of the machine screws which hold the fan guard on. The motor is intended to drive a 12-in. fan at 1600 r.p.m. on a 110-volt circuit.

INTERIOR WIRING.

THE WIRING OF A LARGE HOTEL.

BY CHARLES E. KNOX.

The present article of this series will be devoted to the consideration of the characteristic features of the electric light wiring of a large hotel building. So far as the electric wiring is concerned, a hotel may be considered as being divided into three distinct portions; namely, the working or service portion, the public portion, and the apartment or bed-room portion. The first usually includes the basement and cellar floors, the second includes the ground or first floor, and the third the apartment or bed-room floors. (On account of space limitations characteristic floor plans of the latter two portions only will be shown in this number.)

The service or working portion of the hotel usually includes the kitchen, serving rooms, storage space, machinery, etc. The lighting of these portions is relatively simple. The lighting of the kitchen and serving rooms is, in the majority of cases, most effectively and economically accomplished by means of cluster fixtures, although drop cord outlets are used to advantage in some cases. If cluster fixtures are used they should be controlled by local push-button switches, as the fixtures usually have short stems and the key sockets at the lamps are therefore quite out of reach. Special receptacle outlets should be placed under the hood, over the kitchen ranges. The engine, boiler, pump and other machinery rooms are generally best lighted by means of

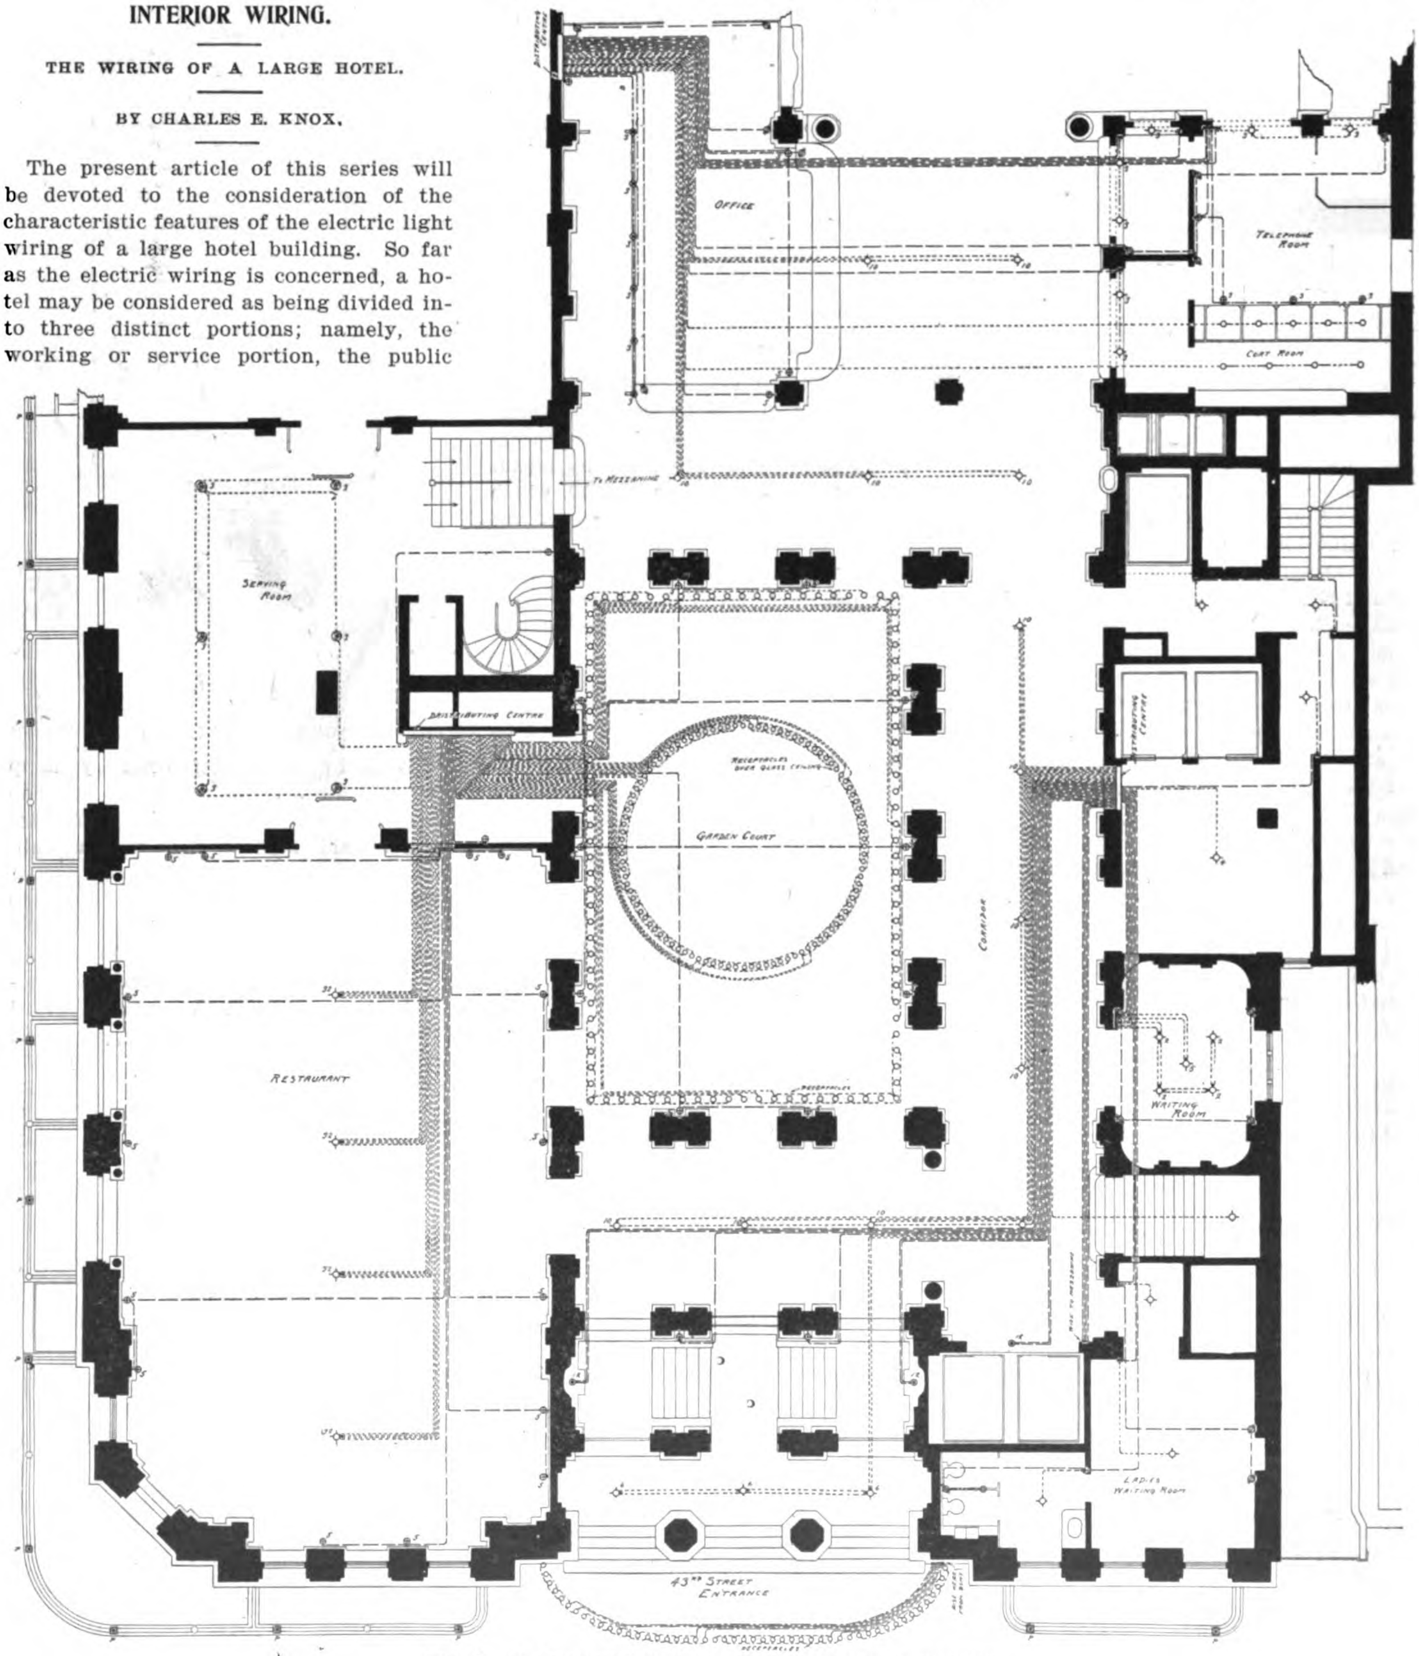

FIG. 1.—GROUND FLOOR PLAN AND DIAGRAM OF WIRING.

drop cord and wall socket outlets, placed with special reference to the machine, or portion thereof, to be lighted.

The lighting of the second (public) portion of the hotel, should for obvious reasons be more or less decorative in effect, and on a larger and more splendid scale than the rest of the house. It is therefore necessary not only to provide a large number of lights on these floors, but to obtain a suitable grouping and arrangement of the lights themselves. To this end a conference between the architect and the electrical engineer should be held for the purpose of fully discussing the question of lighting.

The restaurant is usually lighted by ceiling and bracket fixtures. In some cases individual lights on the tables are used, but this is rarely the case, owing to the difficulty of getting wires to the tables. Where it is possible to decide beforehand on exactly what points the tables will be located, the current supply can be carried to the table lights by means of floor outlets. It is usually impossible, however, to locate the tables beforehand, and it is rarely attempted. Of course, base plug outlets may be used for connecting with tables placed against or near the walls. The lighting of the café, palm garden and other rooms of similar character is usually less conventional than that of the restaurant, for the reason that the architectural treatment of these rooms is generally quite different from the restaurant.

The lights in the restaurant and café should be controlled at a point either inside or just outside the room in which the lights are located. These switches should preferably be placed in the cutout cabinet at which the branch circuits originate. The lights in the entrance corridor, etc., should generally be controlled at the hotel office.

Coming to the third (apartment) portion of the hotel, the first point to be decided upon is the number of lights to be allowed for an average-sized bed room. If it be necessary to keep the number of lights down to the lowest limits, ceiling outlets should be dispensed with and two single side bracket outlets provided, one located on each side of the bureau or dressing table. If the scheme of lighting permits a more elaborate scale, a ceiling outlet or base plug outlet for a reading light may be added, and in some cases both may be provided. Each of the rooms at the Waldorf-Astoria Hotel was provided with two wall lights (one on each side of the bureau), a ceiling outlet and a base plug near the bed for a reading light. The number of lights in the ceiling fixture varied, of course, with the size of the room. The ceiling lights were controlled by two switches placed near the door, one switch controlling a single light (called the "night light") and the other switch controlling the remaining ceiling lights. The side bracket and reading lights were controlled by the key sockets only. A light was also provided in each bed-room closet. This closet light was

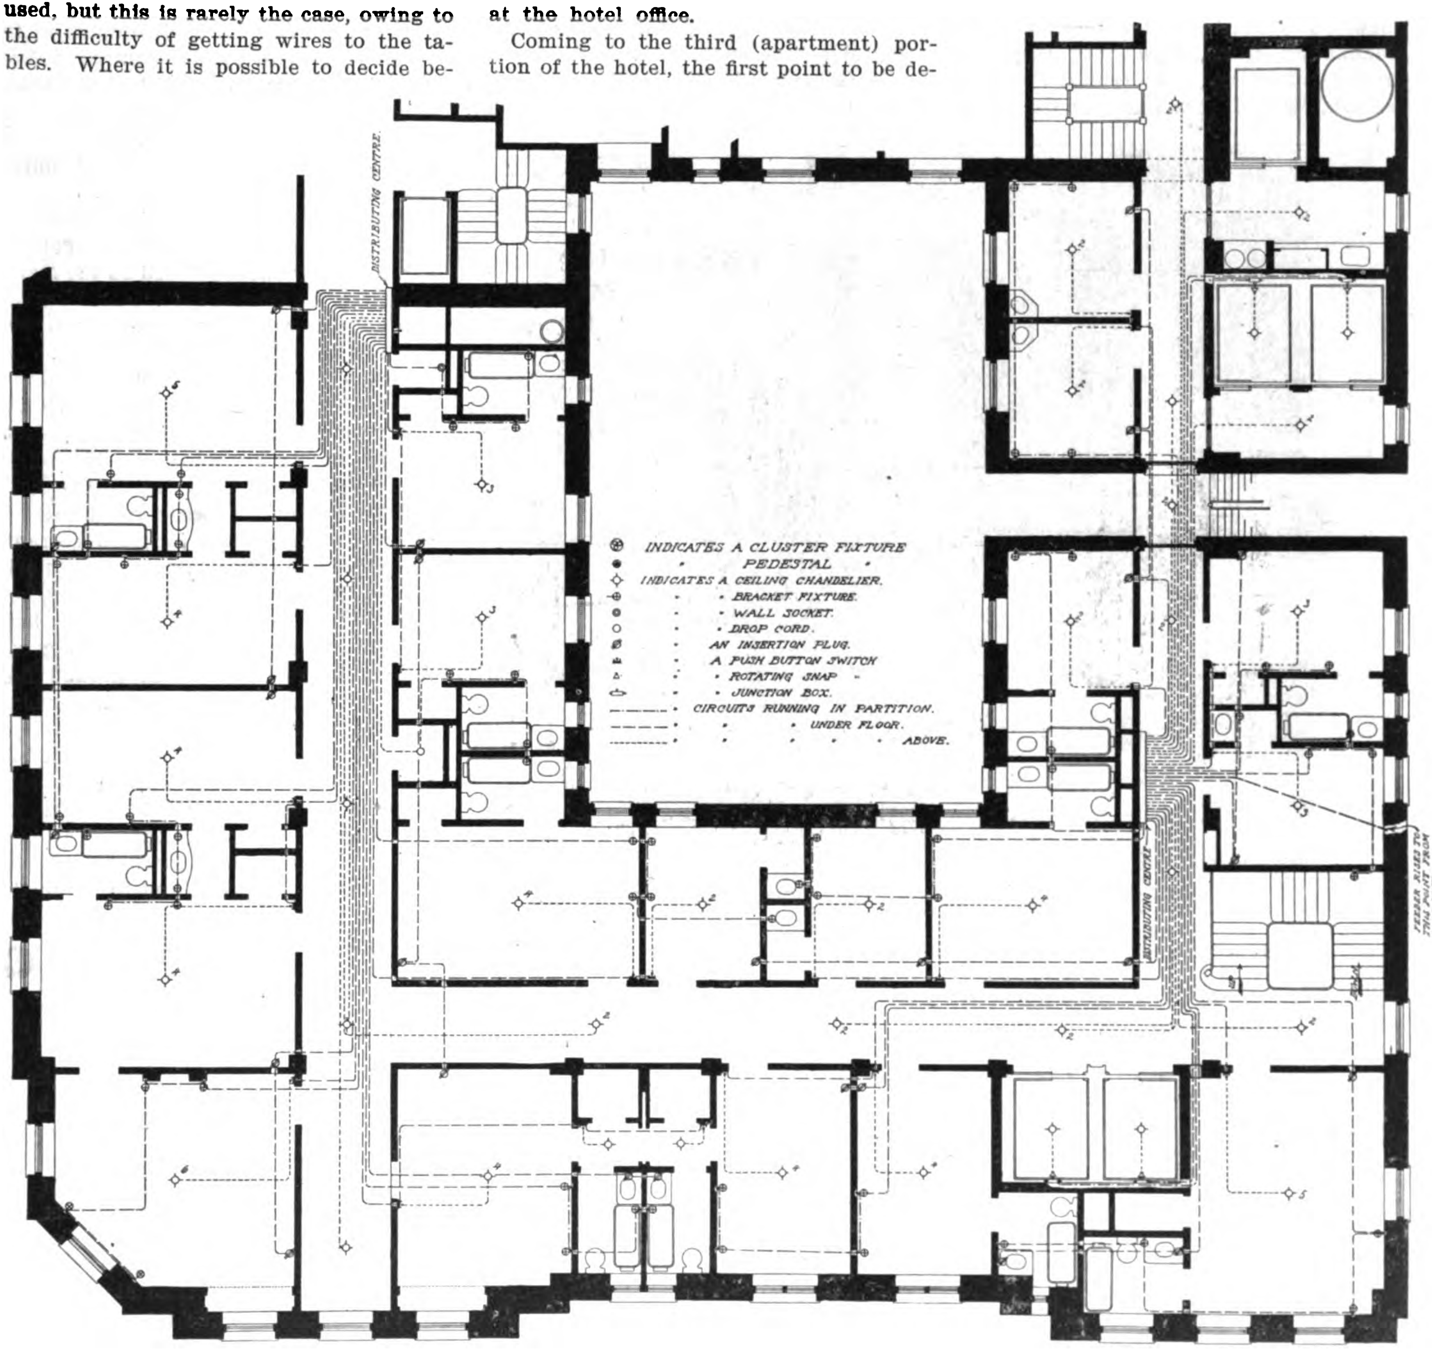

FIG. 2.—PLAN AND WIRING DIAGRAM OF EACH OF THE UPPER FLOORS.

controlled by a push-button (not a door automatic) switch placed just inside the closet door.

In locating the side lights and base plug outlets in the bed rooms it is essential to first lay out the furniture in the rooms so as to have the outlets come in the proper places. This can most easily be done by making paper templates of the bed and bureaus, on the same scale as the plans, and then arranging these on the plans in the best positions. The lights can then be located to suit the particular arrangement in each case. The arranging of the furniture on the plan should, of course, be done by the architect, or with his assistance and under his supervision.

For the purpose of illustration the writer has selected as a typical example of electric light wiring in a large hotel, the new Forty-third street extension of the Manhattan Hotel, New York City. As stated before, only two typical floors are shown. Fig. 1 shows the wiring of the ground floor, and Fig. 2 shows the characteristic features of the upper (bedroom) floors. The current supply is direct current at 110 volts pressure, and is derived from the generating plant in the cellar.

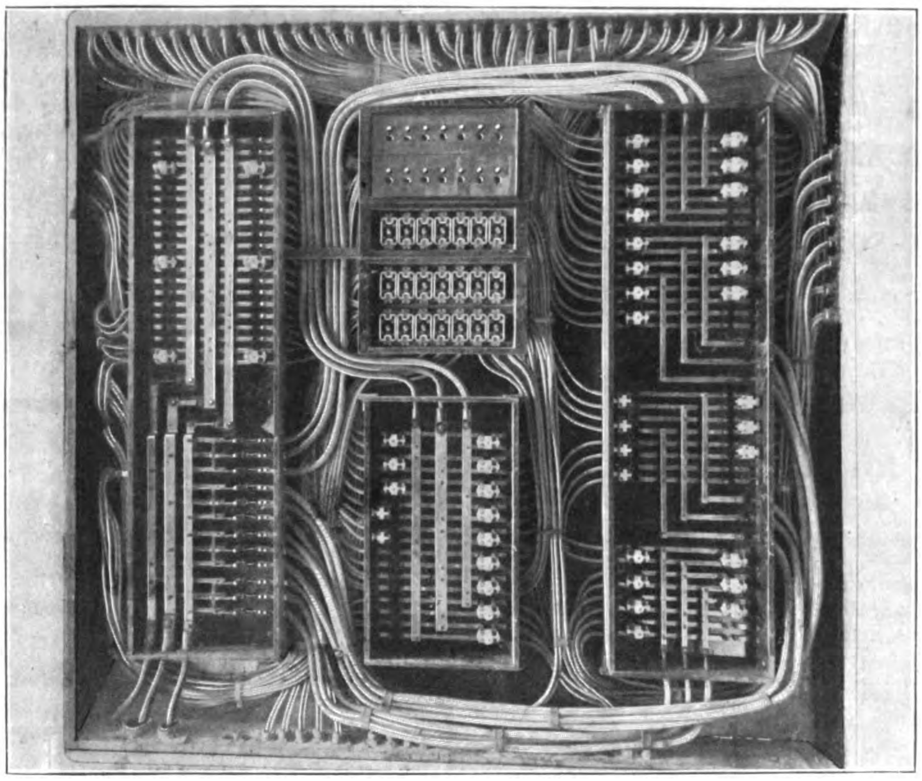

FIG. 3.—WALL CABINET IN THE SERVING ROOM ON THE GROUND FLOOR.

Ground Floor.—Fig. 1 shows the Forty-third street end of the ground floor and includes the restaurant, garden court, office, entrance, waiting rooms and corridors, etc. The lights on this floor are supplied from three centers of distribution located where shown on the plan. Fig. 3 is from a photograph of the distributing center located in the serving room of this floor. The photograph was taken by the writer before the doors and trim were placed in position on the cut-out cabinet, and shows the panel boards, switches, removable fuse-holders, connections, etc. It is possible to trace in this figure the various connections between the main panel boards at the left side and the lower portion of the center, and the subsidiary groups of cut-outs at the right side. The latter four groups of cutouts serve to protect the lights in the garden court; the circuits are controlled by knife switches located on the main left-hand panel. The lights on the ground floor are (except where local switches are shown) all controlled by switches located at the three distributing centers. The circuit lines, outlets, switches, etc., are shown diagrammatically in both Figs. 1 and 2. The explanation of the symbols is given in Fig. 2.

Restaurant.—Each of the four ceiling lights in the restaurant is supplied by four branch circuits originating at the center of distribution in the serving room. The side bracket fixtures are (with two exceptions) supplied in pairs, by branch circuits also originating at this center. Each of the branch circuits supplying lights in the restaurant is controlled by a push-button switch located in the cut-out cabinet.

Garden Court.—The garden court is lighted by two separate groups of individual lights. The first group forms a rectangle along the sides of the ceiling and consists of 102 receptacle lights placed in plaster rosettes specially designed for the purpose. Only the lamps themselves are visible from below, although the outlet boxes and connections are accessible by removing a small metal canopy covering the orifice of the outlet box. The lamps are wired in alternation, and are supplied by 14 branch circuits originating at the serving room centers of distribution. These lights are controlled in two groups by knife switches located at that cut-out cabinet (see Fig. 3). One group consists of 53 lights, the other of 49 lights. The second main group of lights in the garden court consists of 100 receptacle lights placed above the circular stained-glass ceiling or skylight. These lights serve the double purpose of supplying general light in the garden court and to illuminate the stained-glass ceiling or dome. The outlets themselves are accessible from above the glass ceiling. The lights are wired in alternation and are supplied by 14 branch circuits originating and controlled at the serving room distributing center. The lights are controlled by knife switches at that point, in two groups of 50 lights each.

Corridor.—The lights at each of the ceiling outlets in the corridors are supplied by two separate branch circuits; each branch circuit supplies lights at two or more outlets and is controlled by a push-button switch located at the center of distribution at which the circuit originates. This makes it possible to have all or part of the lights at these outlets turned on, as may be required.

Office.—The office is lighted partly by bracket outlets located on the columns and partly by outlets placed on the marble railing at the rear of the office. Plug outlets have also been provided for making connections to desk outlets.

Outside Lights.—The outside lighting is provided for by a group of receptacle outlets over the main entrance and pedestal fixture outlets located above the railing along the front and sides of the hotel. The 50 receptacle outlets are located in an iron canopy over the main entrance. They are supplied by branch circuits originating in the basement, but are controlled (through mains) by two knife switches located at the distributing center in the corridor at the ground floor (see also Fig. 4). The outside standard outlets (market P in Fig. 1) consist of 12 lights each and are supplied by 13 separate branch circuits originating at a distributing center in the basement. The entire group is controlled by a knife switch at that point. Each circuit runs along the basement ceiling to a junction box placed under the corresponding pedestal fixture on the sidewalk; thence the circuit rises in conduit through the stone coping and up through the iron pedestal itself to the fixture at the top of the pedestal.

The coat room and telephone booths are lighted by drop cord outlets, as shown. The lavatory in the ladies' waiting room is lighted by a single receptacle outlet placed on the partition between the closets. The conduit for this outlet runs to a junction box located in the wall at the level of the top of the partition; from this box the conduit runs along the top of the partition to the special receptacle on the partition.

Upper Floors.—There are two distributing centers at each of the upper (bedroom) floors, at which the branch circuits for these floors originate. Each of the bed rooms is lighted by a ceiling outlet, two side wall (bureau) outlets and a base plug outlet near the bed, for serving a reading light. The ceiling lights are controlled in one group by a push-button switch placed near the door. The bracket and plug outlets are not controlled by switches other than the key lamp sockets on the fixtures. The bath rooms are lighted by side bracket outlets placed beside the wash basins. In the larger rooms the extra wash rooms between the bath rooms and the closets are lighted by side bracket lights placed on each side of the basin, as shown. The bath rooms attached to the larger outside rooms are also provided with plug outlets serving for connection for curling-iron heaters, milk warmers, etc. The ceiling outlets in the corridor are wired in alternation so that every other outlet may be lighted, in case all the lights are not needed. The switches for the corridor lights are located at the distributing center at which the circuits originate.

Feeder System.—As will be seen from the diagram, Fig. 4, the cellar, basement and ground floors are supplied by separate feeders. This is done because of the great importance of having continuous and uninterrupted lighting service at these floors. The three distributing centers at the cellar are supplied by a single feeder which terminates at one of the centers and supplies the other two by means of mains extended from the feeder. Three of the eight distributing centers at the basement floor serve to supply the outside lights, as described above. The distributing center for the outside street lamps is supplied by a separate feeder from the main switchboard. The centers for the receptacle lights over the entrance are supplied by mains from the distributing center in the corridor at the ground floor. The other five distributing centers at the basement floor serve for the basement lights only; they are fed by two separate feeders, one of which serves two centers and the other three centers, as shown. Each of the three centers at the ground floor is supplied by a separate feeder.

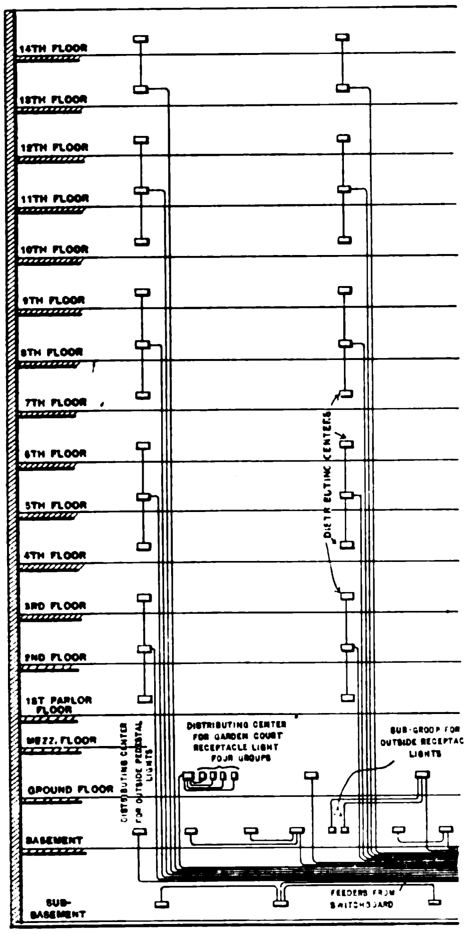

FIG. 4.—DIAGRAM OF RISERS.

The upper floors from the first to the fourteenth inclusive are divided into two symmetrical sections. Each section has its own distributing center, and its own set of supply feeders. The distributing center in each set is located at the same point at each floor. Each feeder from the first to the twelfth floor inclusive serves to supply three distributing centers. The feeder terminates at the middle center of a group of three, and is extended by mains to the corresponding centers at the floors immediately above and below. In the case of the thirteenth and fourteenth floors, the feeders terminate at the thirteenth floor and are extended by mains to the corresponding centers at the fourteenth floor.

◆

REPAIRING AND CONNECTING UP A GENERATOR COMMUTATOR.

BY A. B. WEEKS.

If the commutator has been off for some time, clean the shaft and commutator shell thoroughly, and see that the key and keyway are free from burrs. Push the commutator on as far as it will go, then get a large piece of cotton cloth and sew it around the rear ring of the shell, so that no short-circuits shall occur at this place. Tie strings to the cloth and poke them through the ventilating holes at the rear end of the armature. Then, by means of long rods run through holes in the commutator core (marked H in the sketch) and continued through the armature spider to a piece of heavy strap iron placed across the far end of the shaft, force the commutator to place by setting up nuts on the ends of the rods. White lead should have been put on the shaft at the commutator bearing.

When the commutator is within half an inch of the armature conductors, it is necessary to space the latter so that they will go into the slots in the commutator lugs; this is done by driving tapered hardwood wedges between the armature conductors near the outside end. Then put on a temporary band wire near this end to retain the wires in this position. When they are all entered and the commutator is up to place, take out these wedges and drive them along the side of each commutator lug or connector in order to wedge the armature conductors into place as securely as possible. This done, get ready for soldering, by packing pieces of plain cotton cloth firmly between the armature bars and pushing them back far enough to lap over the inside edge where the cotton cloth has been sewn. Leave the wedges in place until through soldering, which may be done as soon as the irons are ready. Have at least six gasoline soldering pots and some one to keep them going and also to keep the irons in good condition.

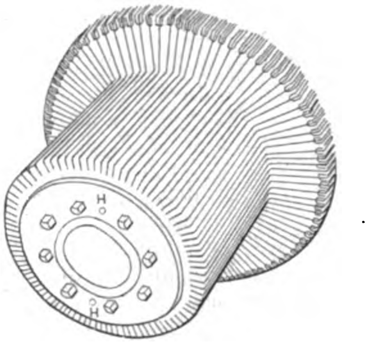

FIG. 1.—COMMUTATOR.

Having completed this part of the work remove all surplus solder, and if there is no convenient way of turning, file the soldered surface with a bastard file, finishing with a smooth file, remove the wedges and clean off the solder from all of the connectors. Take out the cloth packing, pull on the strings that are fastened to the cloth to remove it, and blow out very thoroughly.

◆

WATER OF CONDENSATION.

BY C. W. OBERT.

Water of condensation will be formed inevitably whenever steam passes from a boiler directly into cool pipes or from hot pipes into a cool cylinder, due to loss of heat in heating up the surfaces and walls of the pipes or cylinder. This loss of heat from the steam is absolutely unavoidable since heat will always transfer from hot to cooler bodies, and it is impossible to prevent such loss except by jacketing the pipe and cylinder surfaces and heating them to a temperature equal to that of the steam. The plan of jacketing and heating externally by the application of steam or hot air is ordinarily so expensive and complicated as to be impractical except in cases where extraordinary advantages are obtained, as in an engine cylinder. The plan of internally heating pipes and cylinder surfaces is, however, proving to be so efficient that a more general adoption of it may be reasonably expected in the future; it is accomplished, of course, by using superheated steam. Such extra-heated steam is able to lose a very considerable portion of its heat in raising the temperature of the pipe and cylinder walls without being cooled enough to cause condensation.

In ordinary practice, not prevention but only a reduction of the condensation is attempted. By covering the steam pipes, cylinders and steam passages with some approximate non-conductor of heat, the radiation of heat from their outside surfaces is greatly reduced; consequently the loss of heat and the resulting condensation of the steam are also reduced. With the best of pipe covering, however, there will inevitably be some radiation of heat and resulting condensation of steam. And in any case, whether the pipes, cylinders, etc., are covered or not, there will be very profuse condensation when steam is first admitted into them, because they are then cold or at least very much cooler than when in active use.

If the water of condensation is produced in very small quantities, it will be carried along or entrained by the steam, in which case it naturally cannot accumulate. In fact, small quantities of water will not remain in a pipe through which steam is passing at its usual velocity. But if condensation takes place faster than the entraining action of the steam can carry away the water, as happens in pipes or passages which are directly exposed to cold air, accumulations of water will form which, if not properly disposed of, will cause trouble.

The results of "taking water" by an engine cylinder are painfully familiar to most engineers, but a consideration of the action in detail may be of interest. Unless the amount of water carried into the cylinder is insufficient to fill the clearance space, it will be caught between the piston and the cylinder head in the immediately following exhaust stroke. Since water is very sluggish in its movement as compared with steam, it will not flow out of the exhaust ports readily with the exhaust steam and make room for the full travel of the piston; it passes out at the port so slowly as to form practically a solid barrier behind the piston, and, owing to its almost absolute incompressibility, acts like so much metal, preventing further free movement of the piston. Ordinarily the moving parts of the engine might be expected to simply stop under such restraint, but, at that point of the piston travel it is driven not only by the force of the expanding steam on the "live" side, but also by the inertia of the flywheel acting through the crank and the connecting rod, which, as the crank pin is then nearing its dead center, are forming a straightening elbow joint having the tremendous leverage of a toggle-joint.

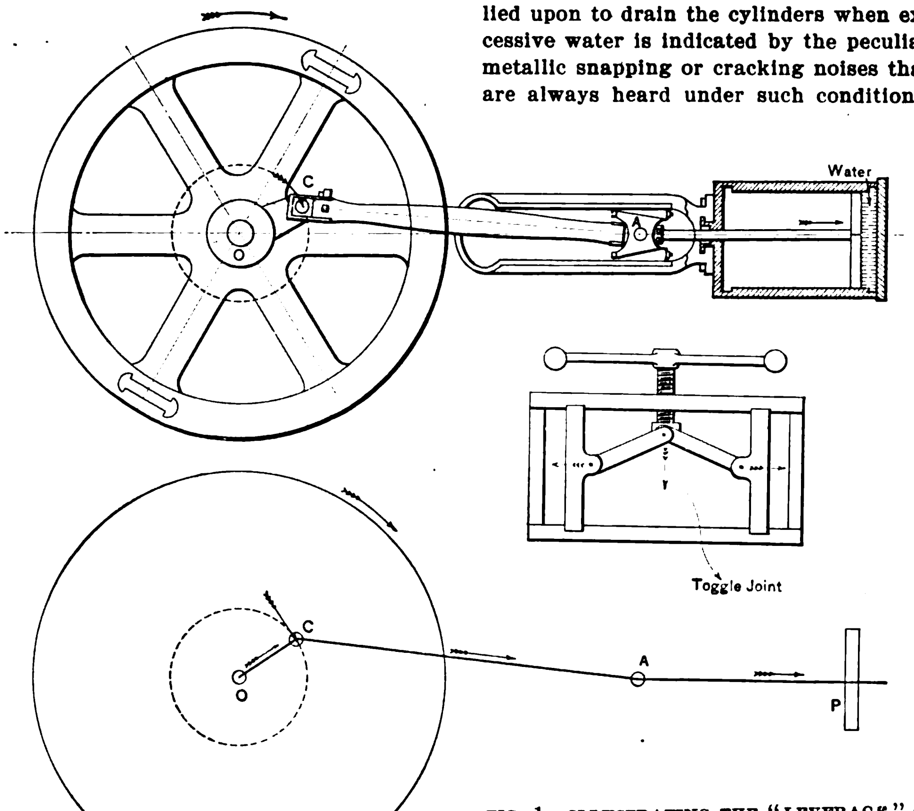

FIG. 1.—ILLUSTRATING THE "LEVERAGE" OF A FLY-WHEEL OVER A PISTON AND THE RESULTING FORCE EXERTED UPON THE PISTON.

Thus, in Fig. 1, the inertia or stored energy of the fly-wheel is forcing the crank pin, C, nearly straight downward, giving a wedging effect which tends to drive the points O and A apart. As O, which is the center of the shaft, is always very rigidly supported, the point A, and consequently the piston rod, is pushed to the right with great force. The lower part of the engraving is a diagram of the forces.

The liability of water to do harm in the cylinder is greatly reduced when the exhaust ports of the engine valves are placed on the bottom of the cylinder so that the tendency will be for such water to drain out before becoming imprisoned between the piston and the cylinder head. However, many engines are not so built, in which case the cylinder cocks must be relied upon to drain the cylinders when excessive water is indicated by the peculiar metallic snapping or cracking noises that are always heard under such conditions. For further protection in such emergencies, automatic relief valves are sometimes provided. These valves, known as snifting valves, are arranged to open outwardly from the clearance space in the event of extreme pressure inside, being held shut under ordinary conditions by a heavy spring. Fig. 2 shows the construction of a snifting valve. It consists of a plain conical valve disc, V, which is held upon its seat by the spring, S, and this spring may be compressed by the adjusting nut, N, to hold the valve shut against all ordinary working pressures in the cylinder, but to open outward for relief at any higher pressure. This device is not, however, to be thoroughly relied upon as a protection at high speeds, because in a high-speed engine the damage may be done before the snifting valve can deliver enough water to ease the pressure, as was demonstrated recently in an accident to a high-speed engine so equipped.

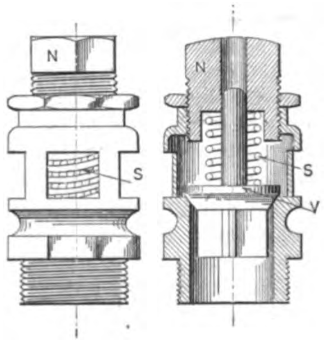

FIG. 2.—SNIFTING OR RELIEF VALVE.

Entrained water is much more easily taken care of by preventing it from reaching the cylinder than by attempting to get it out after it has once got in. By far the best disposal that can be made of condensation in the steam pipe is to grade the pipe so that it slopes gently downward from the boiler toward the engine and then place a receiver in the pipe, close to the engine, to catch all water draining toward it as well as that entrained by the steam.

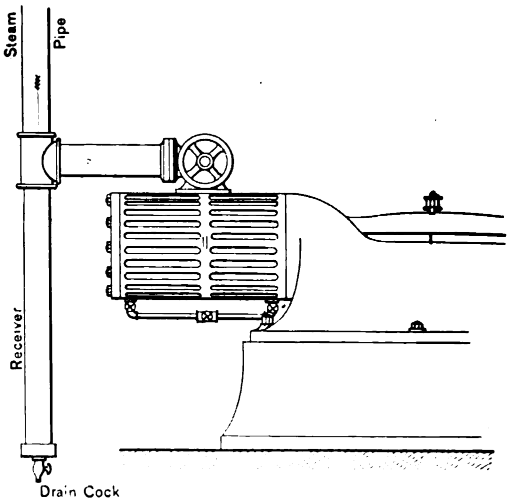

FIG. 3.—RECEIVER FOR ENTRAINED WATER.

There are several different forms of receivers for this purpose in successful use, all of which consist broadly of an extension or an enlargement of the steam pipe into which condensation water may drain by gravity and collect, to be drawn off at convenience. Perhaps the simplest form that may be used is that shown in Fig. 3, which is merely an extension of the vertical part of the steam pipe downward beyond the elbow leading to the throttle valve. The water carried along by the steam will be carried past the elbow into the extension by the combined effect of inertia and gravity. As water collects in the extension it can be drawn off at intervals, of course.

A much more effective form of receiver is the separator, of which some commercial forms are shown by Figs. 4, 5, 6 and 7. This apparatus accomplishes the same result that the receiver does, but in addition it gives the steam a whirling or centrifugal motion as it enters, so that the finely divided drops of water tend to fly to the outside while the lighter dry steam remains toward the center and passes out first through a central opening into the steam pipe beyond. The water thus thrown outward lodges on the walls of the separator and trickles to the bottom. In some forms of separator, the action depends upon capillary action on perforated or roughened metallic baffle plates placed in the path of the steam, the centrifugal action being partially discarded. In those types, of which the Austin is representative, the small particles of water are hurled against the baffle plates, on which they stick and collect, finally dropping into the reservoir below. Combinations of these two fundamental principles are sometimes made use of in separators, giving very effective and satisfactory results. A separator is very efficient if large enough, but not when it is too small, and many separators in use are inefficient for this reason. Well-designed separators have, under test with reasonably dry steam, shown the remarkable result of delivering steam containing less than one per cent (by weight) of water.

WEAK FIELDS AND GROUNDED ARMATURES.

BY FRANK BERRY, JR.

The armature of a railway motor is, under ordinary circumstances, the first part to break down under a heavy strain which may be put upon it mechanically or electrically. If the field of a railway motor be unbalanced to any extent it throws a severe strain on the armature, which ultimately breaks it down. Weak fields may result from a variety of causes: a fast feeding controller, insufficient insulation, short-circuited armature coils, or a few "bridged" commutator segments, which may have got in this condition by using acid and solder too freely. A motor whose fields are unevenly balanced will assert itself by flashing at the brushes, "bucking," and running much warmer than its mate. This is more readily noticed when the motors are thrown in parallel.

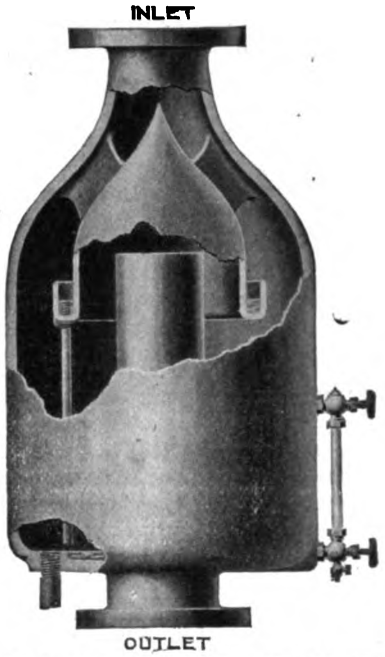

FIG. 6.—BAFFLE-PLATE AND CENTRIFUGAL SEPARATOR

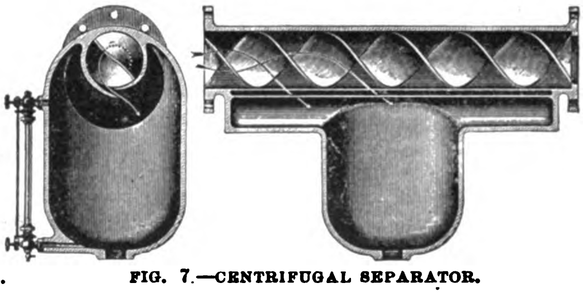

FIG. 7.—CENTRIFUGAL SEPARATOR.

A fast feeding controller can always be remedied by connecting up the resistance so that the controller will cut it out more gradually. This trouble may often be noticed on a road where there are used two controllers of different type, having the same number of connections at the hose, but having the contacts on the drum connected differently, as a well-known controller has. One controller is sometimes set up where the other should be used, without any attention being paid to the resistance until the car is turned in for "bucking," blowing fuses or, more frequently, with a grounded armature. It has come under the writer's observation many times that controllers were connected up so that on the first or second notch the motors were in series directly between trolley and ground.

Short-circuited armature coils may result from some damage received while the coils were being formed, or in course of assembling on the armature, but short-circuits are often due to extremely poor insulation. Judging from appearances, it would seem that the less shellac and tape the armature winders use, the better it is for that which they may be insulating, whereas it is, of course, well known that the more insulation there is on armatures and fields the less liable they are to break down. If this perfectly obvious fact were more generally borne in mind there would not be so many weak fields and grounded armatures; hence the repair bills would be greatly lowered.

◆

COMMON BATTERY TELEPHONE SWITCHBOARD SYSTEMS.

BY W. S. HENRY.

In a common battery system the apparatus at the subscribers' telephone may be arranged in a variety of ways. Before taking up the complete connections of an exchange system a few of the ways for connecting the subscribers' apparatus will be shown. Unless specified to the contrary, the ones shown may be used with either tne Hayes, Stone or most any other method, excepting the Dean, in which direct current for the transmitter is supplied through the two line wires and an alternating current is sent through the same two line wires when the subscriber's bell is to be rung. In some systems the ground is used as one path for the ringing current, either one line wire or both line wires in parallel being used for the other path. In such cases the bell at the subscriber's station is connected between either one or both of the line wires and the ground.

In Fig. 6 is shown one method of connecting the subscriber's station and the circuit at the switchboard by means of which the subscriber can call up the operator. At the subscriber's station the polarized bell, E, and a condenser, C, are connected in series permanently across the two line wires. The transmitter and receiver are in series but are only connected across the two line wires when the receiver is removed from the hook. At the switchboard an impedance coil, I, a signaling battery, B, an annunciator, D, and a spring jack, J, are all in series with the line wires. When the receiver is on the hook no current can flow in the circuit from the battery, B, because the condenser, C, is included in the circuit. However, when the receiver is removed from the hook the transmitter, T, and receiver, R, complete the circuit between the two line wires and they allow enough current to flow from B to drop the shutter of the annunciator, D.

When the operator inserts a plug in the jack, J, the circuit containing the annunciator is opened at the jack by the lifting of the upper spring from the contact under it. The operator, by inserting a plug in the jack, can evidently ring the bell, E (provided, of course, that the receiver is on the hook, T), by pressing a ringing key, thereby connecting the terminals of an alternating - current generator across the cord circuit and hence across the two line wires. This alternating current can act through the condenser and cause the bell, E, to ring.

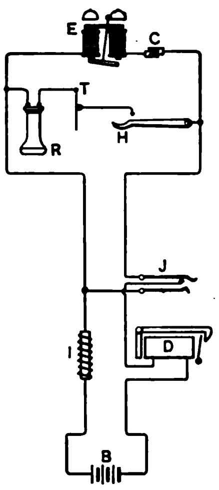

FIG. 6.

The battery, B, is common to all the telephone lines, and in order to avoid cross talk and other disturbing noises that may result from connecting all the line wires together at the battery terminal, an impedance coil, I, is placed in the circuit of each line between one pole of the battery and the spring jack. All the apparatus shown, excepting the battery, B, is duplicated for each telephone circuit. The coil, I, is adjusted for each line so as to allow the same current to flow in each line when the receiver is removed from the hook.

There is an objection to connecting the annunciator, D, directly in the line circuit, although this is the simplest way of arranging the signaling circuit at the switchboard. This objection is the difficulty of maintaining the resistance of the various line circuits at a practically constant value; and a lowering of the resistance, such as would be caused by a short-circuit between the two line wires, for instance, would allow an excessive current to flow from the battery, B, through the annunciator, D, which would be likely in many cases to burn out the magnet. As already stated, the resistance of the impedance coil may be adjusted to give each line the same resistance but this does not prevent a change in the resistance of the circuit due to crosses or other causes. Where the lines are all run in cables indoors this is not so great an objection as it would be on overhead bare wire lines. The condenser, C, at the subscriber's station may be omitted, as shown in Fig. 7. When this method is used the bells at the subscribers' stations should be wound to a very high resistance, 1000 or 2000 ohms, in order that the current normally flowing from the battery, B, when the receiver is on the hook may be very small and therefore not very wasteful. Other arrangements at the switchboard will be shown later.

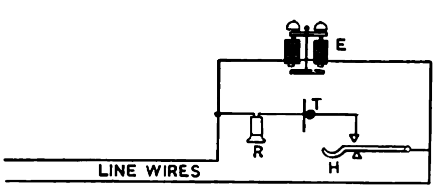

FIG. 7.

Fig. 8. shows the arrangement of the apparatus at the subscriber's station used by the Stromberg-Carlson Company. The battery current coming over the line wires passes through the transmitter, T, and the primary winding, p, of an induction coil. The operation of the transmitter varies this current and so operates the distance telephone; for if a variable current from a distant telephone arrives and passes through the primary of the induction coil, it will induce an alternating current in the secondary winding of the coil, thus causing the receiver, R, to reproduce the original sounds. This method has the advantage of not having the resistance of the receiver or of the secondary winding of the induction coil directly in the line circuit. Moreover, since the receiver is not in the line circuit no care need be taken to connect it in a certain direction with reference to the direction of the direct current flowing in the line. In all systems where any appreciable direct current, as in Figs. 6, 7 and 9, can flow through the receiver, the latter must be so connected that the steady battery current that flows through it tends to increase the magnetism due to the permanent magnet; otherwise the receiver will be wholly or at least partially demagnetized, rendering it useless or very inefficient.

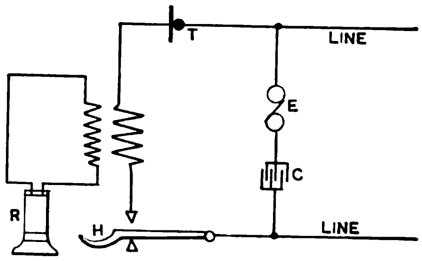

FIG. 8.

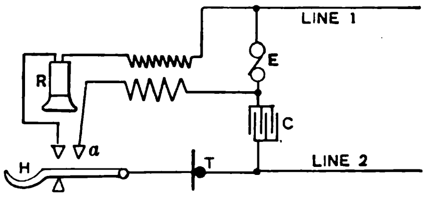

FIG. 9.

In the arrangement illustrated by Fig. 9, which is used by some companies, care must be taken to connect the receiver, R, in the circuit so that whatever direct current from the battery at the central office may flow through it will not tend to demagnetize it. When the receiver is off the hook, a portion of the battery current can flow from line 1 through the bell, E, the primary winding of the induction coil and the transmitter, T; and a portion of the current can flow from line 1 through the induction coil secondary, the receiver, the hook and the transmitter, to line 2. Incoming voice currents, as we may call the alternating or very rapidly fluctuating currents, cannot pass through the bell magnet, E, near so readily as they can pass through the induction coil and the receiver, because the impedance of the bell, E, and the primary winding of the induction coil, which are in parallel with the receiver circuit, are of very high impedance. The voice currents after passing through the receiver, R, may reach line 2 either through the hook, induction coil and condenser, or through the hook and the transmitter; the high frequency voice currents can readily pass through the condenser, C. In this arrangement the bell, E, should not have too high a resistance, otherwise the transmitter cannot get sufficient current with the voltage usually employed.

Lessons in Practical Electricity

ACTION OF AN INDUCTION MOTOR ARMATURE OR ROTOR

As explained fully last month, two coils disposed at right angles on a single core, such as an armature core, and supplied with alternating currents differing in phase by a quarter cycle, will produce a bipolar magnetic field that will rotate in a circle concentric with the core. Now, if the coils be mounted within a ring-shaped core, as in Fig. 1, the result will be precisely the same except that the magnetic poles will be manifested on the interior of the ring. Such an arrangement would be designated a bipolar field, because the two fields produced individually by the two windings combine in a single rotating field within the ring, whose axis is diametral with regard to the hole in the ring. The construction indicated, however, is not practical; in order to allow the insertion and removal of an armature, each of the field coils must be divided into two, and the four resulting coils disposed somewhat as

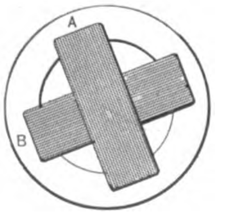

FIG. 1.

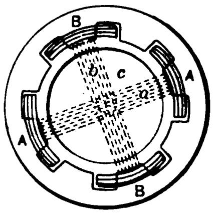

FIG. 2.

indicated by Fig. 2, so that an armature core, C, may be inserted in the central hole.

In this event the two coils marked A assist each other in producing a flux, *a*, across the central core, and the coils marked B produce a similar flux, *b*, at right angles to this, the two combining in a single rotating field, as before. Thus, with maximum current in A and A, the current of B and B will be zero and a flux will be produced as indicated in Fig. 3; when the current in A and A falls to 0.707 of its maximum, that in B and B will have risen to exactly the same degree, and the resultant flux will occupy the position shown in Fig. 4. At the next eighth of a cycle the current in A and A is zero and that in B and B maximum, locating the flux as shown in Fig. 5; and so on, through the complete cycle, as indicated by Figs. 6 to 11. In these diagrams for simplicity the flux is represented by only two dotted lines which indicate its general direction across the core and its division in the ring. With the elementary construction shown, there would be a leakage flux around the sides of the field coils, as indicated in Fig. 11; for the present we must neglect this.

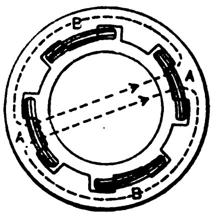

FIG. 3.

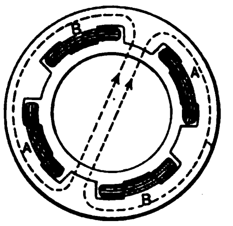

FIG. 4.

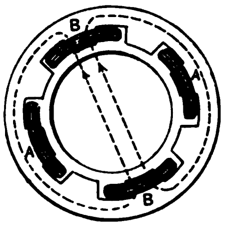

FIG. 5.

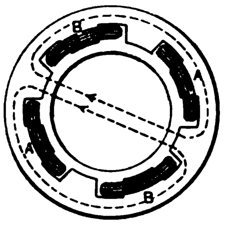

FIG. 6.

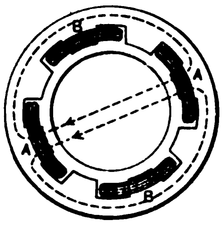

FIG. 7.

Now suppose a single turn of wire be wound on the drum core, as shown by Fig. 12, and the ends connected to form a closed circuit. If this core be inserted in the ring and held still while two-phase currents pass through the coils, the rotating field will be cut by the two wires on the drum every time it makes half a revolution, and will induce in each side of the loop an e.m.f. equal to

$$e = \frac{2.22\ n\ \Phi}{100,000,000},$$

where *n* is the number of revolutions per second made by the flux and Φ is the number of magnetic lines passing through the drum. Consequently the total e.m.f. induced in the loop on the drum will be

$$E_s = \frac{4.44\ \Phi\ n}{100,000,000} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

The e.m.f. thus induced causes a current to flow in the armature loop, the magnitude of which, ignoring self-induction, will be determined by Ohm's law. The e.m.f. and current in the loop will, of course, be alternating, because the direction of the flux is reversed at every half revolution. Now, if the current attained its maximum value at the instant when the sides of the loop had been swept by one-half of the flux, the flux would exert a dragging effort on the wires tending to rotate the drum with a force equal to

$$\frac{2\ C\ l\ B}{11,303,000}\ \text{lbs.};$$

the current being represented by C, the length of the drum in inches by *l*, and the density in magnetic lines per square inch in the air-gap by B. The numerator includes the figure 2 because there are two active conductors at the periphery of the drum. Armature reaction and self-induction in the armature winding, however, have the effect of reducing the torque to a value much smaller than this formula would make it. A general formula might therefore be written thus:

$$T = \frac{W\ C\ l\ B\ k}{10,000,000} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

in which T is the torque in pounds; W is the number of wires around the periphery; C is the current per wire; *l* is the length of the core; B is the magnetic density in the air-gap, and *k* is a fractional constant covering the effect of armature inductance and reaction and the change in the denominator.

It is evident, however, that if the drum is left free to turn, the pull exerted by the rotating field upon the sides of the loop will drag the drum around. It will be also evident upon reflection that as soon as the drum begins to revolve, the wires on it will not cut so many lines of force per revolution as before, but will cut only a number proportional to the difference between its own speed and that of the rotating magnetism. Consequently, the e.m.f. induced in the armature loop will become less as its speed increases, and the armature current and torque will also become less; this will be clearer if the reader will consider that if the drum were driven by a belt at a speed equal to that of the magnetic field the sides of the loop would not be cutting any flux and there would be no e.m.f. induced in it. The operation of an induction motor, therefore, requires that the speed of its armature must be less than that of the rotating field by an amount sufficient to allow the armature conductors to cut the flux at a rate that will induce an e.m.f. in the conductors which will force enough current through them to give the requisite pull or torque to carry the load. Consequently, if load is put upon the afmature, its speed will be reduced until the current flowing will be sufficient to give the required torque.

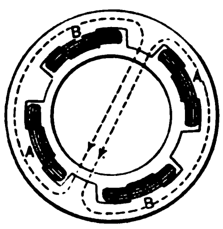

FIG. 8.

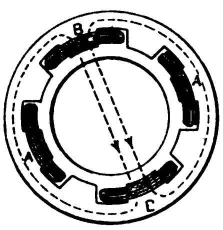

FIG. 9.

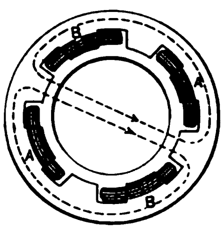

FIG. 10.

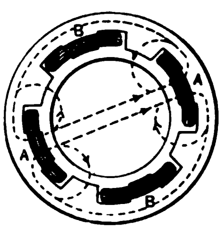

FIG. 11.

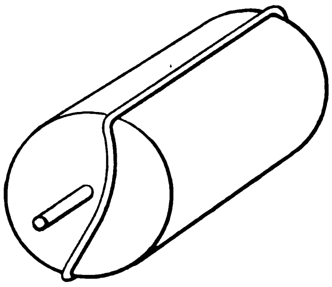

FIG. 12.

For example, still assuming the ideal condition of no lag by the armature current, and no armature reaction, if the speed at which the magnetic field rotates be 60 revolutions per second and the armature speed, running free, be 59.85 revolutions per second, the armature wires would cut 0.15 or 15 per cent of the total flux per second. Now, if the armature should have a load put upon it equal, say, to 20 times its friction load, the speed would be reduced until the wires would be cutting 20 times the number of lines of force previously cut; that is, the total flux would have to be cut 0.15 × 20 = 3 times per second. Consequently, the difference between the speed of the armature and that of the magnetic field would have to be 3 revolutions per second, which would bring the armature down to 57 revolutions. The difference between the armature speed and that of the rotating magnetic field is called the "slip," and it is usually written as a decimal, but referred to as a percentage. Thus, in the case just mentioned, with the armature making 57 revolutions per second while the speed of the magnetic field is 60 r.p.s., the difference of 3 r.p.s. is the slip, and its numerical value is 3/60 = 0.05; it would be reterred to as a slip of 5 per cent.

As stated in the beginning of this lesson, the resultant rotating field due to the combination of two (or more) alternating-current fields of different phases will have the same number of poles as each of the component fields. For example, in the elementary machine under consideration the flux set up by each pair of coils gives a bipolar field, and the two fluxes combined give a resultant rotating field which is also bipolar. Consequently, when one speaks of the number of poles on an induction motor it is always the number of poles per phase that is meant, which is equivalent to saying the number of poles of the resultant field formed by combining the two (or more) phases. The rotating magnetic field makes one revolution during each cycle of the magnetizing currents if the field is bipolar; the speed for more than two poles therefore would be

$$\frac{2\,n}{p} = \text{r.p.s.} \quad \text{(3)}$$

in which n is the frequency of the supply currents in cycles per second, and p is the number of poles.

As previously stated, the e.m.f. induced in the armature conductors will be alternating, and the frequency of this e.m.f. will vary inversely as the speed of the armature. The reason for this apparently contrary variation will be evident upon a little reflection. If the drum should be held stationary, the e.m.f. induced in the conductors by the rotating flux will have the same frequency as the supply current, but if the drum be driven by a belt at the same speed as the flux there will be no e.m.f. induced, and the frequency will therefore be zero. The frequency of the e.m.f. in the armature conductors is given by the formula

$$n_s = n \times s \quad \text{(4)}$$

in which n_s is the frequency of the e.m.f. in the armature conductors, n is the frequency of the supply current, and s is the slip expressed in terms of the frequency. For example, an armature running at 57 r.p.s. in a bipolar field produced by 60-cycle currents, would have a slip, as previously explained, of 0.05. The frequency of the current in the armature conductors, therefore, would be 0.05 × 60 = 3 cycles per second.

Formula (2) shows that multiplying the number of conductors on the armature core will increase the pull or torque. Thus, a core wound with four loops as in Fig. 13, would have four times as many conductors on its surface as the one shown by Fig. 12, and the current would be the same in each conductor because every loop has the same e.m.f. induced in it and is of the same resistance. The torque, therefore, would be practically four times as great. It would make no difference whether the loops were kept separate or connected in series, or in parallel as in Fig. 14; the latter construction is the simplest.

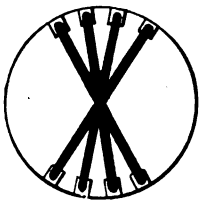

FIG. 13.

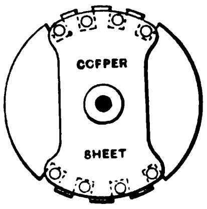

FIG. 14.

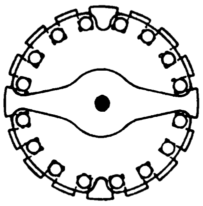

FIG. 15.

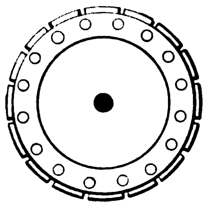

FIG. 16.

As previously shown, the speed of the armature is nearly equal to that of the rotating field, lacking only the small amount represented by the slip, and the field speed, or synchronous speed as it is termed, is $\frac{2\,n}{p}$ revolutions per second or $\frac{120\,n}{p}$ revolutions per minute. The frequency (n) ordinarily ranges from 30 to 60 cycles, so that a bipolar motor with a slip of 5 per cent would have an armature speed of 1710 r.p.m. at 30 cycles, or 3420 r.p.m. at 60 cycles—the more common frequency. This is, of course, too great for motors of any size, so that bipolar construction is seldom if ever used. The smallest machines are usually given four poles, and the number increases with the size of the machine and the frequency for which it is intended. The armature for a four-pole motor, evolved from the bipolar form of Fig. 14, would be constructed as indicated in Fig. 15. However, as there is no tendency for the currents in the two windings to interfere with each other, there is no reason why the two groups should be insulated from each other, so that the construction used in practice is made as shown in Fig. 16—the "squirrel cage" type.

Letters on Practical Subjects

Paralleling of a Direct Connected, and a Belted Generator.

To the Editor, American Electrician;

Sir:—I have to parallel a 200-kw. direct-connected dynamo and a 150-kw. belted machine, both 550-volt railway generators, running at 200 and 500 r.p.m. from separate engines of the same type. If any of your readers has met in his practice a similar problem I would be very much pleased to hear what his experience has been. Should there be any trouble in keeping them running together peaceably? John M. Schmidt.

Elkhorn, W. Va.

Mr. Chipman's Three-Wire Trouble.

To the Editor, American Electrician;

Sir:—Noticing Mr. Chipman's letter in your last number relative to trouble he was experiencing in operating two 110-volt shunt-wound machines on a three-wire system with a 220-volt compound-wound machine in multiple, I would say that this is occasioned from changes of load being unequally divided on his dynamos. When the load increases the compounded machine naturally takes up more than its share, from the fact that increased current in the armature goes through the series field thereby raising voltage and causing the greater part of load to be carried by this machine. On the shunt machines as load increases the voltage drops, thus causing the compounded machine to "back up" on them, so to speak; this will occasion the flashing at the commutator that Mr. Chipman mentions. If the load can be carried on the compound-wound machine alone, a simple remedy to be used in making changes would be a short-circuiting plug for the series field, which would cause this machine to operate as a simple shunt dynamo while it is in parallel with the other machines. The working voltage on the shunt machines would probably have to be lowered more than ordinarily in making this change, as the compounded machine with its series field winding short-circuited would not be likely to have sufficient range of voltage with the shunt field alone to bring it up to a point where it would take the portion of the load necessary before cutting out the shunt machines. By lowering the voltage sufficiently on the shunt machines this difficulty would be obviated.

If the conditions are such that it is necessary to operate the shunt and compounded machines continuously in parallel, better results could be obtained by disconnecting the series field from the armature circuit and putting it in series with the shunt winding, thus making a plain shunt machine of it; the range of voltage then would be wholly regulated by the field rheostat.

Palestine, Texas. Chas. W. Davis.

That Mysterious Current.

To the Editor, American Electrician;

Sir:—In the March number I notice among your notes on page 119 one entitled "A Mysterious Current." The phenomenon described occurs in a large alternating generator and consists of a difference of potential between the end of the shaft and the journal in which it runs, the machine being entirely free from grounds in both field and armature circuits. This difference of potential is accompanied by large current flow whenever substantial contact is made between journal and shaft, and it is presumed in the note that the oil film between journal and shaft constitutes the insulator to a certain extent. It is also stated that this potential increases with the load.

While the data concerning this curious phenomenon is not very full and the actual magnitude of potential difference and that of the current resulting therefrom have not been mentioned, it would seem that the probable explanation of the trouble is the following: The machine subbase with its shaft constitutes a one turn electric circuit. The revolving armature and such other iron as may be included constitutes the core, and the disposition of the winding on the machine and the wires leading out therefrom act to form an exciting primary; naturally, the current in the one turn closed secondary will increase in pressure and volume with the load as described. I would suggest an investigation of this point and a rearrangement of the dynamo leads.

New York. George T. Hanchett.

To the Editor, American Electrician;

Sir:—On page 119 of your March number, the note on "A Mysterious Current," observed in connection with the 1500-kw. alternators at the Snoqualmie Falls plant, describes a current that seems to be similar to that which I have observed in inductor alternators. It is a great deal more pronounced in the single armature type with the field coil on one side of the machine than in the double armature type with the field coil in the center.

While chief engineer for a manufacturing company, one of my duties was to design and test their inductor alternators. Often in testing a machine, sparking would occur between the shaft and journal, and sometimes a continuous ring of fire would appear around the circumference of the rotor, between the rotor poles and the stator laminations. It was found that small particles of iron, which had been attracted by the rotor poles, bridged across from these rotor poles to the stator laminations, thus making and breaking an electric circuit as the rotor revolved. It is plain to see the cause of this current, as the inductor machine is in reality a unipolar machine.

In the single armature type, where the rear end of the rotor is a cylinder, this end revolves inside the cylindrical surface of the frame with a small air gap between them. The field coil being stationary, the lines of force pass down through the frame, through the air gap and into the rotor, and are cut by the rotor surface as it revolves, thus generating a unidirectional current. There would be a current generated in the other half where the lines of force leave the rotor and pass into the armature laminations if it were not for the fact that the cylindrical surface is broken up by the poles, which are laminated.

The current flows from the rotor, along the shaft, through the journals, pedestals, and base to the other end of the shaft, if the electric circuit is not broken. However, in small machines, the potential of this current being very low, the resistance of the oil film between the shaft and the journal is sufficient to prevent this flow of current; and in the inductor alternators used for lighting and power there will be no trouble. In the machines of the larger capacities, say above 300 or 400 kilowatts, the oil film is not sufficient resistance to stop the flow of current, because the voltage generated in the rotor surface increases with the size of the machine, and would probably be too high.

If the electric circuit is complete, the current flowing would be proportional to the load on the alternating current coils. because as the load increases, the magnetic flux must necessarily be increased by a certain per cent, thus causing the unidirectional current to increase.

In the case of the Snoqualmie Falls generators I would suggest the introduction of some insulating material at some accessible point in the path of this superfluous current.

H. Stanley Carr,
Assistant Professor of
Electrical Engineering,
University of Kansas.

[The current referred to in reality was not mysterious, but was due to an error in the way in which the conductors from the armature winding were led to the collector rings, as suggested by Mr. Hanchett. It so happened that these were led in such a way as to give them the effect of the primary of a transformer, the secondary consisting of the shaft and bedplate connected through the bearings. When these conductors were carrying a heavy current a secondary current of low voltage was set up through the shaft, bearings and bed-plate, except when the bearings were sufficiently flooded with oil to form an insulation between the shaft and boxes. When the attention of the Westinghouse Company was called to this phenomenon, an examination was made showing the cause of the induced current, which was removed without any difficulty by a simple change in the position of the leads so as to prevent the inductive action which had previously taken place. The cause having been removed there is now, of course, no current in the shaft.—Editor.]

Another Plain But Efficient Trolley.

To the Editor, American Electrician;

Sir:—At the Highland Boy Gold Mining Company's smelter, Murray, Utah, automatic dumping hopper cars electrically-driven are used to carry the charges to and from the furnaces. The rails are not used as one side of the supply circuit, so that a double trolley is necessary. The overhead trolley is constructed as shown by Fig. 1. Two 2-in. angle irons are fastened by means of lag screws to a wooden stringer 2⅝ ins. thick, and the latter is capped with a V shaped roof. The trolley arm carries two brass contact shoes mounted on plungers and forced upward by coiled springs in the plunger sockets beneath. Fig. 2 gives a side view of the trolley pole. This arrangement has the advantage of not requiring the pole to be turned when the direction of the car is reversed; it works equally well in either direction. The contact shoes straddle the lower edge of the wooden stringer which carries the angle irons, and the trolley shoes are thus prevented from leaving the contacts. The e.m.f. of the circuit is 500 volts. C. D. Woodward.

Murray, Utah.

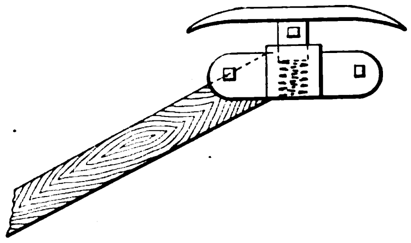

FIG. 1.—THE TROLLEY.

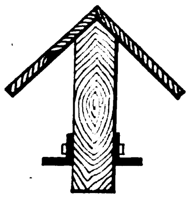

FIG. 2.—OVERHEAD STRUCTURE.

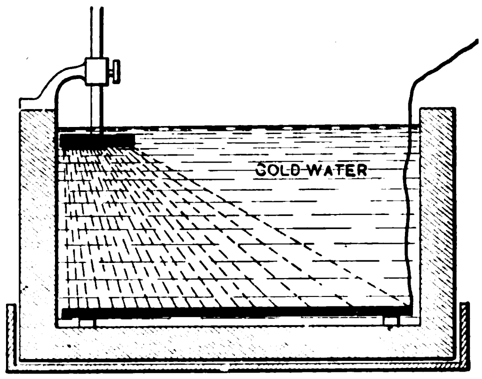
Points in Water Rheostat Construction.

To the Editor, American Electrician;

Sir:—I was interested in reading in your Electrical Catechism recently a description of water rheostats, and it has occurred to me that a few details in the construction of water rheostats which I have found of use in practice might be of interest to your readers in connection with the information already given by the Catechism. The rheostats with which I had experience are used in connection with electric hoists, and one of the difficulties encountered was the insulation of the wet rheostat box from the iron frame of the hoist. This was accomplished by putting the wooden box in a tin drip-pan, as shown by the accompanying sketch, and insulating the drip-pan from the hoist. The rheostat box was rectangular in shape, and the lower iron plate was made to cover almost all of the bottom of the box, as the drawing shows. The upper and movable electrode, however, was made to cover a much smaller proportion of the horizontal area of the water. It was a heavy iron ring mounted adjustably at one end of the box, as the sketch shows. With this arrangement only a part of the water served as an active conductor, and the remainder was not heated except by contact with the active part of the water. The result was a circulation of water within the box, which tended to keep the temperature down. The rheostat was used successfully for heavy loads and rough work. Francis H. Doane.

Scranton, Pa.



WATER RHEOSTAT.

Electrical Catechism

582. How is the heating effect of the current used for lighting?

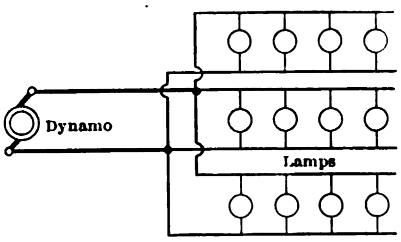
The heating effect is used in the incandescent lamp and in the arc lamp. In the former the current heats a filament of carbon to a high temperature; in the latter it heats the ends of carbon pencils or rods, the end of the positive carbon being heated to the melting temperature.

583. What are the parts of an incandescent lamp?

The lamp consists of a filament of carbon enclosed in a glass globe from which the air has been exhausted. Current enters and leaves through platinum and copper wires which connect the filament inside the globe with the brass cap outside. There are many different makes of incandescent lamps upon the market, differing in excellence according to the skill and facilities of the maker.

584. How are incandescent lamps usually operated?

They are generally connected in multiple between wires having a nearly constant difference of potential. For special purposes, such as lighting electric street cars or for lighting streets, a number of lamps are connected in series across lines having 500 or 1,000 volts or even higher.



LAMPS IN MULTIPLE.

585. What are the common voltages at which incandescent lamps are operated?

It was common to use from 50 to 55 volts with lamps lighted by alternating currents, but it is more common to use from 100 to 120 volts or from 220 to 250 volts. Lamps to be operated by current from batteries are made for 3 volts and upward. It is customary to have all the lamps on an installation for the same voltage, and new lamps should be ordered for the voltage regularly maintained. If the lamps are of too high voltage they will not light up with sufficient brilliancy, the filaments being only dull red or yellow. If the lamps are of too low voltage they will take too much current and will light up brilliantly, but will quickly burn out. As the lamps grow old they become dim, and sometimes it is practicable to move the old and dim lamps to positions nearer the dynamo where the voltage is somewhat higher.

586. What is the relation between voltage and candle-power?

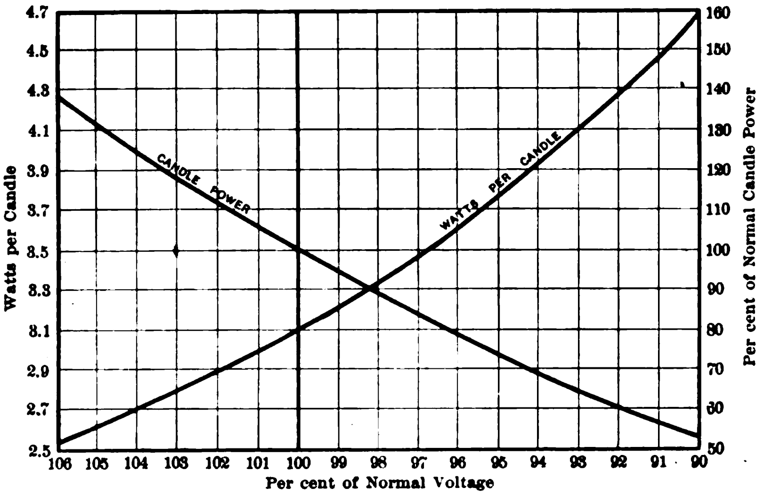
The candle-power of the light increases much faster than the voltage. For example, a lamp intended to give 16 candle-power at 105 volts will give only 14½ candle-power at 103 volts and will give 19 candle-power at 107 volts.

587. What is meant by the efficiency of an incandescent lamp?

The efficiency of an incandescent lamp usually refers to the number of watts absorbed per candle-power. For example, a four-watt 16-c.p. lamp would require four times sixteen, or sixty-four watts. The average practice in America is to use 3.5-watt lamps, the common efficiencies being 3.1, 3.5 and 4 watts per candle.

588. What determines the best efficiency to use?

The cost of power and lamps and the closeness of regulation of the voltage are the principal elements. The more costly the power and the cheaper the lamps, the higher should be the efficiency of the lamps. The life of the lamps is shorter when operated at high efficiency, and the life of the lamps is rapidly shortened if the voltage rises above the normal.



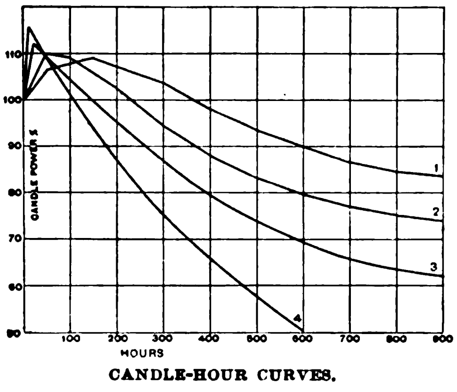
VOLTAGE, LIFE AND EFFICIENCY CURVES

589. To what extent does the voltage affect the life of an incandescent lamp?

This is shown in the following table:

Per Cent of Normal Voltage.	Life Factor.
100	1.000
101	.818
102	.631
103	.562
104	.452
105	.374
106	.310

From this it is seen that the life of the lamp is halved by an increase of 3 per cent and is reduced two-thirds by an increase of 6 per cent.



CANDLE-HOUR CURVES.

590. How are the candle-power and efficiency of the lamp affected by variations of voltage?

This is shown in the following table published by the General Electric Company:

Per Cent Voltage. Normal	Per Cent Candle-power. of Normal	Efficiency. in Watts per Candle.
90	53	4.68
91	57	4.46
92	61	4.26
93	65	4.1
94	69.5	3.92
95	74	3.76
96	79	3.6
97	84	3.45
98	89	3.34
99	94.5	3.22
100	100	3.1
101	106	2.99
102	112	2.9
103	118	2.8
104	124.5	2.7
105	131.5	2.62
106	138.5	2.54

A lamp for 16 candle-power, with 3.1 watts at 105 volts, will give 89 per cent of the light, or 14½ candle-power, at 98 per cent of normal voltage, or 103 volts, taking 3.34 watts per candle.

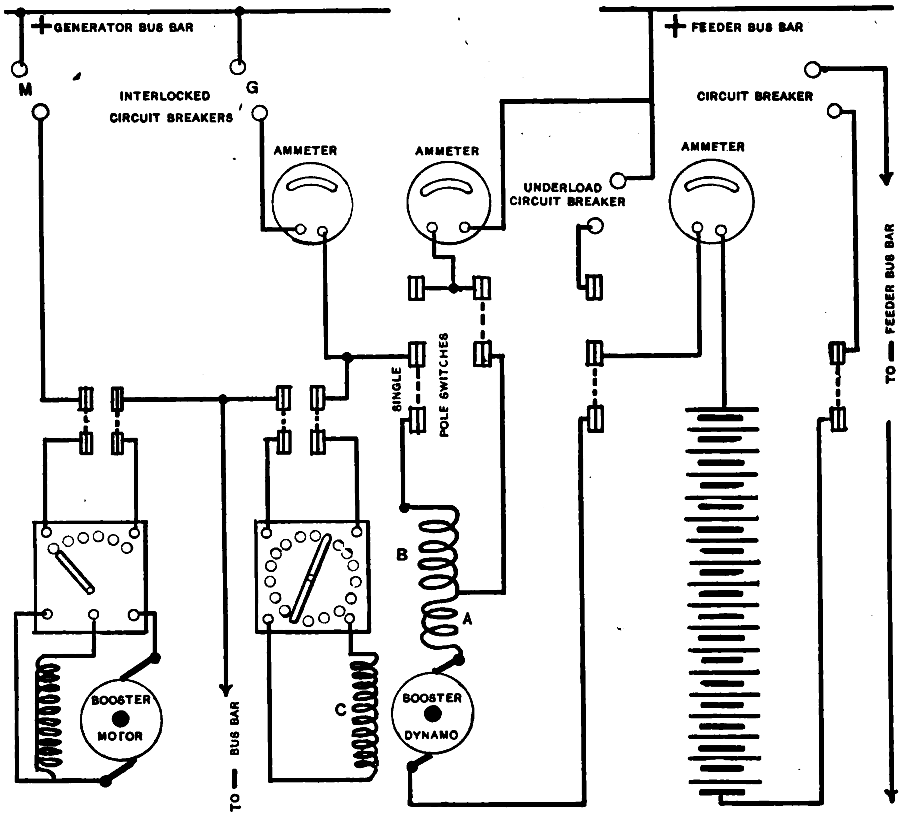
591. What is meant by the "smashing point" of an incandescent lamp?

As a lamp becomes old its candle-power and efficiency drop off, so that after a certain point it becomes cheaper to throw the lamp away or to smash it and get a new lamp than to continue burning the old one. This point is called the "smashing point" of the lamp, and it varies as explained in No. 588.

592 How does the candle-power of an incandescent lamp vary with age?

The candle-power generally increases for a time and then begins to fall, reaching the initial value at about one hundred hours. The rate at which the candle-power falls varies with lamps of different makers and also with different lamps from the same factory. As the efficiency rises the candle-power falls off more rapidly. The accompanying diagram shows results of careful experiments with an excellent lamp, curve 1 showing the percentage of original candle-power after burning various lengths of time when started at an efficiency of 4 watts per candle and kept constantly at the same voltage; curve 2 shows a similar lamp started at an efficiency of 3.5 watts per candle; curves 3 and 4 show similar lamps started at 3 and 2.5 watts per candle.

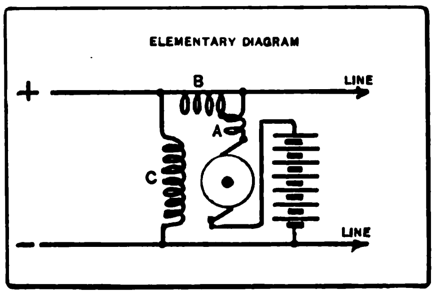
BOOSTERS AND STORAGE BATTERIES

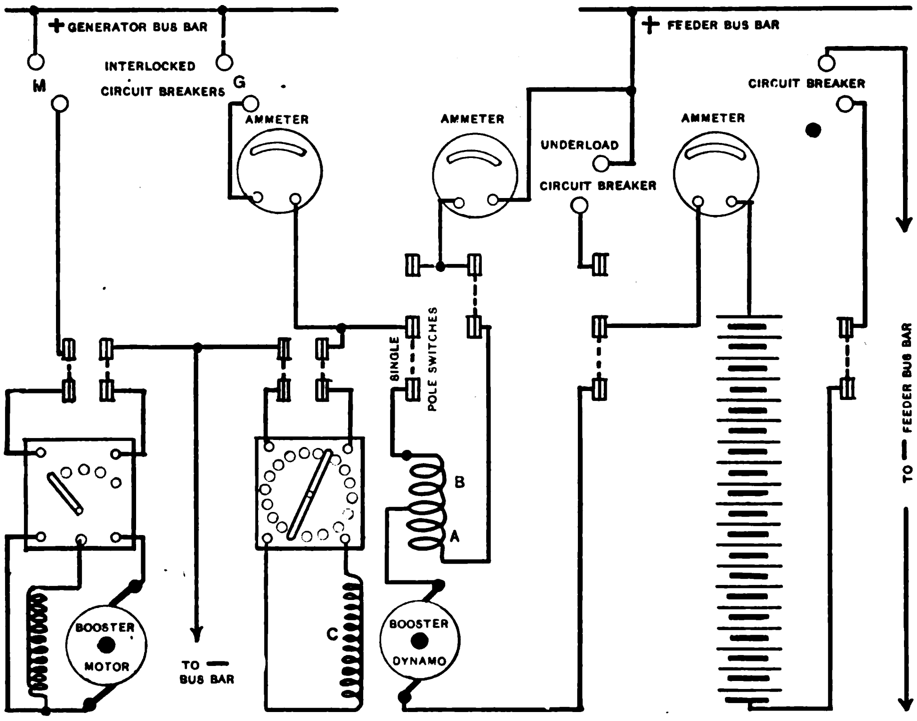


Modified Compound Booster.

The circuit-breakers, M and G, are interlocking, so that when the motor circuit-breaker, M, goes out, it trips the dynamo circuit-breaker, G.

The series coil, A, and shunt coil, C, assist the charging current; the coil, B, assists the discharge of the battery.

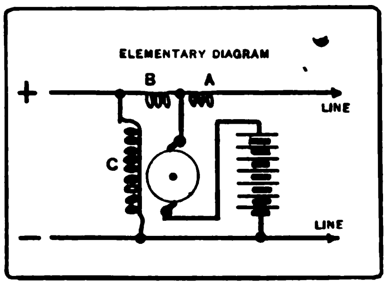




Differential Booster.

The circuit-breakers, M and G, are interlocking, as explained above.

The series windings, A and B, assist the discharge of the battery. The shunt winding of the booster tends to assist the charging current.



Queries and Answers

IMPORTANT.—No attention will be given to inquiries which do not give the full name and address of the inquirer.

How can I magnetize a permanent magnet with alternating current? (2). What kind of steel should be used in the magnet?
T. L. H.

It is not possible. (2). Tungsten steel is the best, but a good quality of tool steel properly tempered will answer.

Is it possible to supply 300 incandescent lamps from a 110-volt dynamo, the lamps to be 1⅛ miles from the station? J. M.

It is possible but not commercially practical.

Is the difference in phase between the primary and secondary e.m.f. of a transformer 90° or 180°? B. E. L.

It is not quite 180°, but so near it that this figure is usually taken as the difference in phase.

How much current will a 20-volt 2-c.p. lamp take? (2). How much power is required to drive a 20-volt shunt-wound dynamo of 40 watts? E. S. L.

About 0.3 ampere. (2). This depends upon the efficiency of the machine; one of average efficiency would require about 0.1 horse-power.

How can I use a 5-volt dental lamp, requiring 1 to 1½ amperes, on a 113-volt alternating circuit? R. M. W.

Connect the lamp in series with a parallel group of three 16-c.p. 110-volt lamps. If this gives too much current in the dental lamp, switch out one of the 16-c.p. lamps or substitute an 8-c.p. lamp for it.

Will a 60-cycle 100-volt induction fan motor run on a 104-volt or 110-volt circuit of the same frequency? (2). What is the difference between an ampere-hour and an ordinary hour of 60 minutes? C. W. F.

Yes. (2). An ampere-hour is a compound unit, involving both time and current; 10 amperes supplied for two hours would be 20 ampere-hours, 4 amperes supplied for 5 hours would also be 20 ampere-hours, and so on.

Can I reverse the direction of rotation of an ordinary direct-current arc dynamo; if so, what changes will be necessary?
G. W. C.

Yes; exchange the flexible wires leading to the brush-holders, and turn the brushes around so that they will trail in the opposite direction.

In rewinding an armature does it make any difference if the pitch of the coil is reduced from 24 to 23 slots, the commutator connection being unchanged? J. A. P.

Theoretically there would be a slight increase in the speed of the armature, but practically there is no appreciable difference.

I have three 6-in. electric bells connected in series to be operated by a single push button, but they do not ring well. What is the proper method of connection? L. A. V.

The three bells can be operated in series if the vibrators of two of them be short-circuited and three times the number of battery cells be used that you would use for a single bell. Any reasonable number of bells may be operated in series by short-circuiting the vibrators of all of the bells except one.

Can I charge 10 cells of storage battery from a 20-volt dynamo? (2). How many amperes will a 20-volt 16-c.p. lamp require?
C. H. S.

Yes, by speeding the dynamo up until its e.m.f. is about 23 volts. (2). This depends upon the efficiency of the lamp; a lamp of average efficiency will require about 2½ amperes.

Why is a motor rated differently when it is enclosed from the rating than when it is open at the ends? J. H. M.

Because when the ends are open air can circulate freely through the motor and carry away much of the heat, whereas when it is enclosed there is no ventilation and the heat must be radiated from the surface of the shell; consequently, an enclosed motor will reach its temperature limit with a smaller load than one which is ventilated.

Please give formulas for the draw-bar pull required by an electric locomotive to draw a train on a level track and on a grade.
J. M. S.

The draw-bar pull in pounds of an electric locomotive on a level track is given by the formula: $0.00000294 \times V^2 \times W$, in which "V" is the velocity of the train in feet per second, and "W" is the weight of the train in pounds. The additional pull due to a grade is equal to $0.0002 \times W \times G$, in which "W" is the weight of the train, and "G" is the grade in feet per mile.

What is the rate of electrodeposition of zinc and that of copper? C. L. C.

Zinc is deposited at the rate of 0.0463 oz. per ampere-hour; cupric copper is deposited at the rate of 0.0415 oz., and cuprous copper at the rate of 0.083 oz. per ampere-hour.

How can I make a spot for a Bunsen photometer? F. D. R.

The best way is to let a drop of melted paraffine fall on heavy absorbent paper and keep the paper warm until the paraffine has all soaked in.

What units do the divisions on a Warner pocket battery gauge represent? A. H.

The divisions are merely degrees of a circle. A battery gauge is not a current meter; it merely serves to compare the strength of two batteries and not to indicate the current or the e.m.f., although the deflection of the needle is in a sense an indication of the current strength.

In the description of the one horse-power motor published in the January 1899, number the statement is made that the resistance of the armature is one ohm, and that the normal current is 8.3 amperes. Why is not the current $\frac{110}{1} = 110$ amperes? (2). It is also stated that the field current is one-half ampere, and the size of the field wire is No. 22. Why is such a comparatively large wire necessary? (3). To what extent may magnet cores be reduced in cross-sectional area by using wrought-iron instead of cast?
A. W. P.

The current is only 8.3 amperes because the counter e.m.f. of the armature is 101.7 volts, so that only 8.3 volts are actually applied to the resistance of the winding. (2). No. 22 wire is used because the resistance of a smaller wire would be so high that not enough current would pass to magnetize the field magnet core sufficiently. (3). The cross-sectional area of a wrought-iron core may be made 4-9 of that of a cast-iron core, on the basis of average saturation for each class of material.

Is there any rule or formula for the size of wire to be used in field coils and armatures? F. P.

No; the allowable loss in the windings depends on the shape and area of the radiating surfaces and the ventilation. Ordinarily it is safe to allow a loss of 0.4 watt in a field coil for each square inch of radiating surface around the outside of the coil. In armatures it is safe to allow a loss of one watt in the winding for each square inch of armature radiating surface, provided the armature runs at a fairly high rate of speed, such as 2500 to 3000 ft. per minute.

What size of wire should a 15-kw. 110-volt bipolar dynamo be rewound with in order to convert it into a 500-volt motor? (2). What power would the motor develop? J. C. K.

Make the size of wire on both the field and the armature seven gauge numbers smaller than the present wire. Wind the field coils to exactly the same depth in inches that they now have, and put as nearly as possible 4.6 times the number of turns per armature coil that the machine now has. It will probably spark considerably at the commutator unless the number of coils is increased. It would be better, therefore, to use twice the number of coils, making the turns in each coil as nearly as possible 2.3 times the present number of turns. (2). Between 15 and 18 horse-power.

How is the flux of multipolar ring dynamo fields calculated? (2). Is the pressure applied to the crank-pin of an engine at any instant the same as the total pressure on the piston, or does the angularity of the connecting-rod make any difference? R. W.

The formula for multipolar dynamos in which ordinary multi-path armature windings are used, is:

$$\frac{100,000,000 \times E}{W \times N} = \text{flux per pole.}$$

In this formula "E" is the electromotive force generated in the armature winding, "W" is the total number of wires around the circumference of the armature, and "N" is the number of revolutions per second. When the armature has the two-path or so-called series winding, the formula is changed to:

$$\frac{200,000,000 \times E}{W \times N \times P} = \text{flux per pole,}$$

in which formula "P" represents the number of poles on the machine and the other letters have the same meanings as before. (2). When the connecting rod and crank are at right angles with each other it is sufficiently accurate to consider that the turning effort or torque on the crank is identical with the total pressure on the piston. At other positions of the crank this is not permissible. The thrust on the pin, however, is practically equal to the total piston pressure at any point; the maximum difference is within 3 per cent.

TRANSFORMERS FOR THE MANHATTAN ELEVATED.

The accompanying illustrations show the salient features of the type of transformer which will be used by the Manhattan Elevated Railroad Company for supplying current to lights on the elevated stations when the electrical equipment of the road is completed. The transformers are of the Westinghouse Company's latest "O. D." type, and are to be of 3.2 and 6.4 kilowatts output. The transformers are of the familiar shell-type which has been used by the Westinghouse Company from the inception of commercial alternating-current work.

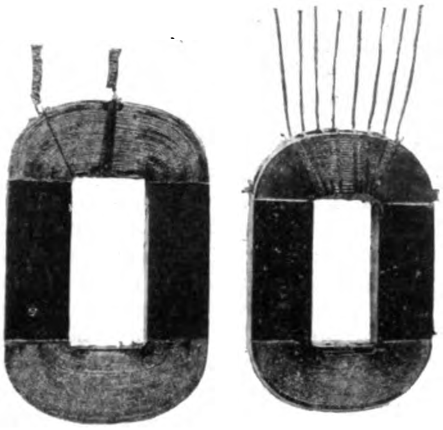


FIG. 1.—TRANSFORMER COILS.

The coils are individually insulated and are spread apart at the ends in such a way as to secure the greatest possible heat radiating surface without in any way lowering the efficiency of the apparatus. The transformers will be arranged for two primary and three secondary voltages, individual sections of the windings being supplied with terminal contacts which can be connected up to give the desired voltage. The secondary coils are wound with copper of square cross-section, which gives about 30 per cent more useful cross-section than round copper, for a given size of coil, and therefore less loss due to the resistance of the windings.

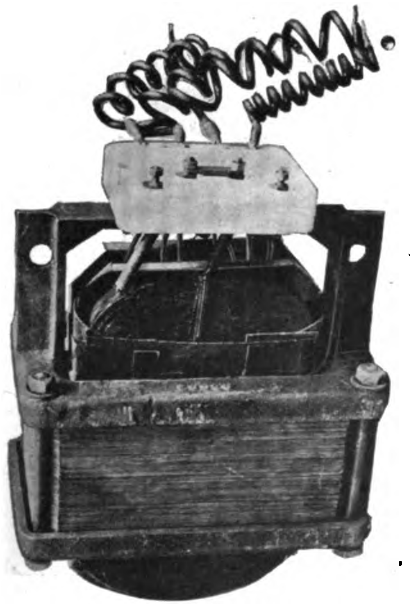

FIG. 2.—COMPLETE CORE AND COILS.

Before the "O.D." transformer was put on the market it was subjected to a series of the most thorough tests in order to remedy any possible defects in design or construction. The transformers are oil insulated and may be arranged with the Scott two-phase three-phase connections.

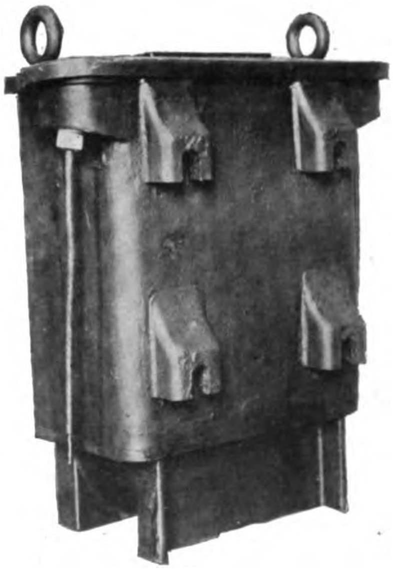

FIG. 3.—"O. D." TRANSFORMER.

◆

TEST OF A HIGH SPEED ENGINE.

The Skinner Engine Company, of Erie, Pa., was recently the recipient of an order for an engine, the acceptance of which, we are informed, involved the following guarantee: (1) The engine was to indicate 120 horse-power when running at 300 r.p.m. under a pressure of 100 lbs., cutting off at quarter stroke, and was to be capable of driving a 75-kw. dynamo at any rational overload. (2) The shaft governor was to be provided with such adjustment that the speed could be reduced 50 r.p.m. in increments of 5 revolutions, the only adjustment permitted being the addition of weights to the arms of the governor. (3) The engine must maintain the same rate of speed light or loaded at any point between the maximum and minimum. (4) The instantaneous change of speed from no load to overload (amount of overload not specified) of a 75-kw. dynamo should not exceed one per cent, the load being thrown on and off by make and break contact switch.

A 14 x 22 Skinner engine was selected to fill these requirements. The engine, we are informed, was tested by the purchaser of the engine, with the results shown by the accompanying table. The dynamo was belt-driven and the load was supplied by a rheostat. The full load was thrown upon the engine by the closing of the switch and all the readings were taken simultaneously. Figs. 1 and 2 are cards taken from tests 5 and 6, Fig. 2 showing the friction load of the engine and dynamo. The manufacturer claims that the speeds at full and no load were exactly the same. In the first test it is claimed that the engine, the nominal horse-power of which is 100, had a load of 174 i.h.p. suddenly put upon it with only a momentary checking of the speed of two revolutions.

◆

A SMALL DYNAMO.

The Midget dynamo illustrated herewith is said to be one of the smallest and most complete dynamos on the market, comprising all the features of modern design. It has an output of 10 watts and is shunt wound, with a toothed drum armature and removable field coil. The pole-pieces are bored out and all the joints are tooled. It is particularly adapted for experimental purposes requiring small current and voltage, and will light a special 6-c.p. lamp, decompose water, electroplate, supply induction coils, etc. It is built by the Elbridge Electrical Manufacturing Company, of Elbridge, N. Y.

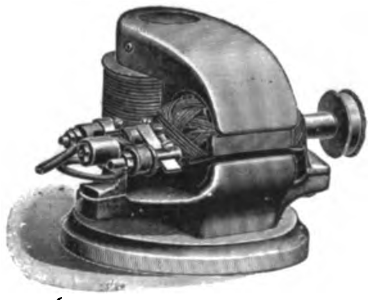

FIG. 1.—MIDGET DYNAMO.

New Apparatus and Appliances

ROBERTS FIXTURE BLOCK.

A recently patented fixture block made by the H. C. Roberts Electric Supply Company, of Philadelphia, is illustrated by Fig. 1. As shown in the engraving, the fixture block is provided with steps to fit different sizes of standard canopies. The block is neat in appearance and the advantage claimed over the old style flat surface blocks is that the canopy when once in place cannot slip sidewise, but is firmly fixed in a central position about the fixture stem. The block fits canopies of 3, 3½, 4 and 4½ inches diameter.

PALMER MARINE MOTOR

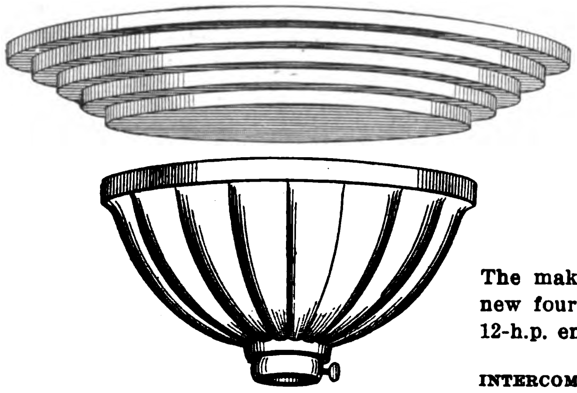

FIG. 1.—FIXTURE BLOCK.

Fig. 5 depicts a new model gasoline marine motor manufactured by Palmer Bros., of Mianus, Conn. It differs from the motors heretofore made by the same concern in having a low base by virtue of which it is claimed the vibration in the boat is greatly lessened. In the Palmer motors a valve regulates the charge from the closed crank chamber, which is compressed with the downward stroke of the piston. The vapor and air are drawn into the crank chamber by the upward stroke and throughly mixed by the motion of the crank. The ignition is by electric spark. The motors range from 1½ to 6 horsepower, and are provided with two mufflers, a gasoline tank and valve, inboard water connection, two sets of batteries, spark coil, two switches, wire, oil and grease. The makers have also lately perfected a new four-cycle double-cylinder self-oiling 12-h.p. engine.

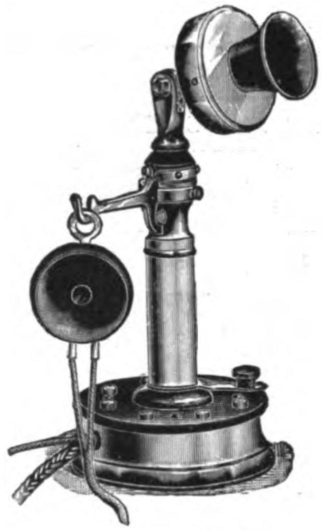

FIG. 3.—DESK OUTFIT.

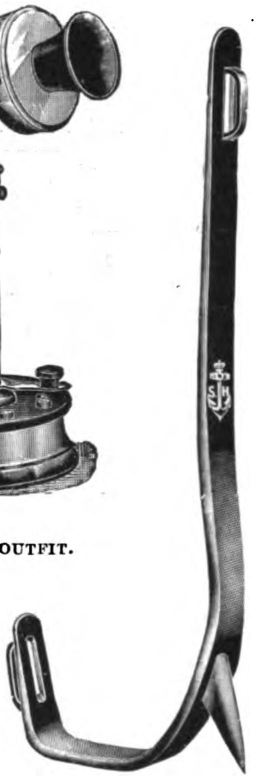

FIG. 4.—LINEMAN'S CLIMBER.

INTERCOMMUNICATING DESK TELEPHONE SET.

Fig. 3 illustrates a new intercommunicating telephone set manufactured by the Spencer Electrical Company, New York. A feature of the desk set is the location of the selective switch, which is mounted on the top of the base. The base is made of cast brass, and the top, on which are mounted the selective switch contacts and the transmitter standard, is made of a hard wood fiber. The selective switch lever is pivoted concentrically with the transmitter standard, making the arrangement very compact. The lever or key is made of spring metal, and its mounting is a ball bearing, which, while holding the lever firmly, makes it easy to swing around without necessitating holding the telephone set immovable with one hand while the other is occupied in swinging the key lever around. The under side of the selective switch is easily accessible as the cast-brass base is hollow. The selective switch is employed only for calling up another station and does not require to be returned to any particular position when the conversation is finished. All of the metal parts of the outfit are substantially nickel-plated and handsomely polished. The system is a central-energy one, and also includes a single central induction coil for all of the telephones.

LINEMEN'S CLIMBERS.

Fig. 4 illustrates a new climber which the Smith & Hemenway Company, of New York City, is putting on the market and which is called the "Swedish Sure Grip" climber. The feature of the climber is that the spur, in addition to being welded to the upright, is also riveted. The manufacturer claims that the experience gained in the manufacture and testing of the climbers warrant the guarantee of every climber turned out. The spur, it is stated, is there to stay, and it is practically impossible to knock it out.

HEAVY DUTY CORLISS ENGINES.

The illustration herewith shows two heavy duty high-speed Vilter-Corliss engines, direct-connected to electric generators at the Menger Hotel, San Antonio, Texas. The engines are operated non-condensing under 100 lbs. boiler pressure. The cylinder of the smaller engine is 13 ins. in diameter by 36 ins. stroke, and the larger one is 14 ins. by 36 ins. Each engine drives two General Electric multipolar generators of 50 kilowatts and 37½ kilowatts respectively; the smaller engine maintaining a speed of 120 r.p.m.,

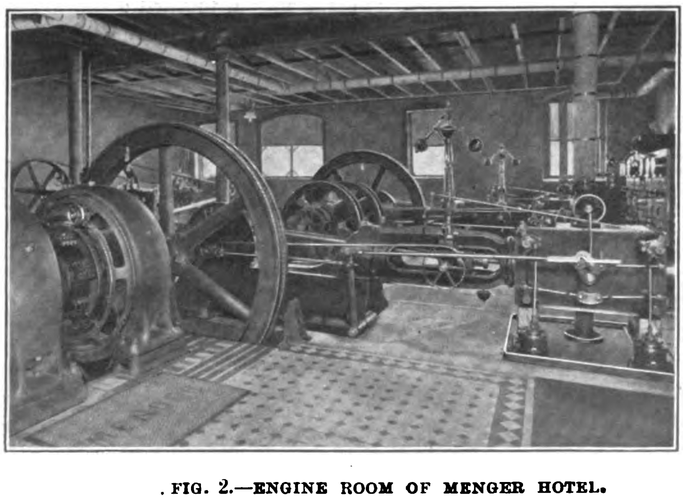

FIG. 2.—ENGINE ROOM OF MENGER HOTEL.

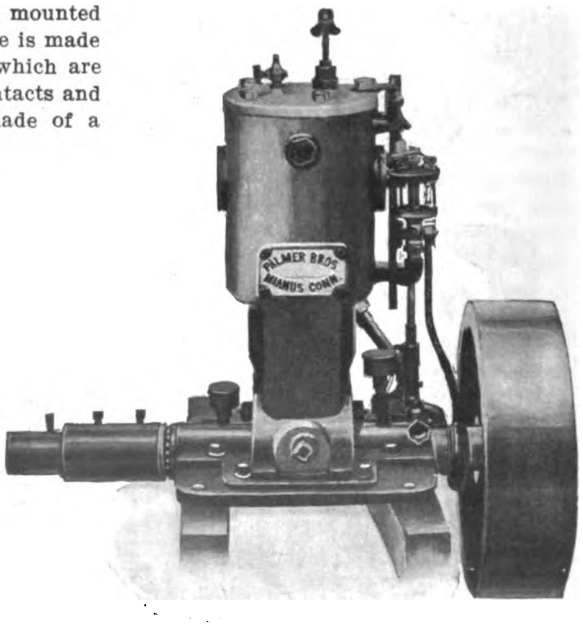

FIG. 5.—NEW MODEL MARINE MOTOR.

and the larger engine running at 125 r.p.m. The generators deliver current at 125 volts for 1000 incandescent lamps, 20 arc lamps, 60 ceiling fans and a number of motors used for various purposes. Both engines are supplied with heavy-duty frames and are specially designed for the particular class of work performed. The valve gear is of the hook release type, while the dash-pots are said to operate noiselessly, and being entirely enclosed are consequently dust-proof. The engine room, of which Fig. 2 represents only a part, is also provided with two 6-ton Vilter ice-making machines, each driven by a 10 x 24 Vilter-Corliss engine. The Vilter Manufacturing Company, of Milwaukee, the builder of these engines, makes a specialty of Corliss engines for electric light and power work, and also of refrigerating and ice-making machines.

SCREW-CUTTING ENGINE LATHES.

Fig. 6 illustrates the "Star" screw-cutting engine lathe made by the Seneca Falls Manufacturing Company, of Seneca Falls, N. Y. These lathes are said to have important and unique advantages over other lathes of corresponding sizes. They are furnished with end thrust ball-bearing spindles, automatic cross feed, plain or compound rests, U. S. standard, Whitworth or metric lead screws, together with taper drawing-in chuck and gear-cutting and milling attachments when desired. A patent foot power is provided which, it is claimed, enables the operator to accomplish more work with less fatigue than any other form. It consists of double treadles with a walking motion; the treadles are movable and work independently of each other, each being connected at opposite ends of a driving-wheel shaft in such a manner as to produce a strong, positive and continuous rotary effort. The rack, small gears and all working screws are made from steel, and all the small parts liable to be bruised are case-hardened. The head-stock, which is strong and heavy, has a hollow spindle of crucible steel, and runs in phosphor-bronze bearings. The tail-stock has a steel spindle provided with a self-discharging center, and an improved locking device which is said to insure perfect alignment. The other parts of the lathe are clearly shown in the engraving. Its actual swing is 10 and 12 inches.

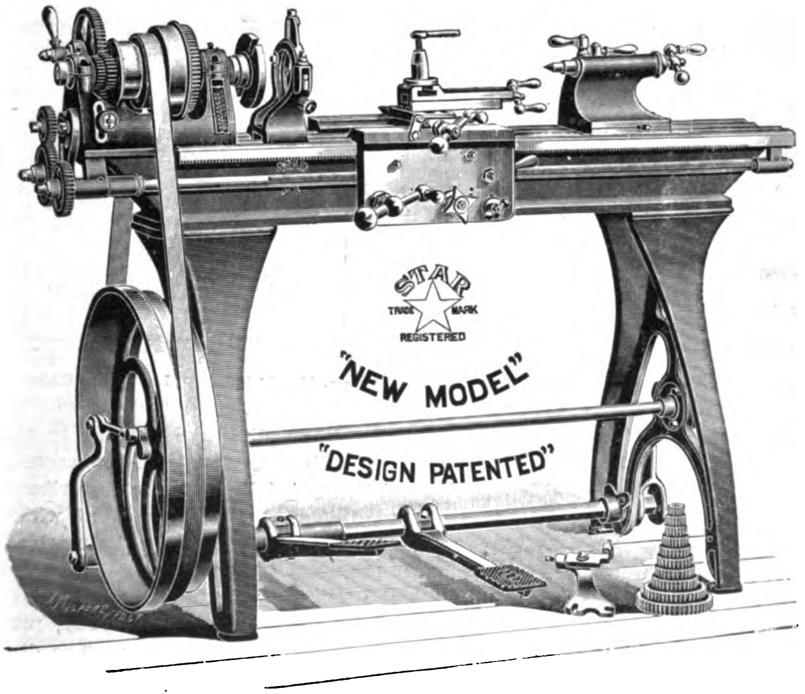

FIG. 6.—SCREW CUTTING ENGINE LATHE

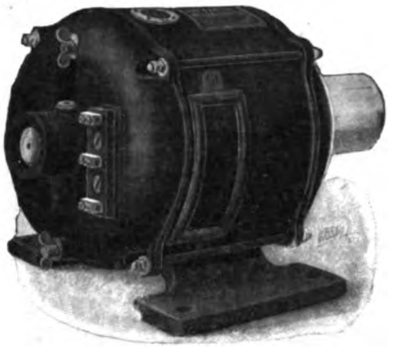

FIG. 7.—DIRECT-CURRENT MOTOR.

NEW DIRECT-CURRENT POWER MOTORS

The accompanying illustration shows a new direct-current power motor built by the Emerson Electric Manufacturing Company, of St. Louis, and which embodies several new features. In both mechanical and electrical design it resembles large engine-type generators. The armature and commutator are mounted upon the same casting, thereby permitting the shaft to be removed without disturbing their relative positions. The armature is, of course, laminated and a straight line type of brush holder is used which is claimed to be both simple and reliable. The motor has six poles and the field magnet is built up of sheet iron stampings, as in induction motors. The motors are entirely enclosed, the commutator end of the case being provided with two small covers, the removal of which gives access to the brushes and brush-holders. A peephole covered with mica is provided in the top of the motor through which the commutator can be plainly seen and any sparking detected. Each motor is tested before delivery and is required to carry a 50 per cent overload.

ENCLOSED NATURAL DRAFT COOLING TOWERS.

In its first designs of Barnard cooling towers the Wheeler Condenser & Engineering Company, of New York, used a power-driven fan to supply currents of air for reducing the temperature of the water; but recently the fan was dispensed with entirely and the water cooled by trickling over meshes of galvanized iron wire, the surface of which was exposed to the atmosphere. The company is now offering a development of this latter type in the form of galvanized wire mats inclosed in a steel case and having a steel flue reaching 75 to 100 ft. above the ground, thereby permitting a strong draught of cool air to pass over the surfaces of the mats at all times. This chimney design, shown by Fig. 8, requires but little space and is very light in weight, besides possessing an additional advantage of getting rid of any vapors rising from the circulating water. The mats in the new form of tower are practically the same as those supplied in the previous de-

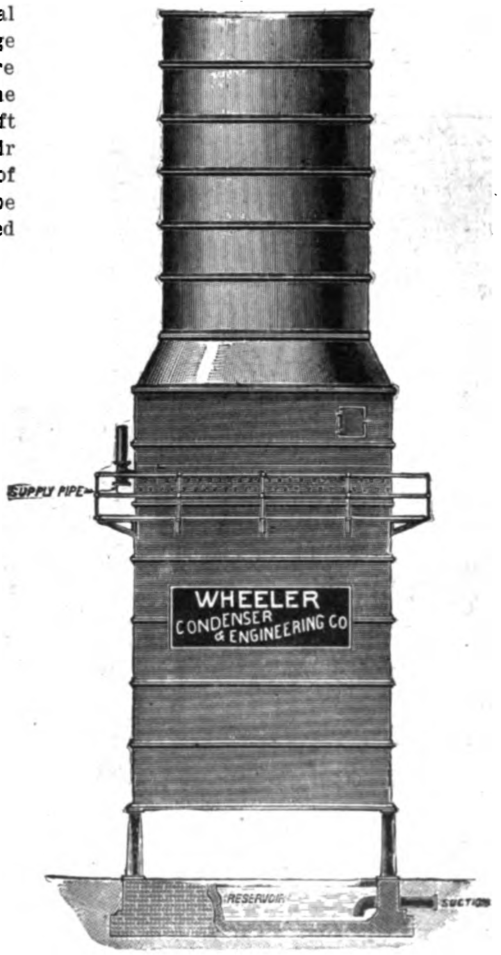

FIG. 8 —WATER COOLING TOWER.

sign of Barnard cooling towers and consist of galvanized wire woven into mats of small meshes, over which a thin film of water passes, so that each drop of water is brought into contact with the circulating air, causing a rapid and positive lowering of the temperature.

MECHANICAL TUBE CLEANER.

The illustration herewith (Fig. 9) represents the Weinland Mechanical Tube Cleaner in operation on a 350-h.p. B. & W. boiler at the Edison Electric Light Station, Columbus, Ohio. The boiler in question has 168 four-inch tubes each 18 ft. long, and the cleaner clears them of scale at the rate of seven an hour; a 3-h.p. motor drives the cleaner head at 1500 r.p.m. The Lagonda Manufacturing Company, of Springfield, Ohio, the maker of the cleaner, states that it can be easily and quickly attached to the boiler front, and changed from tube to tube very rapidly. The rapidity with which the cleaner will perform its work is of course governed by the thickness and hardness of the scale, but the manufacturer is of the opinion that the conditions met with at Columbus are about the average. Two men are required to manipulate the apparatus, one at the machine and the other at the motor rheostat and switches.

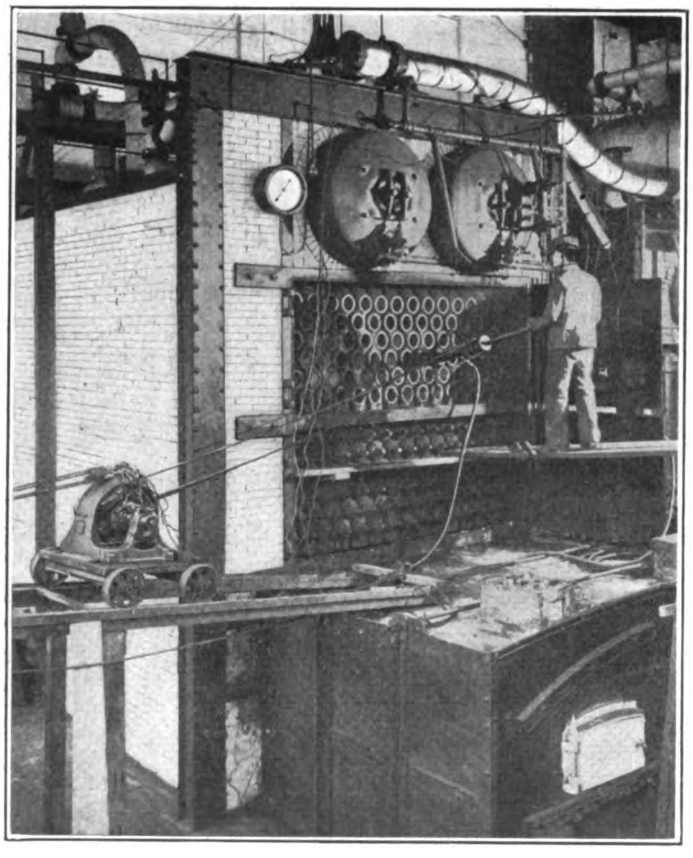

FIG. 9.—MECHANICAL TUBE CLEANER AT WORK.

A NEW ENCLOSED MOTOR.

Fig. 10, herewith, illustrates a motor built by Palmer & Olson, New York which embodies several notable features. As will be seen from the illustration, the motor is almost entirely enclosed, and is adapted for either floor or ceiling work. The magnet is a single casting of soft steel, provided with ventilating slots at the pulley end, and an opening at the commutator end large enough to admit the armature. The rear bearing shell is cast integral with the magnet, and the front bearing yoke is bolted to the frame and is provided with an aperture which exposes the upper part of the commutator and renders the brushes and brush-holders easily accessible. The motors are built for slow speed and are said to run noiselessly. The bearings are self-oiling, of course. The advantages claimed by the makers are that the machines are interchangeable for floor or ceiling work; that they run under full load without any perceptible increase in temperature; the brushes are self-adjusting, and the machines show no external magnetism. Their spheroidal contour also renders them less liable to accident from external causes.

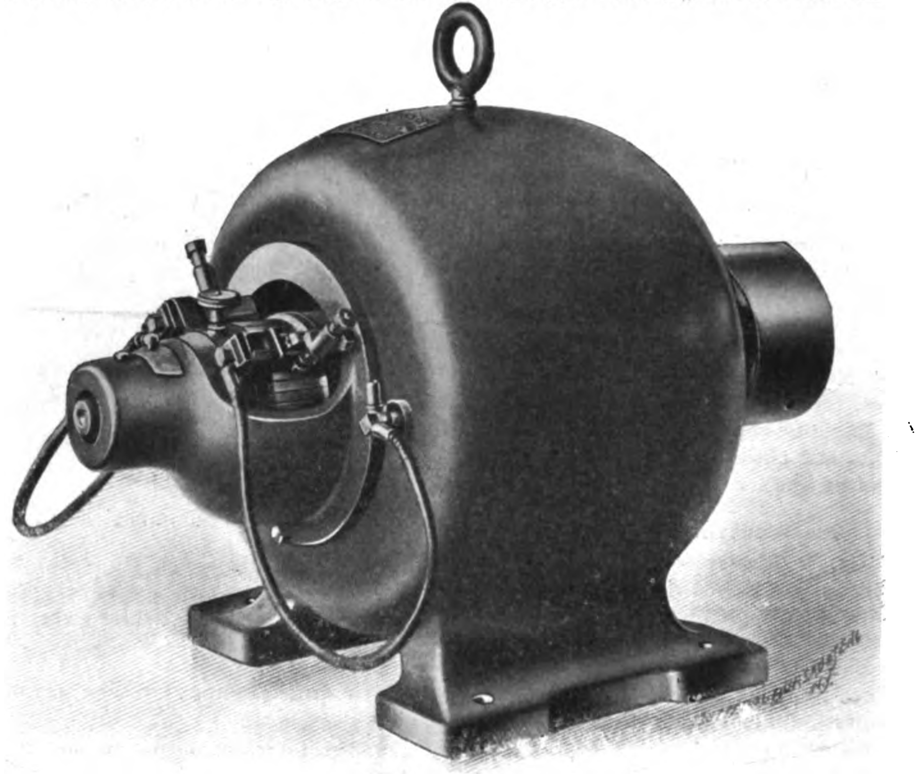

FIG. 10.—SEMI-ENCLOSED MOTOR.

THE STANDARD HOWLER

Fig. 11 is a diagram showing the application of an ingenious device which is original with the Standard Construction Company, of Chicago, and the function of which is to enable the exchange operator to call up a subscriber who has left his receiver off the hook. It is known as the "howler," and consists of a vigorous buzzer or vibrator and a repeating coil, connecting as shown by the diagram. When the exchange operator inserts the plug in a subscriber's line jack and presses the key shown to the right, the buzzer vibrates rapidly, interrupting the current in the primary of the repeating coil. The secondary of the coil delivers to the subscriber's line a rapidly alternating current which produces a howling noise in the receiver, hence the name of the device. It is stated that the noise in the subscriber's receiver can be heard at least 100 ft. away, presumably in quiet surroundings. The diagram shows the "howler" or vibrator separate from the repeating coil, but the actual apparatus is made with both vibrator and repeating coil enclosed in a solid oak box 15 x 16 ins.; the case is provided with four terminals to which the circuit wires are attached.

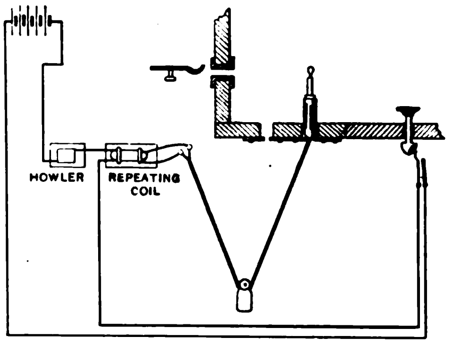

FIG. 11.—STANDARD HOWLER DIAGRAM.

The "howler" here described can, by

slightly modifying the connections, be also used as a busy back signal. Each winding of the repeating coil is divided into two separate coils, so that either the primary or the secondary coils, or both, may be connected in series or in multiple, thus giving four different combinations and three ratios.

LEGAL NOTES.

TROLLEY CONTACT SPRING.—In the suit of the General Electric Company vs. Lorain Steel Company for infringement of the Anderson patent, No. 412,155, Judge Lacombe, of the United States Circuit Court for the Southern District of New York, has granted a motion for a preliminary injunction against the Lorain Steel Company. The patent in question covers the use of metallic conducting brushes between the hub of the trolley wheel and the trolley fork.

RAILWAY CONTROLLER PATENTS.—The United States Circuit Court of Appeals for the second district of New York has declared invalid the Knight controller interlocking patent, No. 428,169, dated May 20, 1890. This patent covers an interlocking arrangement between the controller handle and the reverser handle, designed to prevent the operation of the reversing lever when the controller handle is in any position except that of no current. The Court also declared invalid patents No. 223,167, of August 14, 1883, and No. 401,085, of April 9, 1889, issued to Prof. Elihu Thomson, and covering respectively the application of a magnetic blowout to street railway controllers, and the application of a shield of insulating material between the opposed surfaces of the arc-rupturing device and the electrodes between which the arc is formed.

OBITUARY.

ERIC E. ERICKSON, president of the Erickson Electric Equipment Company, Boston, died at his home in Boston, February 14, after a short illness. Mr. Erickson was well known among the older members of the electrical fraternity, having been connected with various interests since 1885. In the days of the Edison Isolated Lighting Company he was connected with its Boston department. Of later years he was identified with the production of Aetna railway insulation. Three years ago he organized the Erickson Electric Equipment Company for the purpose of installing complete lighting and power plants. Mr. Erickson was fifty years of age at the time of his death.

FRANCIS O. MATTHIESSEN, president of the Weston Electrical Instrument Company, of Newark, N. J., and for several years a director of the American Sugar Refining Company, died recently in Paris. He retired from business about a year ago and had since been traveling for his health. Mr. Matthiessen was born in the Duchy of Holstein, in 1833, and came to the United States in 1859. He was a director of the Goubert Manufacturing Company, the New Jersey Street Railway Company, the Glucose Sugar Refining Company, of Chicago, and was a member of the South Side Sportsmen's Club, the New York Club, the Metropolitan Museum of Art, the Museum of Natural History, and of the New York Chamber of Commerce.

PERSONALS.

MESSRS. EUGENE GRIFFIN and W. J. CLARK, of the General Electric Company, sailed last month for Europe.

MR. H. C. MARSH, who has been connected with the Westinghouse Company's Seattle office for the past year, has been transferred to the Cincinnati office of that company.

MR. CALVERT TOWNLEY, who has been for some time manager of the Boston office of the Westinghouse Company, has been appointed general agent for that company with headquarters in New York.

MR. FRED SARGENT, the well-known electrical engineer of Chicago, was in New York last month on professional matters, and while here purchased considerable apparatus for a new plant which he has under construction.

MR. W. C. JESSUP, a graduate of the engineering school of Columbia University, has joined the forces of the Morris Electric Company, New York, and will devote special attention to the Keystone instruments which this company handles for New York.

MR. WM. B. McCURDY, manager of the New York office of the American Electric Fuse Company, Chicago, was married on March 4 to Miss Estelle M. Dwight, at the bride's home in Chicago. Mr. and Mrs. McCurdy will make their home in Brooklyn.

MR. H. C. HUTCHINSON, who was for several years general superintendent of the Cincinnati Electric Illuminating Company, has been appointed general manager of the company. Mr. W. E. Hopton, of Jersey City, has succeeded Mr. Hutchinson as general superintendent.

MESSRS. WM. C. WOODWARD and M. LOUD, of the Narragansett Electric Lighting Company, Providence, R. I., were visitors in New York City last month. Messrs. Woodward and Loud are rejoicing in the condition of their company's business, which ranks next to that of the Edison Illuminating Company of Boston.

MR. W. H. PELTON, the head of the Pelton Engineering Company, of Cleveland, Ohio, has been ill for the past few weeks as the result of a severe shock received while inspecting an arc-light plant which his company recently installed at Lakewood, Ohio. Mr. Pelton is still in a weak condition and it will probably be some little while before he resumes active work.

DR. LOUIS DUNCAN and DR. CARY T. HUTCHINSON have been appointed consulting electrical engineers to assist Chief Engineer William Barclay Parsons, of the New York City Rapid Transit Commission. Messrs. Duncan and Hutchinson will have charge of all the electrical work to be done in the tunnel now under construction in New York. Drs. Duncan and Hutchinson have been since 1891 associated in much of the important electrical engineering work that has been done. They, in conjunction with Mr. Sprague, designed and built the first large electric locomotive, in 1891, for the North American Company. They were the engineers of the Baltimore & Ohio tunnel work, completed in 1894, and which has been operating so much to the satisfaction of the Baltimore & Ohio Railroad Company that this company has now asked them to investigate the proposition of conducting their entire train service over the Allegheny Mountains by electricity. This will be one of the most extensive electric-traction problems ever undertaken.

TRADE PUBLICATIONS.

LUNDELL FAN MOTORS. Sprague Electric Company.—Catalogue No. 303, containing illustrations and descriptions of the Lundell fan motors for 1901, described in another part of this number.

FLEXIBLE METALLIC TUBING. Albanus L. Smith & Company, Philadelphia, Pa.—A new catalogue of flexible metallic tubing which is adapted for conveying air, steam, gas, oil or water.

LUNDELL MOTORS. Sprague Electric Company, New York.—This is Bulletin No. 205, comprising a well-illustrated catalogue of Lundell motors of both single field-coil and radial-pole types.

EXHAUST HEAD. B. F. Sturtevant Company, Boston, Mass.—A folder giving descriptions and prices of the Sturtevant exhaust head, the size of which ranges from a 1-in. exhaust pipe up to 36 ins.

DIRECT-CURRENT ARC LAMP. The Falcon Electric Manufacturing Company, New York.—Bulletin No. 7, descriptive of Falcon enclosed arc lamps for use on direct-current circuits, and known as Type A.

SELF-COOLING TRANSFORMERS. Westinghouse Electric & Manufacturing Company. —Circular No. 1040, superseding Circular No. 1010, and describing self-cooling transformers ranging in output from 10 to 500 kilowatts.

SEARCHLIGHT PROJECTORS. General Electric Company.—Bulletin No. 4241, describing a line of projectors recently brought out by the General Electric Company which includes sizes ranging from 9 to 36 ins. in diameter.

RHEOSTATS. The Simplex Electrical Company, Cambridgeport, Mass.—A catalogue describing the Simplex "unit" system of dynamo field rheostats, motor-starting rheostats, motor-controlling rheostats, and theater dimmers.

FAN MOTORS. General Electric Company. —Catalogue No. 1031, illustrating the General Electric Company's 1901 line of fan motors for alternating and direct currents. The principal members of the two lines are described elsewhere in this issue.

HOT-WIRE AMMETERS AND VOLTMETERS. Stanley Electric Manufacturing Company, Pittsfield, Mass.—This is Bulletin No. 113, superseding Bulletin 106, and describing the hot-wire instruments manufactured by the Stanley Company.

AUTOMATIC TELEPHONE SYSTEM. The Clark Automatic Telephone Switchboard Company, Providence, R. I.—A catalogue of standard size devoted to the Clark automatic telephone system, which was described in the last issue of this paper.

SWITCHBOARD AMMETERS AND VOLTMETERS. Westinghouse Electric & Manufacturing Company.—This is Circular No. 1041, superseding Circular No. 1014, and describing round-pattern ammeters and voltmeters for switchboard service on direct-current and alternating-current circuits.

CALENDAR. Seaboard Air Line Railway.—This is a belated calendar for 1901 of the hanging type, comprising a cardboard backing with a large monthly-leaf calendar pad. The upper part of the calendar is handsomely illustrated with a portrait of a little girl consulting a map on which the Seaboard Railway is prominent.

TRANSPOSITION OF TELEPHONE WIRES. Ericsson Telephone Company, New York.—This is the fifth of the Ericsson series of pamphlets containing talks on telephone matters. The present issue describes an improved method of making transpositions in telephone wires for eliminating the effects of mutual induction.

ELECTRIC LOCOMOTIVE AND CRANE CAR. Bullock Electric Manufacturing Company, Cincinnati, Ohio.—Bulletin No. 38, illustrating and describing the Bullock Company's combined electric locomotive and crane. The locomotive consists of a flat car having a small cab at one end and a jib crane mounted in the center.

ELECTRIC MINE LOCOMOTIVES. Baldwin Locomotive Works and Westinghouse Electric & Manufacturing Company.—This is a handsome catalogue of mining locomotives, containing views of the various types of locomotives built jointly by the two companies named, and also illustrations of the motors and other parts separately.

GRAPHITE AS A LUBRICANT. Joseph Dixon Crucible Company, Jersey City, N. J.—This is the seventh edition of the Dixon Company's well-known brochure on the subject of graphite used as a lubricant for steam engines and other machinery. The book contains several enthusiastic testimonials from users of graphite for this purpose.

SMALL TELEPHONE SWITCHBOARDS. Kellogg Switchboard & Supply Company, Chicago, Ill.—Bulletin No. 2, containing valuable information concerning the Kellogg line of small switchboards and particularly the express type. The bulletin is beautifully executed on plate paper, the illustrations being equal to the finest grade of magazine work.

ELDEN CIRCUIT BREAKERS. S. B. Condit, Jr., & Co., Boston, Mass.—A tastefully-executed little catalogue in which are described and illustrated Elden alternating-current and direct-current circuit-breakers of the usual type; circuit-breakers designed especially for use with composite alternators, and oil-break circuit-breakers for high-tension alternating-current circuits.

SERIES ALTERNATING-CURRENT ENCLOSED ARC SYSTEM. Manhattan General Construction Company, Newark, N. J.—Bulletin No. 114 C, descriptive of the Manhattan reactive regulating coil for maintaining constant current in a series circuit supplied from a constant-potential origin. The bulletin also describes the Manhattan series enclosed-arc lamp for use in connection with this regulator.

INTERIOR CONDUIT. Sprague Electric Company, New York.—This is Catalogue No. 404 of the well-known iron-armored, brass-armored and plain interior conduit and fittings, and also contains a description of the newer Greenfield flexible metallic conduit and fittings. The catalogue also describes the tools used for installing conduits, together with switches and fuse blocks designed for use in the conduit junction boxes.

BUSINESS NEWS.

G. E. LINTON & CO., Worcester, Mass., have removed their factory to No. 25 Hermon Street, where they have much larger quarters and better facilities.

CROSS OIL FILTERS IN AUSTRALIA.—The Deep Leeds Transmission Company, of Australia, recently installed a Cross oil filter, made by the Burt Manufacturing Company, of Akron, Ohio, in its electrical power station.

THE PHELPS COMPANY, Elmwood, Ill., manufacturer of the Hylo baby filament lamp, has established an office at 177 Summer Street, Boston, Mass., which is in charge of J. L. Russell, the company's New England manager.

THE DIEHL MANUFACTURING COMPANY, of Elizabethport, N. J., has just filed a very large order for ceiling fans and electroliers of very handsome design to be installed in the Imperial Palace on the Island of Formosa.

AMERICAN CIRCULAR LOOM COMPANY, Chelsea, Mass., will shortly remove its Western office from 141 South Clinton Street, Chicago, to 130 Jackson Boulevard, Chicago, in the Electrical Building, at the corner of Desplaines Street.

THE TUDOR BOILER COMPANY, of Cincinnati, Ohio, has commenced the construction of the Babcock & Wilcox type of boilers. This company has just sold three 300-h.p. water-tube boilers to the Chicago Iron Works at East Chicago, Ind.

STANDARD UNDERGROUND CABLE COMPANY, of Pittsburg, Pa., has removed its Boston office to the Tremont Building, Tremont and Beacon Streets. The Boston office remains under the efficient management of Mr. A. B. Saurman.

A CORRECTION.—Owing to a typographical error the torch forming the subject of the advertisement of Messrs. Clayton & Lambert, of Detroit, Mich., in the last two numbers of this paper, was designated as No. 3 instead of No. 8, the correct number. The No. 3 torch uses a pump, while the No. 8 does not.

W. H. CHAPMAN, Portland, Me., manufacturer of the well-known Chapman voltage regulator, has removed his headquarters from 163 Kennebec Street to more commodious quarters at 103 Middle Street, where improved factory facilities will enable him to promptly handle his rapidly increasing business.

NATIONAL CARBON COMPANY, Cleveland, Ohio, desires to call attention to the fact that the fire at its works, which was reported by the daily papers to have destroyed the entire works, resulted only in some damage to the company's laboratory, and has not curtailed in the slightest degree its ability to fill orders.

THE CUTLER-HAMMER MANUFACTURING COMPANY, of Milwaukee, Wis., announces that at its annual meeting recently held, all of the old officers were re-elected; the officers are: F. R. Bacon, president; F. L. Pierce, vice-president; H. H. Cutler, general manager, and J. G. Hickcox, secretary and treasurer.

"CLING-SURFACE" IN HAWAII.—The Hilo Electric Light Company, of Hilo, Hawaii, in a recent letter says: "We take pleasure in stating that Cling-Surface does all you claim for it in improving the operation of belts. At first we used too much, but since refraining for a time from using it, the belt is now running finely."

ORDERS FOR BALL ENGINES.—The Lake Erie Iron Company, Cleveland, Ohio, has recently installed an electric-power plant, the engine being of 175 horse-power, self-oiling, and built by the Ball Engine Company, Erie, Pa. The Northern Pacific Railway Company has also recently purchased from the Ball Engine Company a 150-h.p. self-oiling engine for electrical service.

GREEN FUEL ECONOMIZERS.—The Rhode Island Suburban Railway, of Providence, R. I., has contracted with the New England office of the Green Fuel Economizer Company for an equipment of economizers for 7000 horse-power of water-tube boilers. The Cambridge Electric Light Company, Cambridge, Mass., will have a Green economizer in its new modern power station.

THE WESTERN ELECTRIC COMPANY, Chicago, is receiving many favorable reports from the different plants using its alternating-current series inclosed arc-lighting system. Economy of operation, ease of management, long carbon life, reliability in action and freedom from accidental injury are some of the points which the system is said to afford under all conditions of practice.

THE UNITED STATES CARBON COMPANY, of Cleveland, Ohio, reports that its business at present is extraordinary for this time of year. Usually the demand for arc-light carbons begins to fall off about February 1, in anticipation of the longer spring days, but thus far this year there has been no decrease in the demand, which bids fair to hold up steady into the spring months.

B. F. STURTEVANT COMPANY, Boston, Mass., recently installed an interesting mechanical draft plant at the works of the Diamond Rubber Company, Akron, Ohio. Two fans are employed, and the Rubber company writes that with forced draft at one end and induced draft at the other the apparatus produces a terrific draft, enabling them to make steam with extreme rapidity.

WARREN MANUFACTURING COMPANY, Chicago, Ill., recently received, among other favorable letters, the following from Morelia, Mexico: "Please send me another can of pulley cover. It is the best thing I have run across for saving belting. I have never had a hot box since I put it on my pulleys, and run my belts very loose, taking in consideration that I run at high speed. Signed, Carlos Allen."

THE STANLEY ELECTRIC MANUFACTURING COMPANY, of Pittsfield, Mass., at its annual election of officers re-elected Dr. F. A. C. Perrine president, W. W. Gamwell treasurer, and W. Taylor secretary. Under Dr. Perrine's energetic management the affairs of the company have progressed rapidly and a very large extension of the works at Pittsfield has been found necessary, and is now being carried to completion.

GILLILAND ELECTRIC COMPANY, Adrian, Mich., manufacturer of fine cabinet work and special metal work, announces that it is obtaining a large amount of business from electrical manufacturers. The company's factory is running full time, but its

Sole Manufacturers,
909-100 Washington Street, CHICAGO.

facilities are being increased so that within a short time it will be in a position to take care promptly of any kind of special work in the nature of electrical specialties, telephone parts, etc.

QUAKER CITY RUBBER COMPANY, Philadelphia, has received many strong testimonials to the merits of its P. P. P. rod packing, which was described in the January number of the American Electrician. This packing, it will be remembered, is composed of two wedge-shaped sections of long-wearing material, and a semi-oblong section of absorbent material, the latter serving as a retainer for the oil. The packing is made in all sizes from 3/16 in. up to 1¼ ins. by sixteenths, and up to 3 ins. by eighths.

ALBANUS L. SMITH & CO., Philadelphia, Pa., announce that the list of users of flexible metallic tubing is rapidly growing. The present list of patrons on file includes such representative concerns as the Pennsylvania Railroad, Pennsylvania Steel Company, Standard Oil Company, Philadelphia Edison Company, Wm. Cramp's Ship & Engine Building Company, Spreckels Sugar Refining Company, American Iron & Steel Manufacturing Company, Chapman Wrecking Company, and the Consolidated Gas Company, of New York.

THE MARIETTA MANUFACTURING COMPANY, of Marietta, Pa., against whom an injunction was obtained by the Diehl Manufacturing Company, prohibiting the manufacture of its Crescent ceiling fans, has just completed an agreement with the Diehl Company by which it is enabled to continue the manufacture by paying a royalty. This company is undergoing reorganization, but will push the manufacture and sale of Crescent fans to the utmost, combining the valuable features covered by the Diehl patents with those covered by its own.

THE MARINETTE IRON WORKS, of Marinette, Wis., states that it is making extensive improvements in its plant, building a 120-ft. addition to the machine shop, installing an electric crane there and large boring mills. The company is installing a Taylor gas producer, manufactured by R. D. Wood & Company, in connection with which Walworth gas engines of the company's own make will be used throughout the plant. The company is overcrowded with orders for engines, not only from the United States, but also from several foreign countries.

THE VAN DORN-ELLIOTT ELECTRICAL COMPANY, of Cleveland, has been incorporated by J. H. Van Dorn, H. H. Hodell, F. Schneider, W. A. Dutton and W. H. Elliott. Capital stock, $50,000. The new company takes over the electrical repair, armature winding and manufacturing business heretofore carried on by Van Dorn & Dutton, also the electrical repair business carried on by W. H. Elliott of that city. The gear manufacturing business carried on by Van Dorn & Dutton will be continued as heretofore under the old name. The new company will occupy a portion of the Van Dorn & Dutton plant. J. H. Van Dorn will be president.

THE TRIUMPH ELECTRIC COMPANY, Cincinnati, Ohio, reports the following recent orders: One 250-kw., three-bearing, slow-speed, belted-type generator for the Laclede Gas Light Company, of St. Louis, a duplicate of the machine sold to the same concern four months ago; one 80-kw. generator for the St. Louis Coffin Company; one 80-kw. belted generator for the Mannering Electric Light Company, of Mannering, Iowa; two 60-kw. belted generators for the Carrolton Electric Company, Carrolton, Iowa; and an unusually large number of orders for small machines.

THE LEA-HOOVEN MANUFACTURING COMPANY, of Anderson, Ind., was recently absorbed by the Anderson Tool Company of the same city, which was reorganized for this purpose. This company will enter extensively into the manufacture of the well-known Lea-Hooven arc lamp, and will also continue to make the electrically-driven tool grinders which have met with such high favor. The company's facilities have been doubled within the past six months, and still further extensions are contemplated in the near future. The officers of the new company are C. A. Eastman, president, and A. G. Lea, general manager.

WEINLAND TUBE CLEANERS COMMENDED.—The Lagonda Manufacturing Company, Springfield, Ohio, recently received the following significant letter: "We have in use four water-tube boilers, and for a number of years have tried all kinds of experiments to get the scale taken out; in every case we met with total failure until by good fortune we used the Weinland tube cleaner. The machine is an absolute success for these boilers, and we most cheerfully recommend it to anyone. Scale ¾ in. thick and over has been taken from our boiler tubes." Signed, G. M. Gunderson, manager United States Brewing Company, Chicago, Ill.

THE AMERICAN ELECTRIC FUSE COMPANY, Chicago, Ill., announces that it has more than doubled its working capacity, and has installed new and complete machinery for the purpose of turning out its well-known specialties. The company expects to place on the market in the near future important additions to its standard line of fuses, fuse boxes, lightning arresters and connectors. In addition to these specialties the company also manufactures a complete line of silk and cotton-covered magnet wire, and carries a stock of all sizes constantly on hand. The eastern office of the company is located at 116 Nassau Street, New York, and is in charge of Mr. W. B. McCurdy. This office carries in stock a full line of fuses, fuse wire, lightning arresters, wire connectors, etc. The Western office, at San Francisco, will be conducted on the same line as the Eastern office.

PLATINUM
In Sheet or Wire, any Degree of Hardness. FOR ALL PURPOSES.
BAKER & CO.,
NEWARK, N. J.
New York Office, 120 Liberty Street.

J. HOLT GATES & CO., Chicago, have just installed a 250-h.p. electric power plant for the Grower Building, Chicago, in connection with a Vilter Corliss engine. This firm has been very busy this winter. Among other installations is one just started at the village of Blue Island, Ill., which includes a 2500-light Warren inductor alternator with a new style four-valve Ideal self-oiling engine. The series alternating-arc system of the Manhattan General Construction Company, consisting of two 25-light regulators and two 15-kw. step-up transformers, was also installed, together with a large number of 50-c.p. incandescent lamps in series with the arc lamps. Messrs. Gates & Co. have also installed for the municipality of Newberry, Mich., a 1200-light Warren inductor alternator direct-connected to an Erie Ball engine running at 300 r.p.m. A prominent feature of this plant is that there is not an oil cup on the outfit, and it is almost entirely automatic.

OLDS MOTOR WORKS, Detroit and Lansing, Mich., suffered a loss of about two-thirds of the Detroit plant by fire on March 9. The company has secured temporary quarters, however, in which new machinery has been already installed, and is now in a position to take orders for Olds mobile gasoline runabouts for May delivery. The Lansing plant will take care of the company's gasoline engine business by running night and day, so that all orders will be filled with the usual promptness. The temporary plant in Detroit already has a capacity of 10 complete gasoline runabouts a day, and will have caught up with its orders by May 1. The fire was not caused by an explosion of gasoline, as some of the papers stated; there was no gasoline stored in the building. The explosions heard during the fire were from the carbonic-acid gas tanks used in inflating tires. The origin of the fire was a leakage in the natural-gas pipes, which opened a 3-in. main into the center of the building; this fact explains the rapidity with which the fire progressed.

THE BULLOCK ELECTRIC MANUFACTURING COMPANY, of Cincinnati, Ohio, is enjoying a fine export trade in addition to its home business. Among recent sales abroad were these: Glasgow (Scotland) Evening News, three motor-generators; London Daily Express, three motor-generators; Montreal Water & Power Co., one 400-h.p. three-phase motor; Aberdeen (Scotland) Journal, one 30-h.p. teaser equipment and one motor-generator. Among domestic orders were the following: Carnegie Steel Company, one 25-h.p. type "H" motor; Greuner & Co., Johnstown, Pa., one 30-kw. type "I" generator; Brown & Sharpe, four type "N" motors for direct connection to machine tools; Wier Frog Company, Cincinnati, Ohio, three 10-h.p. type "N" motors; Pullman Company, two 150-kw. type "H" generators; Mosler Safe Company, Hamilton, Ohio, one 50-h.p. type "H" motor; Susquehanna Valley Electric Company, Sidney, N. Y., one 65-kw. single-phase generator; Central Lard Company, New York, one 65-kw. engine-type generator; Buffalo Evening News, one 70-h.p. type "H" motor.

THE CROCKER-WHEELER COMPANY, Ampere, N. J., reports the following recent sales of direct-connected generators: Schwartzschild & Sulzberger, two 250-kw. United States Mint, Philadelphia, two 200-kw., one 150-kw., one 75-kw.; Brown Shoe Co., St. Louis, one 200-kw.; Hahne & Co., Newark. N. J., two 200-kw., one 100-kw.; E. I. DuPont de Nemours, Wilmington, Del., one 200-kw.; Navy Yard, Washington, D. C., two 150-kw.; National Electric Supply Co., Washington, D. C., one 50-kw.; Bement, Miles & Co., Philadelphia, Pa., one 50-kw.; Toledo Bridge Co., Toledo, Ohio, one 50-kw.; White Star Line, one 50-kw. In addition to these, the following motors have been sold: Philadelphia Engineering Works, 46 motors aggregating over 700 horse-power and making upwards of 3000 horse-power sold to that company; Pencoyd Iron Works, 4 motors aggregating 60 horse-power and making over 4000 horse-power sold to them; Schwartzschild & Sulzberger, two 75-h.p., two 50-h.p., seven 25-h.p., 14 motors aggregating 160 horse-power in addition to 500 horse-power already sold to them.

THE PELTON WATER WHEEL COMPANY, San Francisco, recently furnished equipment for plants as follows: Keswick Electric Power Company, California, head, 1200 ft., three units of 1600 horse-power each, for electric transmission; British Columbia Electric Railway Company, Victoria, B. C., (second station), head 700 ft., one unit of 900 horse-power for electric transmission and lighting; Big Creek Power Company, California, head 920 ft., 900 horse-power, driving two generators for power and light (second station); 100-h.p. plant for Pigeon Bay, New Zealand, operating an electric-light generator; 75-h.p. installation for a tea estate in Java, electric-light plant; 2000-h.p. unit under 500-ft. head, for electric-transmission plant in Colorado; 150-h.p. wheel, 250-ft. head, operating flour mill and electric-light plant in Utah; 75-h.p. wheel, 400-ft. head, operating electric-light plant in Borneo; 50-h.p. wheel, running generator for mine in Idaho; double unit of 250-h.p. capacity, electric transmission plant near Auburn, Cal.; 30-h.p. wheel, electric-lighting plant, Apia, Samoa; 30-h.p. wheel and transmission machinery for electric-light plant, Guatemala; 30-h.p. wheel for electric lighting, Sydney, N. S. W., and a 6-ft. wheel, 200 horse-power, for a silk mill in Japan.

THE ELECTRIC STORAGE BATTERY COMPANY, of Philadelphia, has found it necessary to open a sales office at San Francisco in order to take care of the increasing volume of business from the Pacific Coast states and the extreme western territories. This office is located in the Nevada Block and is in charge of Mr. R. B. Daggett, who has for a long period been connected with the company's staff of engineers at the Philadelphia office; his experience gained there will enable him to handle the different problems of modern storage-battery practice arising in this district.with skill and promptness. The company has recently closed a contract with the United Electric Light & Power Company, of Baltimore, for the installation of a battery of "Chloride" accumulators, consisting of 132 elements, having a capacity of 1200 ampere-hours, and with tanks allowing an ultimate increase by additional plates, to a capacity of 2100 ampere-hours. The location of the battery is 5000 ft. from the power house and it is to be operated in connection with two boosters having a capacity of 500 amperes at 35 volts. The current is furnished from the power house at 220 volts, and as it is intended to use 110-volt lamps and 220-volt elevator motors, a third wire will be taken from the center of the battery to form the neutral of 220-volt three-wire system. The two constant-current boosters will be used on the outside wires for regulating the elevator load. Another notable contract recently closed is one for the installation of a battery of Chloride accumulators for the estate of Henry Villard at Dobbs Ferry, N. Y. The battery is to be used for residence lighting, and consists of 68 elements, having a rating of 280 ampere-hours at normal discharge, and will be operated in connection with two 12½-kw. dynamos driven by two 20-h.p. gasoline engines. For ordinary requirements the battery will be charged during the day and will carry all the lighting load, but on special occasions will be operated in parallel with the dynamos.

SOLID TRAINS TO NORTHERN MICHIGAN.

The Chicago, Milwaukee & St. Paul Railway is now running solid trains of palace sleeping cars, dining cars (serving meals a la carte) and first-class day coaches, through from Chicago to Calumet, Houghton, Hancock and other points in the Copper Country without change of cars, with direct connection for Marquette, Negaunee, Ishpeming, etc., and passengers from the East, South and Southwest will find this a most desirable route.

All coupon ticket agents sell tickets via the Chicago, Milwaukee & St. Paul Railway.

COMEAD MFG. CO., Buffalo, N. Y.

American Electrician.

Vol. XIII. New York, May, 1901. No. 5.

A COMBINED ELECTRIC LIGHTING AND STEAM HEATING PLANT.

INCANDESCENT AND ARC LAMPS AND STEAM RADIATORS SUPPLIED FROM ONE POWER HOUSE.

BY W. N. ZURFLUH.

The plant which is here described was originally designed to light and heat two business buildings in Springfield, Ohio—namely, the Arcade Building and the Press-Republic printing establishment. The plant has since been enlarged, however, to take care of some commercial lighting in the business part of the city. The ordinary direct-current system is used, with a circuit e.m.f. of 110 volts. The plant is located near the center of the city, and is just in the rear of the new Kelly Building, occupied by the Springfield Publishing Company. The building is of dark-red brick laid in red mortar with limestone foundations and free stone trimmings and water table. Its length is 102 ft., width 49 ft., and the side walls are 18 ft. high. The foundations are heavy for so low a building, being 36 ins. thick for the side and middle walls under the engine room. In the boiler room they are 24 ins. thick in the side walls; both end walls are 18 ins. thick. The brick walls are 17 ins. thick and have 22-in. buttresses for the roof trusses. The ends of the building have been closed in with wooden walls, so as to provide for future extensions with small expense.

The engine room site was excavated to the same grade as the boiler room and the floor placed so as to provide 6 ft. of space beneath it for exhaust steam pipes and dynamo connections. This floor is supported on Georgia pine beams 12 ins. square, the ends of which rest on the side walls and engine foundations. On these beams and at right angles 12-in. x 6-in. joists are placed on which the first floor of matched pine 2⅝ ins. thick is laid and finally a hard maple finishing floor ⅞ in. thick on top of this. The manner of placing the generating units allows the plant to be duplicated without disturbing the present installation. The end walls are framed with pine studding and are covered with ⅞-in. beaded pine flooring, both inside and outside. The roof is supported by the dividing wall between the engine and boiler rooms, and six steel trusses which are held together by nine pine purlines bolted to them. The roof sheeting is matched pine strips 2⅝ ins. thick and 6 ins. wide, on which the Scott's old-style tin roofing is fastened. This is laid on rosin-sized paper and is ridged with a double pressed ¾-in. ridge. Two skylights of hammered glass are placed in the east side of the roof, one each for the engine and boiler rooms. These supply light for the eastern side of the house, as no windows nor doors open on that side. A cement floor is laid in the boiler room.

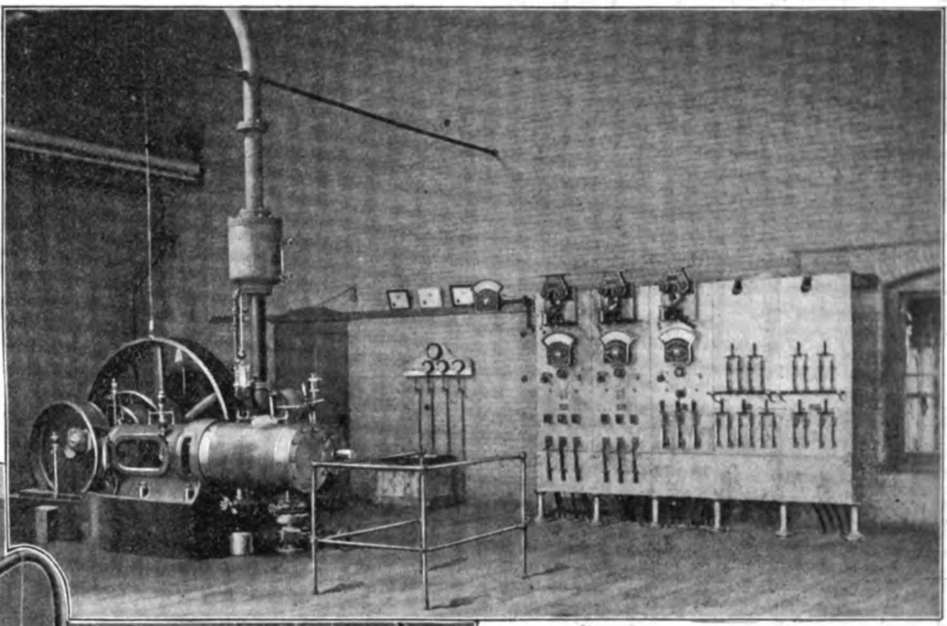

FIG. 2.—VIEW OF SWITCHBOARD.

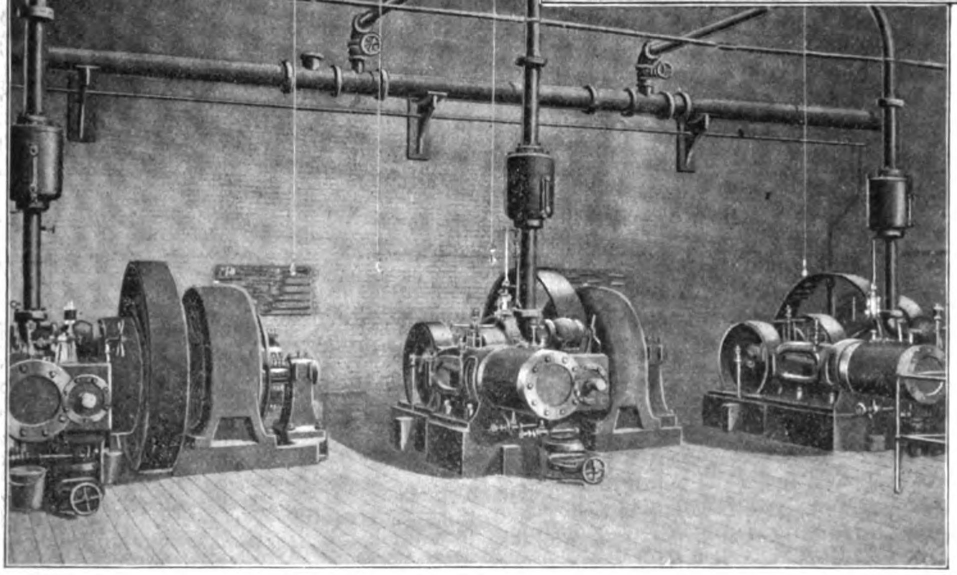

FIG. 1.—VIEW OF ONE END OF ENGINE ROOM.

There are at present two boilers of the B. & W. water-tube type, built by the Aultman & Taylor Manufacturing Company, Mansfield, Ohio. They have a combined capacity of 400 horse-power. Each boiler has two steam drums 23 ft. 3⅝ ins. long by 36 ins. in diameter, each drum being connected to 10 tube-sections. They are hung in the usual manner and were tested to a pressure of 190 lbs. per square inch before being bricked in. The steam pressure carried is 120 lbs. The fronts are the usual standard full-flush design as to the upper parts, but the lower parts were designed and installed by the stoker builders. The usual iron water columns and brass pipe fittings are provided. An accident worth mentioning occurred to one of the water columns on the first night the plant was in operation. It is common practice to mount the water columns without providing valves between the steam drums and the columns. As such valves were not specified in the contract, they had been omitted by the erector against the protest of the present writer. During the early evening of the first night the plant was in operation the drain pipe at the bottom of one of the water columns blew out, taking the screw-thread with it, and as there was no way to shut it off a shut-down seemed certain. However, the hole was fortunately plugged with a sharpened stick of wood, but not until the boiler pressure had been seriously reduced and steam had been raised in the other boiler.

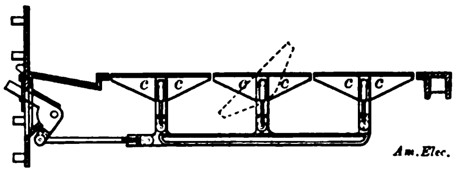

FIG. 3.—DUMPING GRATE.

Both boilers are provided with underfeed and underdraught mechanical stokers, built by the American Stoker Company. These are of the latest remodeled pattern. In place of the old style of grate a new pattern is used which has two sets of T-shaped tilting bars, there being three bars (*c*, *c*, *c*, Fig. 3) on each side of the stoker. These are hung on trunnions at the middle and can be tilted to a position at right angles to their normal position by means of a bar connecting each set together. The hopper and feeder worm are similar to previous patterns, but the casing and form are changed. The air comes into the lower part of the stoker, as shown in Fig. 5, at *A* and passes upward, emerging from the upper part of the stoker through two rows of holes, *B*, *B*, which allow the draught to blow through the bank of coal as it is fed inward and upward by the worm. The coal as it comes up from the worm, forced by the pressure of the continuous stream following it, spreads over the stoker proper and as it receives the extra supply of oxygen the combustible is thoroughly consumed and the refuse is pushed sidewise on to the dumping bars, *c*, *c*, *c*, just mentioned, which deliver it to the ash-pit. The exhaust steam from the stoker is turned into the ash-pit. As the details of the steam action are the same as in former patterns of this stoker it is unnecessary to burden this article with that description. The stoker blower and engine were made by the Sturtevant Company, the engine being a 5-in. x 5-in. vertical automatic. The air leaves the blower through a galvanized-iron duct which starts with a diameter of 18 ins. and enlarges to 28 ins. This duct is covered over by iron plates resting on brick walls at the level of the floor.

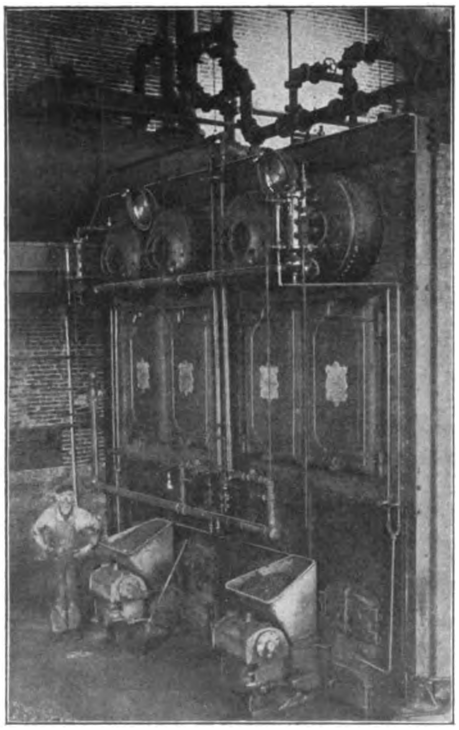

FIG. 4.—PARTIAL VIEW OF BOILERS.

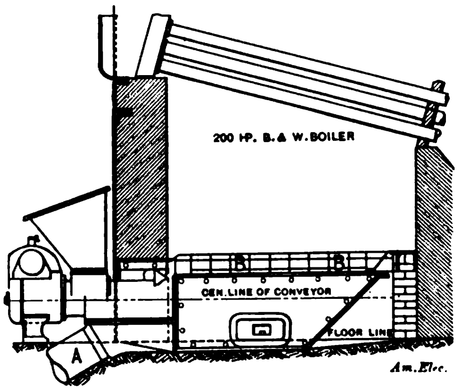

FIG. 5.—STOKER SETTING.

The chimney is a combination brick and steel structure, 94 ft. high. The lower 34 ft. is of brick with a 6-ft. diameter and 13-in. walls; the inside of this part is lined with fire brick. The steel portion is 60 ft. high and also 6 ft. in diameter; this part is built of No. 8 and No. 10 sheet steel, and rests on a heavy cast-iron plate on top of the brick stack.

The steam plant is equipped with both a purifier and a heater, of the Hoppes Manufacturing Company's make. The heater is fitted with one tier of trough-shaped pans, five pans being placed in a tier; each pan is 5 ft. long, and the heater has a total heating and lime-catching surface of 150 sq. ft. The purifier has three tiers of trough-shaped pans, six pans being placed in each tier; each pan is 6 ft. long, with a total heating and lime-catching surface of 546 sq. ft. The rated capacity of the heater and purifier is 300 horse-power each. Although this capacity is less than that of the total boiler rating, the return of the water of condensation makes up the deficiency when the plant has a load of over 300 horse-power. Two Stilwell-Bierce pumps, 10 ins. x 7 ins. x 4½ ins., located alongside the boilers, handle the boiler feed; they take the water from a well. The piping connections are described in another part of this article.

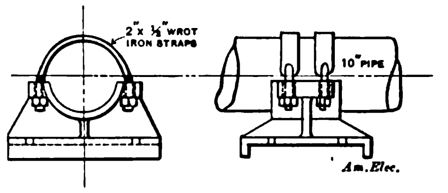

FIG. 6.—ANCHOR SADDLE.

The engines are of the well-known high-duty type, with double valves, built by the Buckeye Engine Company. Three have been installed so far; all three have cylinders of 14¼ ins. bore and 16 ins. stroke, and they are direct-connected to the dynamos. The usual Buckeye governor and auxiliary devices are used. Each engine is rated at 156 horse-power, with 120 lbs. initial steam pressure, running at a speed of 225 r.p.m. The engines are guaranteed to carry a maximum load of 220 horse-power in case of an emergency. The foundations for the three generating sets are of brick and Portland cement, so constructed that they are continuous and form one solid mass. The upper parts on which the engines and dynamos rest are made up of concrete artificial stone.

Fig. 8 shows the steam piping for the boilers and engines, and Fig. 9 the piping for the pumps and heater. All steam piping is of extra heavy wrought iron, with flange connections. This part of the work was installed by the M. H. Crane estate, Cincinnati, Ohio. The main steam pipes from the boilers are 8-in. and lead to a 10-in. header which extends along the east wall, through an opening in the partition wall, to the engine room, where 5-in. branches supply the engines individually. This header is supported on five hanger brackets of special design, one of which is shown by Fig. 7; it is anchored where it passes through the dividing wall by a saddle, Fig. 6, held by four ¾-in. rods embedded 30 ins. in the wall. A special 2-in. pipe also hung in the brackets serves as a "bleeder" for the water

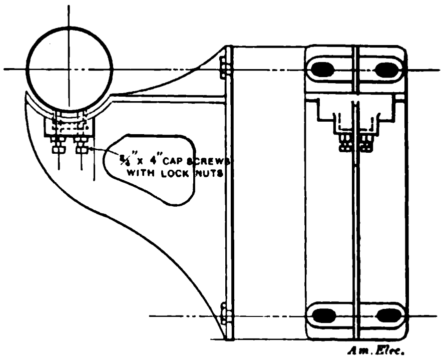

FIG. 7.—PIPE HANGER BRACKET.

of condensation forming in the pipe; this "bleeder" discharges through a trap valve into the sewer. Expansion in the header is taken care of by rollers in the brackets on which the pipe rests, the pipe being rigidly strapped to the iron saddle where it passes through the dividing wall. Each engine receives steam through a gate valve placed in the individual supply pipe where it leaves the header. The engine steam pipes have fire bends of 7-ft. radius and deliver steam through Cochrane sep-

FIG. 10.—PLAN OF BOILER CONNECTIONS.

arators (built by Harrison Safety Boiler Works) placed just above the throttle valves. Detroit lubricators are used. The individual exhaust pipes discharge into a 12-in. header which has two outlets, one to the underground heating system and the other through the feed-water heater to the roof, where an exhaust head is provided, as shown in Fig. 8.

Besides the two 8-in. steam pipes from the boilers there is also another set of 4-in. pipes (see Fig. 10) which tap the pipe provided for the safety valves. Two rise from each boiler and unite in a 6-in. header which supplies the pumps, stoker engine and the underground system with live steam and also forms a by-pass to the main 10-in. steam header just as it enters the engine room. This part of the piping is shown in Fig. 10. The water supply piping, shown in Fig. 11, has connections so either pump can be made to supply a 60-bbl. steel tank on the roof, from which tank the water runs by gravity to the purifier and is then pumped into the boilers by the other pump. The city water is also available, although it is only used in case of the failure of the well. The boilers have blow-off connections through 3-in. pipes to a cistern in the boiler room. This cistern is provided with an overflow drain and a vent for the steam received by the discharge of the blower engine and the pumps.

There are three six-pole dynamos, each of 100-kw. capacity, direct-connected to the engines, as previously stated. These are General Electric machines. The brush

e.m.f. is 120 volts at no load and 125 volts at full load. The dynamos are over-compounded 10 per cent, but this is reduced by a German silver shunt to 3 per cent. The series field windings were designed to have as nearly as possible the same resistance, and tests showed a reasonable division of the load when all three were run in parallel. Below are the results of one of the tests made by the consulting engineer, Mr. Bert L. Baldwin. Loads of 410, 550, 533, 970 and 1170 amperes were shifted from one machine to the three. No. 1 dynamo took a larger portion of the load, which was due to its having been run longer and being consequently in better condition. It was also found later that No. 1 could be made to take less load by reducing its voltage below that of No. 2 and 3 before throwing on the load. The General Electric Company has since the time of the test sent another resistance shunt for the No. 1 dynamo.

DIVISION OF CURRENT BETWEEN DYNAMOS.

No. 1 Dynamo.	No. 2 Dynamo.	No. 3 Dynamo.
165	109	145

560	230	350

The switchboard has five panels, three for the dynamos, and two for the feeder

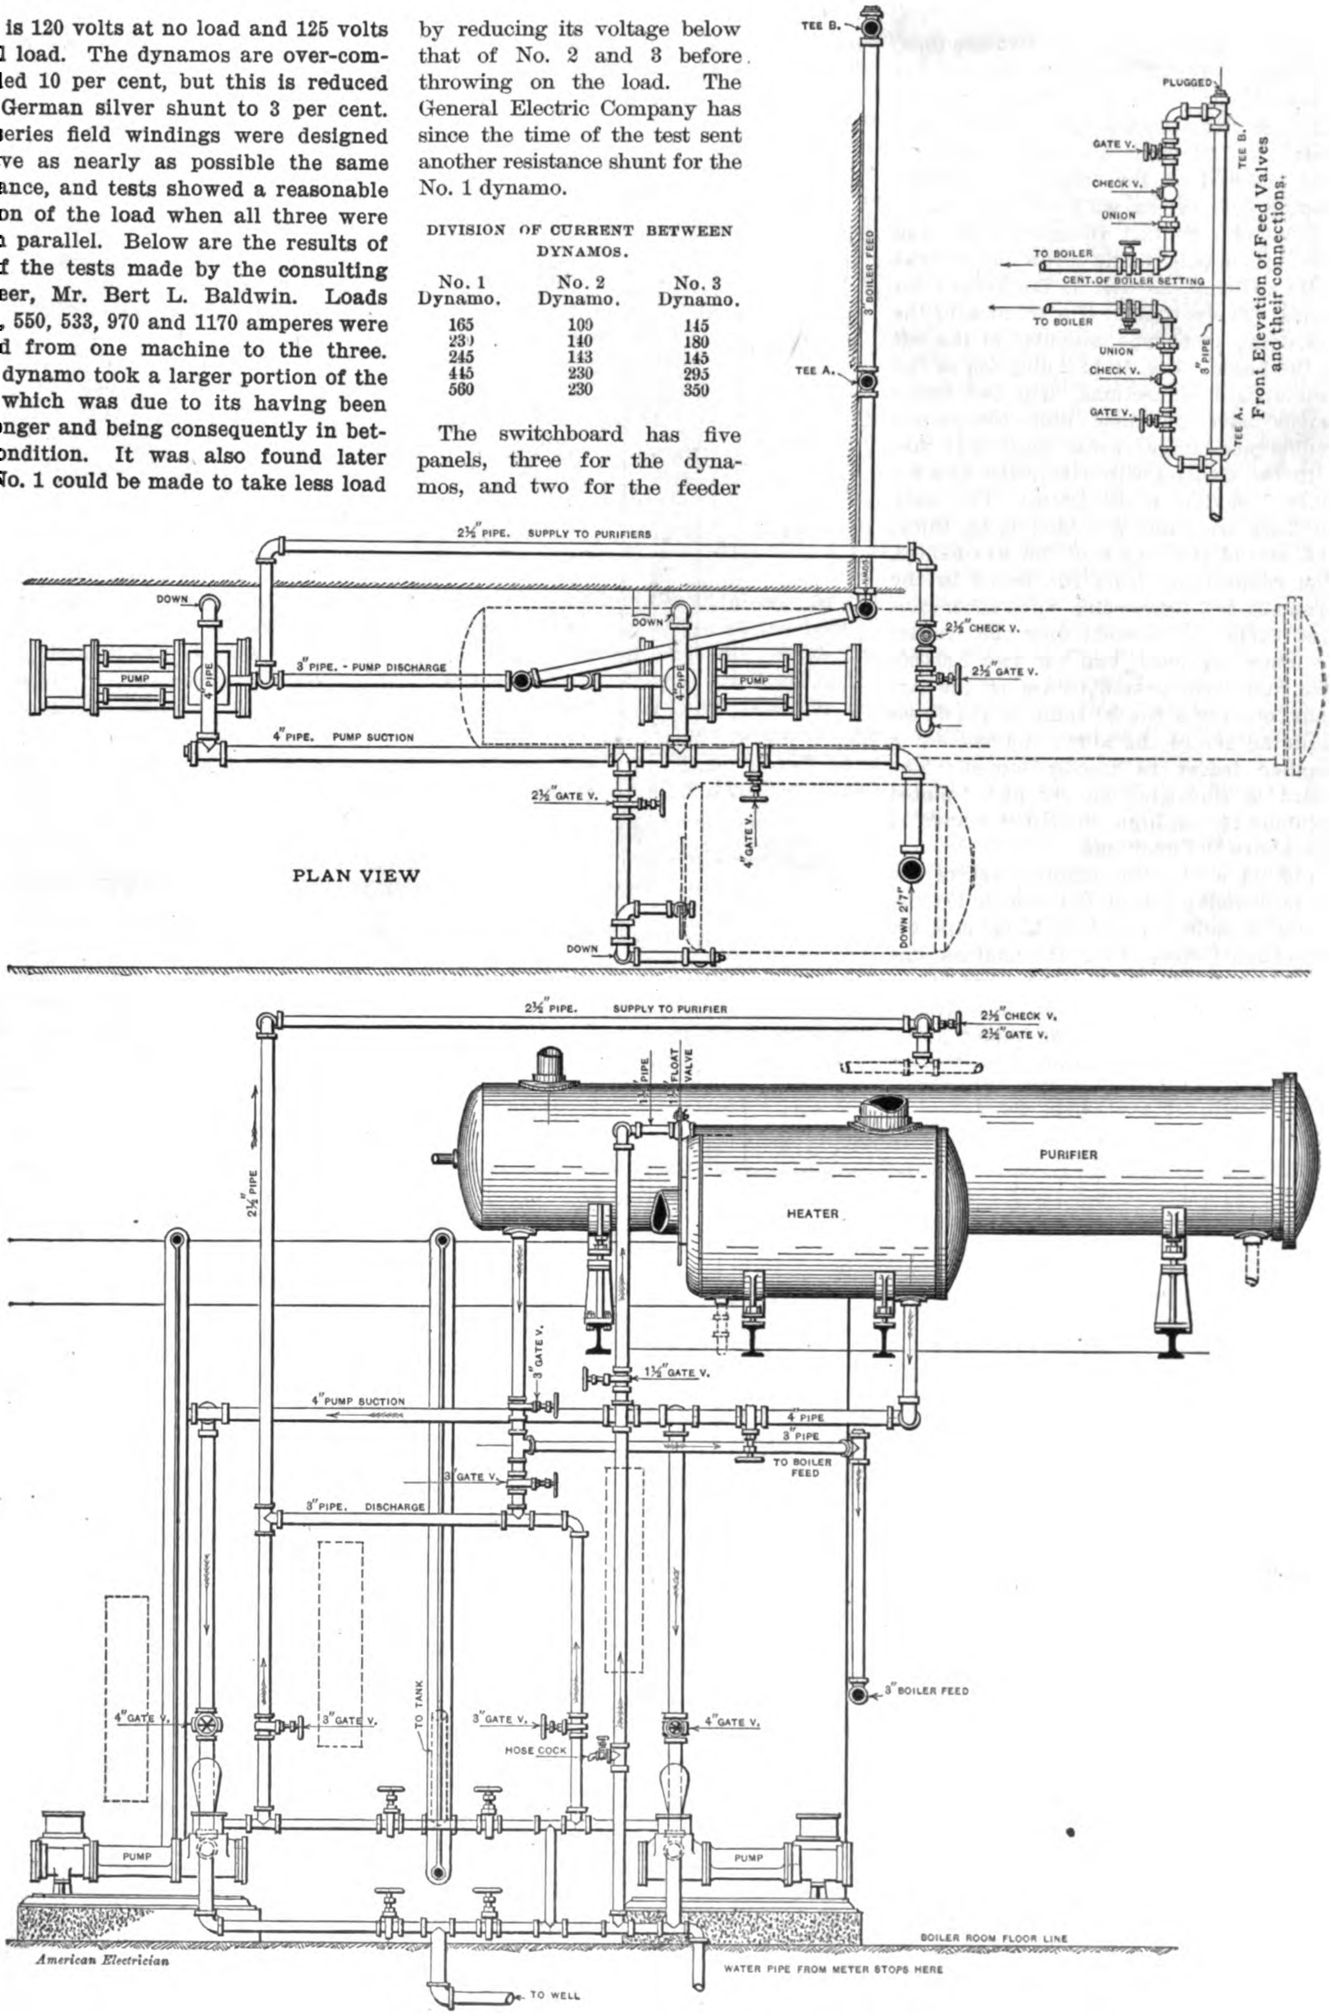

FIG. 11.—ELEVATION AND PLAN VIEWS OF WATER CONNECTIONS.

switches. Each panel is in two sections, the upper being 62 ins. by 24 ins. and the lower 16 ins. by 24 ins. Each generator panel carries a 1200-ampere Weston ammeter; a 1200-ampere circuit-breaker; a field rheostat on the back of the board; a shunt field switch, with discharge lamp; a four-point contact voltmeter plug, and three single-pole single-throw quick-break knife switches, as well as the usual pilot lamps. The voltmeter is a Weston, of the "swinging-arm" type, mounted at the left of the board. Fig. 13 is a diagram of the switchboard connections. The two feeder panels have on them nine 500-ampere double-pole single-throw knife switches with the General Electric spring clip for quick breaking of the circuit. The main bus-bars are 5 ins. wide and ¼ in. thick, and extend the length of the five panels. The connections from the board to the dynamos are 400,000-circ. mil rubber-covered cable. At present only four feeder switches are used, two for two 500,000-circ. mil lead-covered cables to the Arcade, one for a No. 00 cable to the Press Building across the alley, and one for a smaller feeder to nearby stores. The board is supported on six nickel-plated columns 12 ins. high, so that it stands 12 ins. above the floor line.

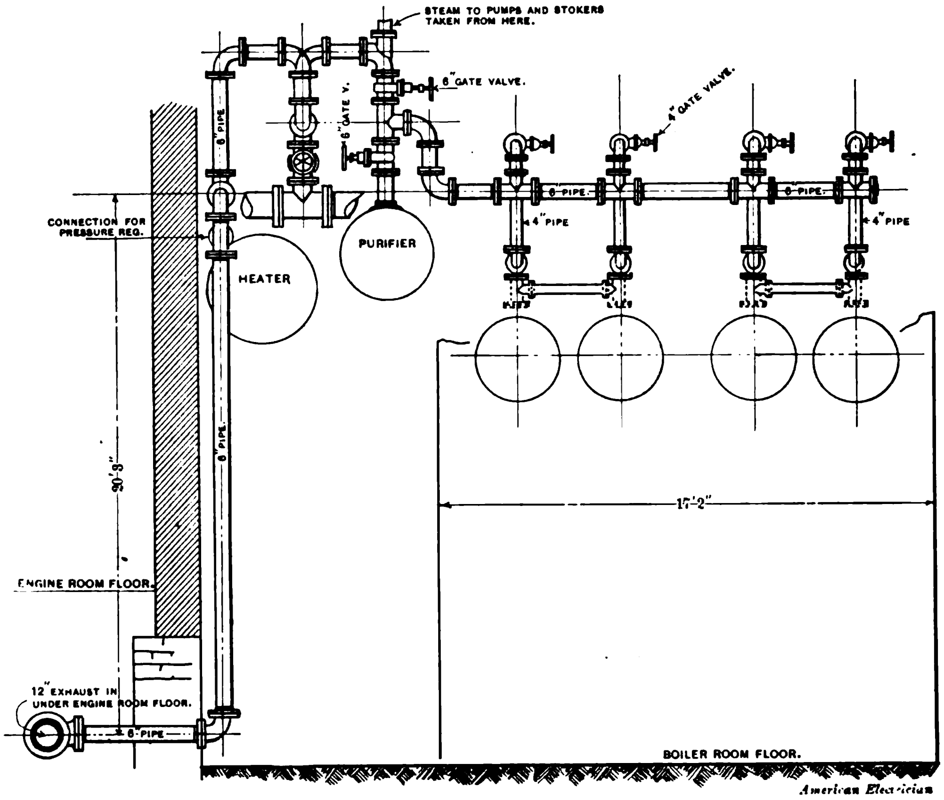

FIG. 12.—FRONT ELEVATION OF PURIFIER CONNECTIONS.

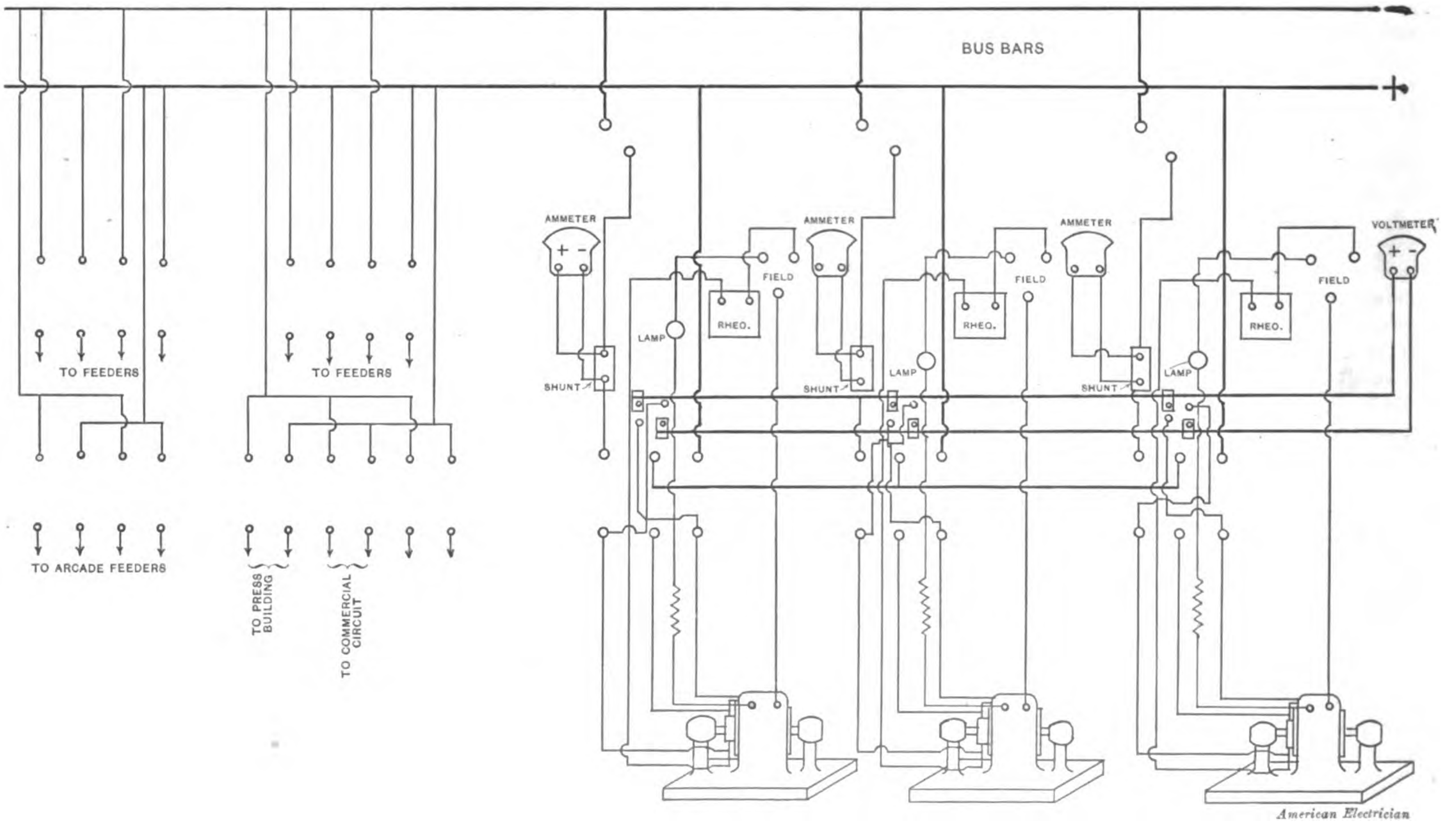

FIG. 13.—DIAGRAM OF SWITCHBOARD WIRING.

Fig. 14 shows the arrangement of the three steam pipes in the trench leading to the Arcade; there is a 12-in. pipe for the exhaust steam from the engines, one 3-in. pipe to convey high-pressure steam to the vacuum pump under the Arcade and supply other needs for higher pressure at the hotel, and another 3-in. pipe which is the return to bring back the water of condensation; the Paul system of steam heating is used in the Arcade Building. The principle of the Paul system is, briefly, the drawing of steam through the pipes by attaching a pump at the outer end of the system and thus creating a partial vacuum which is filled by the following steam, even at a low pressure such as that of exhaust steam. The return water of condensation is pumped into an iron tank of 60 barrels capacity placed on the roof, from which point it is again pumped into the boilers. The oil from the engine exhausts is removed by a trap. Each of the underground pipes is covered by patented double wooden coverings of octagon shape, having the two parts separated by tarred paper. The sections are 8 ft. long and each length had the outer covering removed for 6 ins. on one end and the inner cover removed on the other end, so the lengths can be driven together, making tight fits at the joints. The inner and outer parts of the pipe covering are made up of matched wooden boards bound together by wrappings of galvanized-iron wire, and it is coated with tar on the outside. The tarred exterior is rolled in sawdust to facilitate the handling of the covering.

It was the intention of the engineer to drain all of the condensed steam in the pipes in the direction of its flow, since the plant is on higher ground than the places to be heated. The steam pipes and the electric cable conduits were laid side by side in the same alley, taking up a width of 7 ft. As the alley is but 10 ft. wide the undertaking was a difficult one on account of the dirt to be handled and the nearness of the building foundations. No serious difficulty was encountered in excavating, however, until the crossings at Limestone street were reached. Here were first the telephone ducts which began close to the pavement and extended 40 ins. below it; under these was a water pipe, still lower a 12-in. tile sewer, and finally a foot lower another tile sewer 6 ins. in diameter. This compelled the pipes to be placed 5 ft. below the proposed grade, which brought the steam pipes, especially the exhaust pipe, which is the under one, dangerously near the level of a creek only 50 ft. away. At a point 220 ft. from the end of the line it was found necessary to raise the pipes 26 ins. and insert an elbow. A "bleeder" pipe and water trap were placed here to drain the exhaust steam pipe. This drain pipe was carried under the mains to the Arcade Building where it discharges into the sewer.

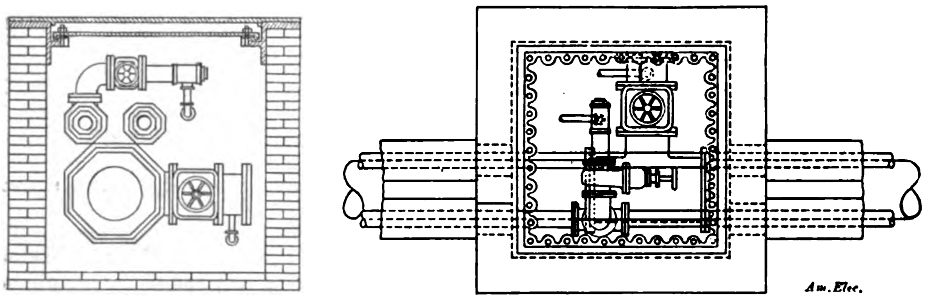

FIG. 14.—DETAILS OF STEAM PIPE MANHOLE.

Manholes were placed at four points along the line, one at the first turn in the alley at the rear of the plant, where anchor piers were also provided; another 150 ft. further along, at which point a brass expansion joint for each pipe was placed, the third at a point 200 ft. further along the line, also provided with expansion joints, and the fourth at the end of the line where a set of tees and branch line valves are placed. Anchor piers are also placed midway between the expansion joints and at the end of the line. These consist of brick and cement and have the pipes embedded in them. The latter have collars bolted on to make them hold in the piers. Fig. 14 gives details of a manhole. The expansion joints have heavy chains and collars attached to prevent them from pulling apart when the pipes contract.

The conduit for the electric cables is the well-known Camp tile. It is laid in rows with ⅛ in. of Portland cement between each row to bind the tiles, and a wall 6 ins. thick, consisting of one part Louisville cement, two parts sand and five parts screened gravel, completely envelops the tiles. The line starts with 32 ducts at the power house, a manhole being placed at this point, so that it opens one side into the building. At the corner of the cross alleys at the rear of the plant is another manhole. From this the main line of 20 ducts runs west to the Arcade. There are 12 "blind" ducts in the east wall and 16 "blind" ducts in the north wall of this manhole. The 20 ducts continue to the third manhole at Limestone street, where 16 blind ducts are placed on the north and 12 on the south side. At the Arcade manhole, or No. 4, there are 8 ducts carried into the basement of the building, while the balance stop at this manhole. At present but 4 ducts are used for the lead-covered cables supplying current to the lights and motors used at the Arcade. Fig. 15 shows the arrangement of the ducts and the details of a conduit manhole.

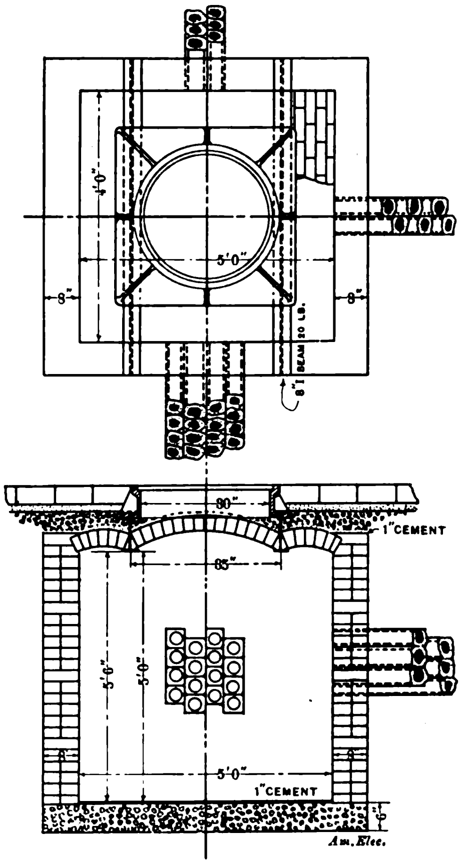

FIG. 15.—CONDUIT MANHOLE.

The laying of the tile itself was rapid, the greatest difficulty being the excavation and preparation of the trench. This was given an average depth of 4½ ft., the bottom being carefully smoothed. Then a layer of concrete 6 ins. thick was put on the bottom of the trench; this was allowed to harden for 12 hours. A thin layer of Portland cement was put over the surface of the concrete, on which the tile was laid. The usual Camp conduit mandrels were inserted and pulled through the tile, smoothing out the surplus cement at the joints. A layer of tile was run for a hundred or more feet and then another layer put on top of this, and so on, until the number of layers desired were in place, each layer having ⅛ in. of Portland cement to bind it to its neighbor. The tiles were not at once covered on top and along the sides, but allowed to stand until the thin layers of cement had sufficiently hardened. The concrete side walls and top were then filled in and allowed to become hard before filling in the trench. This was done in order to prevent the tiles from being displaced by careless workmen when the earth was tamped on top of them. It was found necessary to provide 1½-in. pipe vents for each manhole owing to leaky natural gas pipes.

After the ducts were ready to receive the cable a "pilot" wire was drawn into each of them from one manhole to the next. From the first manhole at the power house to the next is but 70 ft., so it was an easy matter to push a No. 8 galvanized-iron wire through. As the second manhole from the plant marks a right-angle turn, the cable was started here and the pilot wires pulled from it to the next manhole, a distance of 265 ft., by means of jointed rods made up in 4-ft. lengths. As each joint was pushed into the duct another one was screwed on and the entire length finally pushed to the next manhole. Each section of a jointed rod consisted of a 4-ft. oak piece 1 in. square. The sections were fastened together with the old-fashioned pump rod screws used in the oil fields. This home-made contrivance cost five cents a foot completed and did the work of a high-priced jointed rod. The pilot wires having been pulled through the ducts, served to pull through a stout rope to which the cables were spliced. The latter were pulled through the ducts by means of a hand winch. Each of the 500,000-circ. mil Paranite cables was pulled through from the power house to the Arcade basement without a splice. At the Arcade end the cables are connected to a marble switchboard designed for this purpose.

The exhaust steam system causes a back pressure of from 3 to 5 lbs. during severe cold weather, but this runs down to 2 lbs. at the time of milder winter weather. The plant is owned by Mr. E. S. Kelly, for whom it was designed by the well-known engineering firm of Bert L. Baldwin & Company, of Cincinnati, Ohio. The plant is in operation all day and all night, and it is the intention to keep it running continuously, never shutting it down entirely.

POLE SETTING ON THE NEW ORLEANS DRAINAGE COMMISSION LINES.

The level of the city of New Orleans is so low with reference to surrounding bodies of water that most of the drainage has to be done by means of centrifugal pumps, which deliver the water into Lake Ponchartrain. Originally the work was done by scattered steam plants, but recently electrically-driven pumps have been substituted. These are located at different pumping stations and are supplied with current from a large central generating station which has been established for this purpose.

The pole lines run through low ground and swamps in many cases, and the New Orleans soil and climate tend to rot timber very rapidly. The plan of pole setting on a large part of the transmission lines was to put a box of slightly larger dimensions than the pole in a concrete setting, as shown in Figs. 1 and 2, herewith. Then the pole was slipped into this box and clean, sharp sand poured in around it. A sufficient space was left between the pole and box so that a narrow scoop can be put in to take out the sand without disturbing the concrete setting when it becomes necessary to put a new pole in the place of the old one. Square poles are used on all the work.

FIG. 2.—METHOD OF SETTING POLES ALONG GUTTER.

Fig. 1 shows the arrangement for a line of poles set along a railroad track, and Fig. 2 shows the arrangement for poles set along the gutter on Broad Street. In very soft ground it was necessary to fasten the poles to piles driven 26 ft. below the surface of the ground. The details of this construction are shown in Fig. 3. For the details of the pole-line construction we are indebted to Mr. Ben Willard, New England agent of the General Electric Company, which was the contractor for the electrical equipment of the drainage work.

A SIMPLE METHOD OF LOCATING A SHORT CIRCUIT BETWEEN ELECTRICAL CONDUCTORS.

BY ARTHUR R. ROE.

When a short-circuit occurs in concealed electric light, annunciator or electric gas-lighting conductors, it is often very difficult, with the aid of the most delicate instruments obtainable, to exactly locate the fault; and in the majority of cases absolutely impossible unless an accurate plan of the system of wiring showing the length and location of every wire is available.

By the method under consideration, concealed conductors can be more accurately traced than if the operator were in possession of an exact diagram of the wiring, and the fault can be accurately located in less time than would be occupied in setting up the instruments required by other methods. This method is based upon the well-known law of induction, that a current started and stopped in a conductor induces inverse currents in neighboring conductors.

All the apparatus required for the test are an exploring coil in electrical connection with a telephone receiver, and a battery of from 3 to 8 cells, connected in parallel through an interrupter to the faulty circuit, as shown in Fig. 1, in which J is the exploring coil and T the telephone receiver.

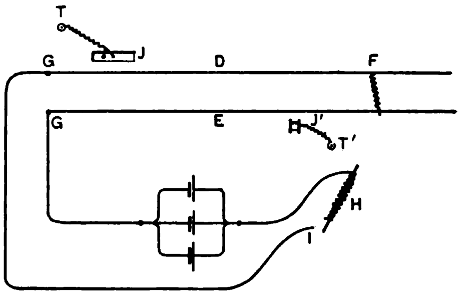

FIG. 1.—CONNECTIONS FOR LOCATING SHORT CIRCUIT.

The exploring coil, Fig. 2, should be wound with No. 36 or 40 B. & S. gauge silk-covered copper wire, on an oblong brass frame, insulated before being wound, 3 ins. long and 1 in. high, with a ½-in. space for the winding; the central core being formed of two 3/32-in. brass pins C and C, run through short lengths of hard rubber tubing of ¼ in. or 5/16 in. outside diameter, as indicated by dotted circles at C and C. The terminal, A, is connected directly to the frame, as is also the inside end of the coil; this terminal should be provided with two nuts and two washers, as it forms also a convenient means of attaching the coil to a pole, to the upper end of which a strip of soft copper with a hole drilled in its upper end to fit the post, A, is soldered to a thimble, L (Fig. 3), the latter being fitted to the end of the pole. By using a strip of soft copper the coil may be placed in any position in relation to the pole. The pole should be sufficiently long to enable the operator to run the coil along the ceiling of any room he may desire to explore; it is convenient to have the pole divided into four or five lengths, as is a fish pole, for ease of transportation, and also for adjustment to ceilings of different heights, as well as to reach into partitions, etc.

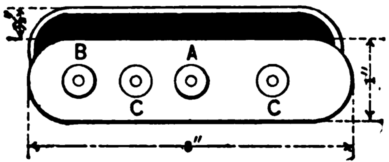

FIG. 2.—EXPLORING COIL.

Terminal B must be well insulated from the frame, as it forms the other terminal of the coil. Terminals A and B should be connected by flexible conductors to a double-head telephone receiver. The material of which the coil frame is made is, of course, optional; however, the brass frame is cheaper to make, and more durable than one of any other material.

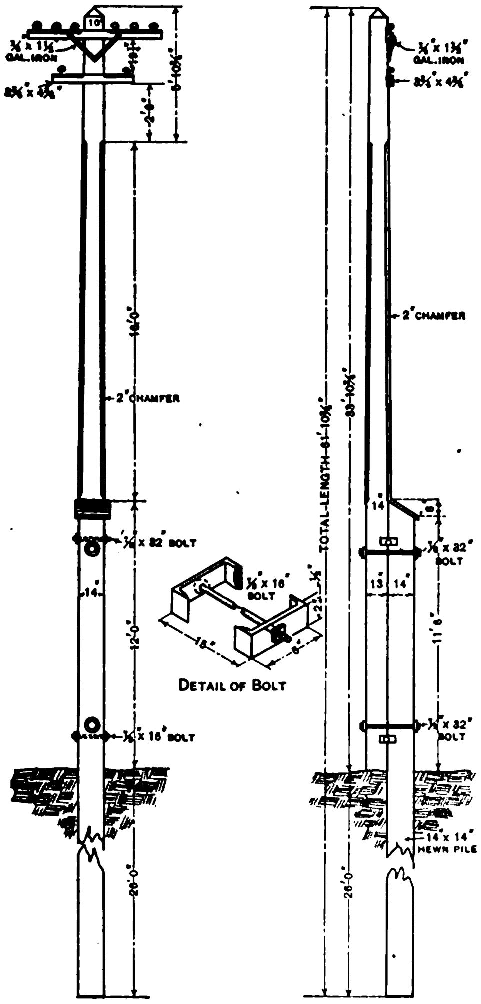

FIG. 3.—METHOD OF SETTING POLES IN SOFT GROUND.

In Fig. 1 the battery is shown connected in parallel with the faulty wires, D and E, at G and G, through a manually-operated interrupter, H, consisting of a coarse file, and a wire, I, which is rubbed in long even strokes over the surface of the file by an assistant. A slowly vibrating electrical interrupter of low resistance may be employed, but the file gives better results in the hands of an intelligent assistant, as for instance, when the battery shows signs of becoming weak, judging by the spark, a predetermined signal can be conveyed to the operator to rest for a certain period of time to allow the insertion of another set of cells, or for a sufficient period of time for the original set to recuperate.

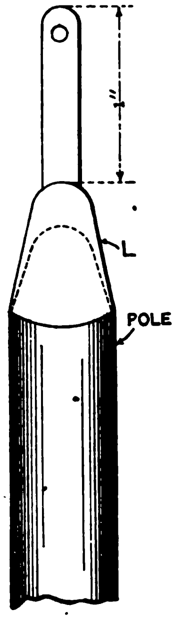

FIG. 3.

Upon the interrupter being set in motion, when the exploring coil, J, is held with its longitudinal axis parallel with either D or E, a sound will be heard in the telephone receiver, T, until the coil is brought over the point, F; if the short-circuit be of low resistance no sound will be heard in the telephone receiver when the coil is carried beyond point F; if the connection has some resistance, then when the coil passes the point, F, a noticeable diminution in the volume of sound emitted will be noticed, so that in either case the point, F, where the short-circuit exists, may be exactly located. When the coil is held with its longitudinal axis at right angles to the wires, as at J, no sound will be heard in the telephone receiver. By noting these facts, concealed wires may be easily and accurately traced and short-circuits accurately located.

With a battery of from three to six cells connected in parallel to the faulty wires the sound is quite audible in the telephone receiver when the conductors are concealed in ordinary lath and plaster walls, and are not more than 4 ins. from the outer surface of the walls; should the distance be greater, two to four additional cells may be necessary, depending largely upon the sensitiveness of the operator's ear.

The method of procedure is as follows: The interrupter, either hand or electrical, is set to work and the operator, with his exploring coil connected, as in Fig. 1, to the double-head receiver, runs the exploring coil along the walls, ceiling or floor until the receiver emits the characteristic sound; he then follows in a line directly through the longitudinal axis of the coil, or in a direction following which the receiver continues to emit sound, until a point is reached at which the receiver becomes silent, or at which there is a marked decrease in the volume of sound emitted; at this point the short-circuit will be found to exist.

The method of procedure is the same in testing for short-circuits in annunciator and electric gas-lighting circuits, except that in testing the latter the faulty circuit should be disconnected from any instrument to which it may be connected, and this free end connected to one side of the battery, through the interrupter, and the other side of the battery connected to a gas pipe.

The tests can be made with a single hand or head telephone receiver, but, for obvious reasons, the double-head receiver is preferable.

Before attempting a test the operator should have an assistant run some bare copper wires, with several "taps," along the under side of a bench or on the inside of a closet door, and cause him to make a short-circuit on one of the taps. The operator can then experiment with these circuits, and in a short time he will find it very easy to trace the wires and locate any short-circuits that may exist, and at the same time learn the significance of the different sounds emitted by the telephone receiver.

WINDINGS FOR ELECTROMAGNETS AND SOLENOIDS.

The first essential in the determination of the winding for an electro-magnet proper or one of the solenoid form is the exciting force of the coil in ampere-turns. This factor is preferably determined by experiment, the method being extremely simple and consisting of winding on the core or bobbin a temporary coil, preferably of much larger wire than will probably be used in the actual coil, making the length of the temporary coil about what the length of the permanent coil will be. The depth of the coil is immaterial within reasonable limits; it will be found most convenient to wind exactly 100 turns of wire in the temporary coil, so that the ampere-turns will be 100 times the current flowing through the coil. Then pass current through the temporary winding from any convenient source, regulating its strength by means of a resistance coil until the magnet does the work for which it is being built. The ampere-turns required in the permanent coil will be 100 times the current which flows in the temporary coil when the magnet does the work required of it.

If facilities are not at hand for making the preliminary trial, the ampere-turns may be found approximately by means of the tables given in last month's article, provided the magnet is a purely tractive one—that is, intended to exert its force through the medium of an armature in actual contact with its pole-faces—or of either of the "stopped" solenoid types represented by Figs. 5 and 6. The ampere-turns necessary to drive magnetic lines through any path are directly proportional to the length of path and to the density in lines per square inch of cross-sectional area offered by the path; also inversely proportional to the permeability of the path. It is not necessary, however, to burden one's mind with formulas which take into account permeability; the tables

TABLE III.—SHOWING THE MEAN LENGTH PER TURN OF MAGNET WIRE REQUIRED FOR DIFFERENT AMPERE-TURNS, PER VOLT OF E.M.F. AT THE COIL TERMINALS. TEMPERATURE, 140° FAHR.

given last month give the ampere-turns required, per inch of path length, by paths of air, cast iron, cast steel and wrought iron.

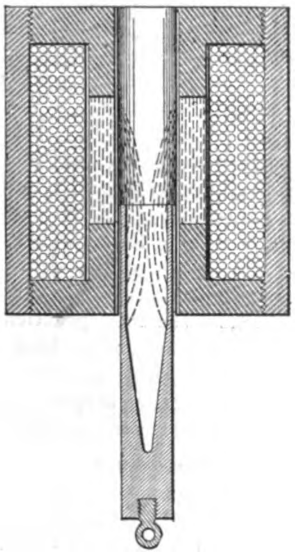

FIG. 4.—IRON-CLAD SOLENOID.

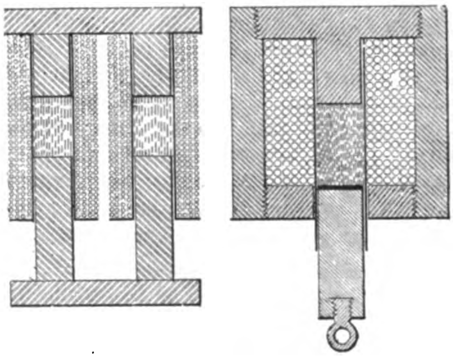

FIGS. 5 AND 6.—STOPPED SOLENOIDS.

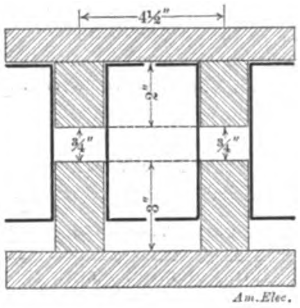

FIG. 7.—CORE DIMENSIONS.

As an example, let us suppose a stopped solenoid like Fig. 5 were given the dimensions indicated by Fig. 7, and a pole-face density of 14,000 lines per square inch were required. The density in the air gap may be considered the same as the pole-face density—14,000; Table I gives 4387 as the number of ampere-turns per inch, so that the total number to force the lines across both gaps will be 1½ × 4387 = 6580½. If each yoke has the same cross-sectional area as the round core, the density there may be also considered to be 14,000, although it will be less because of leakage. The total length of that part of the path which is of iron is practically 19 ins.; at a density of 14,000 the ampere-turns per inch of iron are 4.17, so that 4.17 × 19 = 79.23 ampere-turns will be required for the iron path in addition to the 6580½ for the air-gaps—practically 6660 in all. When the ampere-turns are calculated in this way it is always best to allow for differences in the quality of iron or steel and the effect of leakage by adding about 5 per cent to the result. Thus, in the above case, instead of taking 6660 as the accurate number, it would be advisable to figure the winding for, say, 7000 ampere-turns. It is always best, however, to make the preliminary trial with a temporary winding, as described in the first paragraph above.

Having ascertained the number of ampere-turns required in the coil, the size of wire to be used will depend upon the voltage which it is intended to apply to the terminals of the coil, and to the average length per turn of the winding. The voltage, of course, will be known, and the average length for a coil surrounding a circular core is equal to the circumference of a circle whose diameter is equal to that of the bobbin core plus the thickness of the winding. For example, suppose the magnet core to be used will be 1½ ins. in diameter. Assuming a depth of winding approximately equal to the diameter of the core, the diameter + the depth or thickness of the coil will be 3 ins., so that the mean length per turn will be 9.42 ins. Table 3 herewith shows the relation between the ampere-turns, the mean length per turn of wire, and the size of the wire, for an e.m.f. of one volt at the terminals of the coil. In other words, the values for mean length which are given in the body of the table are the mean lengths of turn per volt. Consequently, in order to use the table, the mean length of turn which the coil will

TABLE IV.—GIVING VALUES OF $\sqrt{\frac{0.00306\ d'}{l\ d^3}}$ MULTIPLIED BY 1000 FOR CONVENIENCE IN SUBSEQUENT CALCULATION. BASED ON DOUBLE COTTON INSULATION.

Note:—It is customary to allow only 2¼ sq. ins. per watt for large magnet coils, and allow the correspondingly greater temperature rise. To apply the tables to such magnets, find the length of coil in the ordinary manner and multiply the result by 0.92.

actually have must be divided by the voltage which will be applied at its terminals. The mean length of turn being 9.42 ins., if the e.m.f. at the terminal of the coil is to be 20 volts, then the mean length per volt will be 0.471. Having determined the number of ampere-turns which the coil is to have it is only necessary to trace horizontally in the line opposite this number until the nearest number smaller than 0.471 is reached; the figure at the top of this column is the size of wire to be used for the coil. For example, suppose that the number of ampere-turns required is 3500; tracing horizontally in the table from 3500 in the left-hand column the nearest number to 0.471 is 0.465 and the size of wire at the top of the column in which this number is found is No. 18.

TABLE V.—GIVING VALUES OF $\sqrt{\frac{ml}{C}}$ × AMP. TURNS, DIVIDED BY 1000 TO COMPENSATE FOR THE MAGNIFIED VALUES OF TABLE IV.

Amp. turns.	Ratio of mean length to circumference: ml ÷ C.

As the mean length per volt found in the table does not correspond with the mean length per volt of the coil, the thickness of the coil must be reduced in order to bring its mean length per volt to the value desired. The table shows that No. 18 wire wound to such a diameter as to give a mean length of 0.465 in. per volt will give 3500 ampere-turns to the coil. The voltage must be 20, so that the actual mean length of the coil must be 20 × 0.465 = 9.3 ins. Dividing this by 3.1416 gives the mean diameter which the coil must have, but it is simpler to refer to a table of circumferences and areas, as before; the result is 2 31/32 ins., and subtracting the diameter of the bobbin core (1 17/32 ins.) from this leaves 1 7/16 ins. for the thickness of the winding. In this connection it should be remembered that when the mean length per turn of wire cannot be made exactly what a calculation calls for it should be *less* than the calculated mean length. The reason for this is that with the terminal voltage fixed, the ampere-turns of any coil will be less as the mean length per turn increases; consequently, making the actual mean length greater than its calculated value will result in a weaker magnet than the builder is trying to obtain. It will be found upon calculation that there is no number of layers of No. 18 wire which will give a thickness of precisely 1 7/16 ins.; 29 layers of this size of double cotton-covered wire will give a thickness of 1.44 ins., and as 1 7/16 = 1.4375, the discrepancy is so small that it is not worth while to reduce the actual mean length of the winding by using 28 layers instead of 29.

Having found the size of wire to be used and the corrected mean length per turn that the coil must have, the next point claiming attention is the heating of the coil. Unless it has sufficient external surface to radiate heat at the proper rate, the temperature will be excessive and the coil destroyed. The desired radiating surface can be obtained only by varying the *length* of the coil. With a constant potential at the terminals, the ampere-turns remain practically unchanged irrespective of the length of coil (not length of wire) parallel with the core. For ordinary magnet coils the proper surface, measured around the body and neglecting the heads, may be ascertained by means of the formula:

$$\frac{210\ W}{140 - t} = S \ldots\ldots\ldots\ldots (1)$$

in which W is the number of watts lost in the coil; t is the temperature of the surrounding air and S is the external surface area in square inches. Of course, one cannot change the design of a magnet coil with every change in the surrounding temperature, t; but if this be taken as the average atmospheric temperature in which the coil will work, any increase in atmospheric temperature will not be sufficient to endanger the coil. It is usually quite safe to base heating calculations upon an atmospheric temperature of 70° Fahr. for coils intended to be used in ordinary surroundings; when they are to be used in boiler rooms or other overheated places, the basic temperature should be taken at 100° Fahr. This gives two modifications of the formula, as follows:

Atmosphere at 70°:

$$3\ W = S \qquad (2)$$

Atmosphere at 100°:

$$5\tfrac{1}{4}\ W = S \qquad (3)$$

These formulas show that under ordinary conditions 3 sq. ins. of coil surface will be required for each watt lost in the coil, and 5¼ sq. ins. per watt under boiler room conditions. To satisfy formula (2), the length of the coil parallel with its core may be determined by any one of the following formulas:

$$L = E \times \sqrt{\frac{0.00294\ d'\ d^2}{l\ C\ ml}} \qquad (4);$$

$$L = \sqrt{\frac{0.003\ E\ At\ d'}{l\ C}} \qquad (5);$$

$$L = At \times \sqrt{\frac{0.00306\ d'\ ml}{l\ d^2\ C}} \qquad (6).$$

In these formulas, E is the terminal voltage; At, the ampere-turns; d, the diameter of the bare wire, and d' its diameter over insulation, in mils; C, the circumference of the coil; l, the number of layers of wire, and ml, the mean length per turn. All measurements are in inches except the diameters of the wire. To satisfy formula (3) the numbers 0.00294, 0.003 and 0.00306 in the above formulas must be changed to 0.005147, 0.00525 and 0.005355, respectively.

The easiest one of these formulas to solve without the aid of a slide rule or other calculating apparatus is (5); formula (6) becomes easier to handle, however, with the aid of Tables IV and V. Table IV gives the square root of $0.00306 \div l \times d' \div d^2$, multiplied by 1000 in order to obtain more convenient values, and Table V gives $At \times \sqrt{ml \div C}$, correspondingly divided by 1000. It is only necessary to find in each table the proper value and multiply these two values together in order to find the length of the coil. For example, the stopped solenoid, Fig. 7, required 7000 ampere-turns, or 3500 in each coil. The size of wire was found to be No. 18; the number of layers, 29; the mean length, 9.33, and the circumference of the coil is 13.85 ins. In Table IV the number in the No. 18 wire column opposite the number of layers (29) is 1.784. The mean length ÷ circumference is 0.67365; the nearest to this at the top of Table V is 0.67, and in this column, opposite the ampere-turns (3500) is the number 2.865. Multiplying this by 1.784, obtained from Table IV. gives 5.11, and this is the length of coil necessary to prevent overheating.

As the original intention was to give the cores and air-gap a total length of 5¾ ins., which would be reduced to 5 ins. with the air-gap closed, the short cores would have to be made a little longer in order that the winding may be full 5 inches, and that heads ⅛ or 3/16-in. thick may be used, without having the yoke of the sliding cores strike the coil heads.

In conclusion it may be well to emphasize the fact that the characteristic of a magnet or solenoid cannot be accurately determined without experiment, either as to the pull or the actual heating. However, the tables and data given in this article and in the one printed last month will save considerable time and expense in predetermining the approximate size and power of a traction magnet or a stopped solenoid; and as the assurance that the magnet or solenoid will do the work required of it is much more important than the saving of a small amount of wire or iron, it will be found sufficiently accurate for all practical purposes to use the tables and data without preliminary experiment, by allowing a little margin in final calculations.

Tables III, IV and V may be used for solenoids of the common open type, after a preliminary test for ampere-turns, but only Table III can be used for the iron-clad type (Fig. 4) because its winding is not exposed to the air.

In cases such as the electromagnets of an arc lamp, where it is desired to keep the size of the magnet down to the smallest possible dimensions and at the same time guard against serious overheating, the tables will only serve as a preliminary guide in approximating the dimensions and winding of the magnets, after which the permanent dimensions and windings will have to be determined from experiment with a temporary magnet built from this preliminary data. For the purpose of rewinding the field magnets of a dynamo, the tables are sufficiently accurate without making any preliminary experiment other than exciting the magnet by means of a temporary winding in order to ascertain the minimum number of ampere-turns required. Having obtained this value, the tables may be used without further experiment and without any allowances. The voltage at the terminals of the entire shunt winding, however, should be taken as 10 per cent less than the no-load voltage at the brushes, and this value divided by the number of magnet coils to ascertain the voltage at the terminals of one coil.

In last month's article, near the top of the first column on page 157, the statement "only a few magnetic lines go over to the armature, most of them going around the outside of the coils to the yoke;" should read "only a few magnetic lines go over to the armature, most of them going *across from pole to pole* and around the outside of the coils to the yoke."

ELECTRICALLY CONTROLLED BULKHEAD DOORS.

BY GEORGE E. WALSH.

The evolution of the water-tight bulkhead for ships from the old wooden types of half a century ago to the modern steel constructions represents progress along certain lines of shipbuilding that is of more than passing note. Theoretically the bulkhead question was settled years ago, but it has needed only new shipwrecks and disasters at sea to convince marine architects that practically the devices were inadequate. When a ship meets with a serious accident at sea the necessity of closing the bulkhead doors quickly becomes paramount, and the existence of the ship and passengers may depend entirely upon the celerity with which this can be accomplished. The repeated failures of bulkhead doors to close promptly enough to save the ship have caused dissatisfaction and anxiety in many quarters, but nowhere more than among marine architects and shipowners.

The theory of water-tight bulkheads is simple and its application should be practicable; the stumbling-block has been in the doors which lead through the bulkheads.

There are upward of twenty and thirty bulkhead doors in a large steamer, and it may be necessary to close one or all on short notice. The mechanism which operates these doors must be beyond any chance of getting out of order. More than one disaster has been caused by the mechanism refusing to work when urgently needed, and the criticism has in some such cases been directed toward the bulkheads instead of the mechanism which controlled the doors. To meet an emergency it should be possible to close the doors of all the bulkheads either below decks or at some directing point above. The time required for an officer to go below decks to close the bulkhead doors has more than once been sufficient to give the water a chance to fill several compartments, and thus defeat the object of the water-tight compartments.

Both the hydraulic and pneumatic methods of controlling the bulkhead doors have proved failures, or at least uncertain enough to involve an element of danger. The hydraulic apparatus for operating bulkhead doors has been largely abandoned in modern shipbuilding, because of the unsatisfactory results obtained. The pneumatic system still has its advocates, and for the present it may hold its own. But there is danger in the use of either air or water for this all-important work. Both air and water must be conducted through pipes, valves and other complicated apparatus, and not only may these become disabled, but the air and water will, in time, leak out of them. Electricity is peculiarly well adapted to the performance of this work on a steamer. One great thing in its favor is that a sudden and great power can be exerted at a critical moment, exceeding often by far the normal rated power of the apparatus. This is important when it is necessary to close the doors simultaneously or in rapid succession. Electricity is used so generally on shipboard now for a great variety of purposes that a new auxiliary source of power does not have to be installed to control the bulkhead doors in an emergency. Indeed, at the critical moment, the full power of the existing electric plant could be exerted to close the doors, and the force would always be ready for an emergency without entailing waste or loss.

In many ways electricity is superior for operating bulkhead doors, and it only needed a practical invention to make this agent the generally accepted one in the navy and on merchant steamers. There have been in operation now for nearly a year electrically-controlled bulkhead doors on the United States cruiser "Atlanta." The apparatus was devised by Naval Constructor Francis T. Bowles, of the Brooklyn Navy Yard, and a model of it was placed on exhibition in the War Material Building at the Paris Exposition. So successful has this apparatus proved that the Navy Department has decided to equip all future warships with the electrical mechanism, while many of the warships now in service will gradually be changed also in this respect. Electrically-operated bulkhead doors have been adopted by some of the ocean merchant steamers, notably the "St. Paul," and its general adoption in the merchant marine seems only a question of time.

The electric bulkhead door possesses many features of a novel and unique nature. It is so wired that the officer in charge can operate it from the bridge, and by pushing a button he can tell at any moment the condition of the door. A tiny lamp near the button indicates whether or not the door is in good working order. When the door is closed the lamp is dark, as the current is automatically cut off. One or a dozen doors can be closed simultaneously or in rapid succession. The full power of all the motors can be concentrated upon one door if the necessity arises, making it possible to drive the door into a closed position against a tremendous opposition by inflowing water.

In addition to the control the navigating officer may have on deck, there is a local control below decks which takes precedence over the first in an emergency. The officer between decks may find it necessary to go through the door, and the delay caused by communicating with the officer on deck might prove fatal. He can consequently open or close the door by hand, and when he has passed through, the control on the bridge is immediately restored. Controlling stations can be distributed over different parts of the ship, so that in an emergency some one would surely be within easy reach of a push button.

The speed of operation and practically absolute assurance that the doors will close are the two greatest features of the system. Doors can be closed in ten seconds, and with such obstructions as coal, wood, paper and water in the way they have been closed in numerous experiments in from half a minute to one and a half. Tests already made indicate that the danger of improperly controlled and working bulkhead doors will no longer neutralize the advantage conferred by the provision of water-tight compartments on board ship.

A French Corliss-Type Steam Engine.

Among the high-economy steam engines built by European manufacturers for electrical service, a particularly interesting one is that of Dujardin & Co., Lille, France, the horizontal triple-expansion type of which is illustrated herewith. The engine here shown was built to drive a 1000-kw. alternator, the rotating member of which is mounted midway on the crank shaft, as indicated by Fig. 5, which is a plan view of the engine. There are two low-pressure cylinders, one mounted in tandem to the high-pressure cylinder, and therefore delivering power in common with that cylinder to one of the crank shafts, while the other low-pressure cylinder is arranged in tandem with the intermediate cylinder and delivers power to the second crank; the two cranks are displaced 90° from each other, as usual.

All of the cylinders are steam-jacketed, the high-pressure jacket taking steam direct from the boiler on both sides and the cylinder heads. The other cylinders and the intermediate receivers, of which there are two, are jacketed with steam which has been expanded to a little over one-half of the initial pressure, so that its temperature is still considerably above that of the exhaust from the high-pressure cylinder into the first receiver. The volume of the first receiver is 1.8 times the displacement per stroke of the high-pressure piston; the second receiver has a volume equal to the displacement per stroke of the intermediate piston. The high-pressure cylinder is 24 ins. in diameter, and all three of the others are 41 ins. in diameter; the stroke is 5 ft. 5 ins. The normal speed of the engine is 72

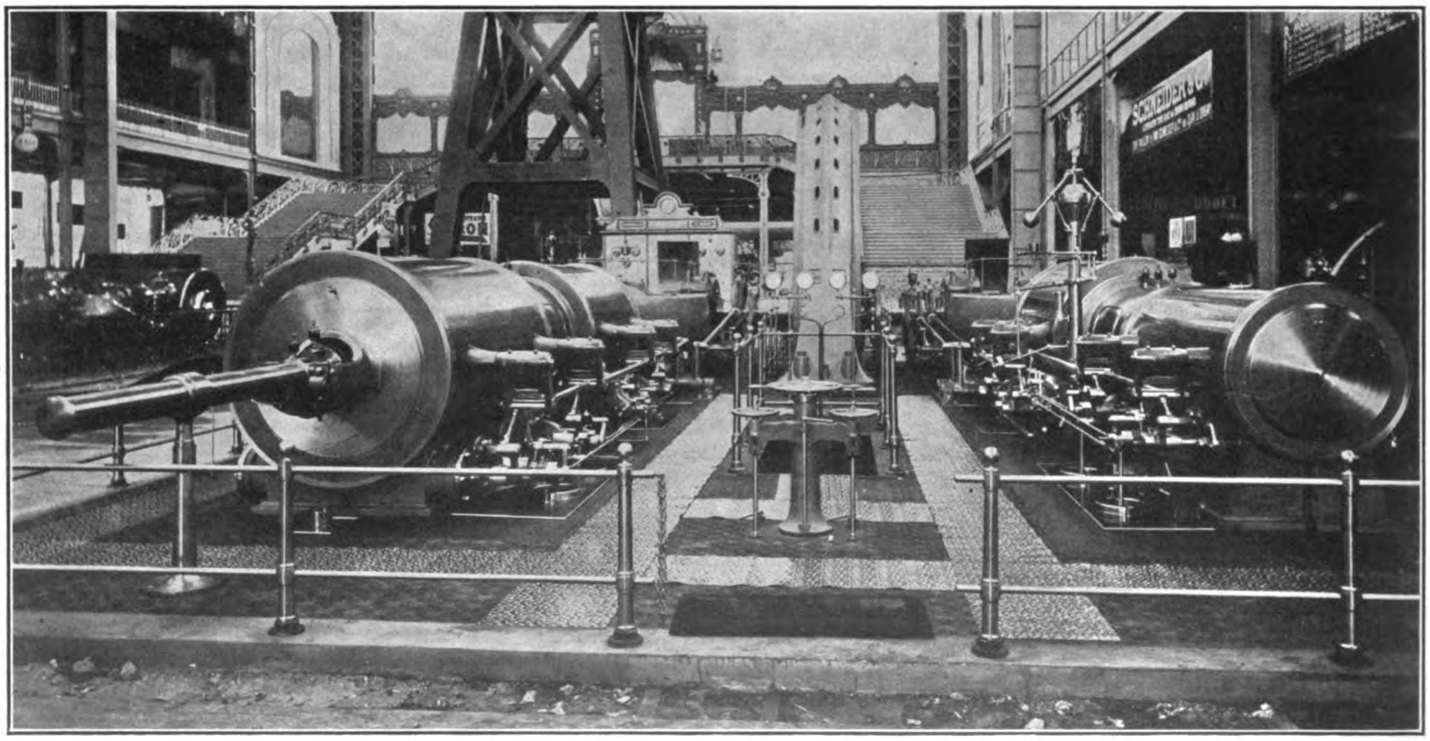

FIG. 1.—HORIZONTAL TRIPLE EXPANSION ENGINE DRIVING 1000-KW. ALTERNATOR.

r.p.m., so that the average piston speed is 780 ft. per minute. With steam at 160 lbs. boiler pressure and the cut-off giving 19 expansions, the engine indicates 1700 horse-power. As indicated in Figs. 1 and 5, the piston rod of the intermediate cylinder is extended into a tail-rod, and this has a bearing in a guide external to the cylinder, so that the gland is not depended upon to keep the rod in alignment.

A feature which is somewhat unusual in European engines is the placing of all four valves, which are of the Corliss type, beneath the cylinder. The admission and exhaust valves are arranged in pairs very close to each other, as indicated in the upper part of Fig. 2, the exhaust valves being nearest the ends of the cylinder. Three eccentrics are used on the high-pressure side of the engine. One of these drives positively the four valves of the low-pressure cylinder on that side, through very simple mechanism, indicated by the letters, *L*, *L*, in Fig. 2. Another eccentric drives the four valves of the high-pressure cylinder, the exhaust valves positively and the admission valves through a trip gear. The third eccentric gives a reciprocating movement to the trip or cut-off gear.

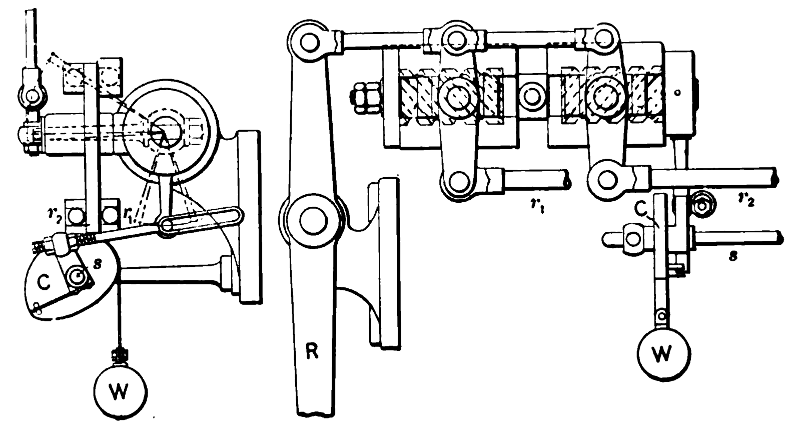

FIG 3.—DETAILS OF GOVERNOR MECHANISM.

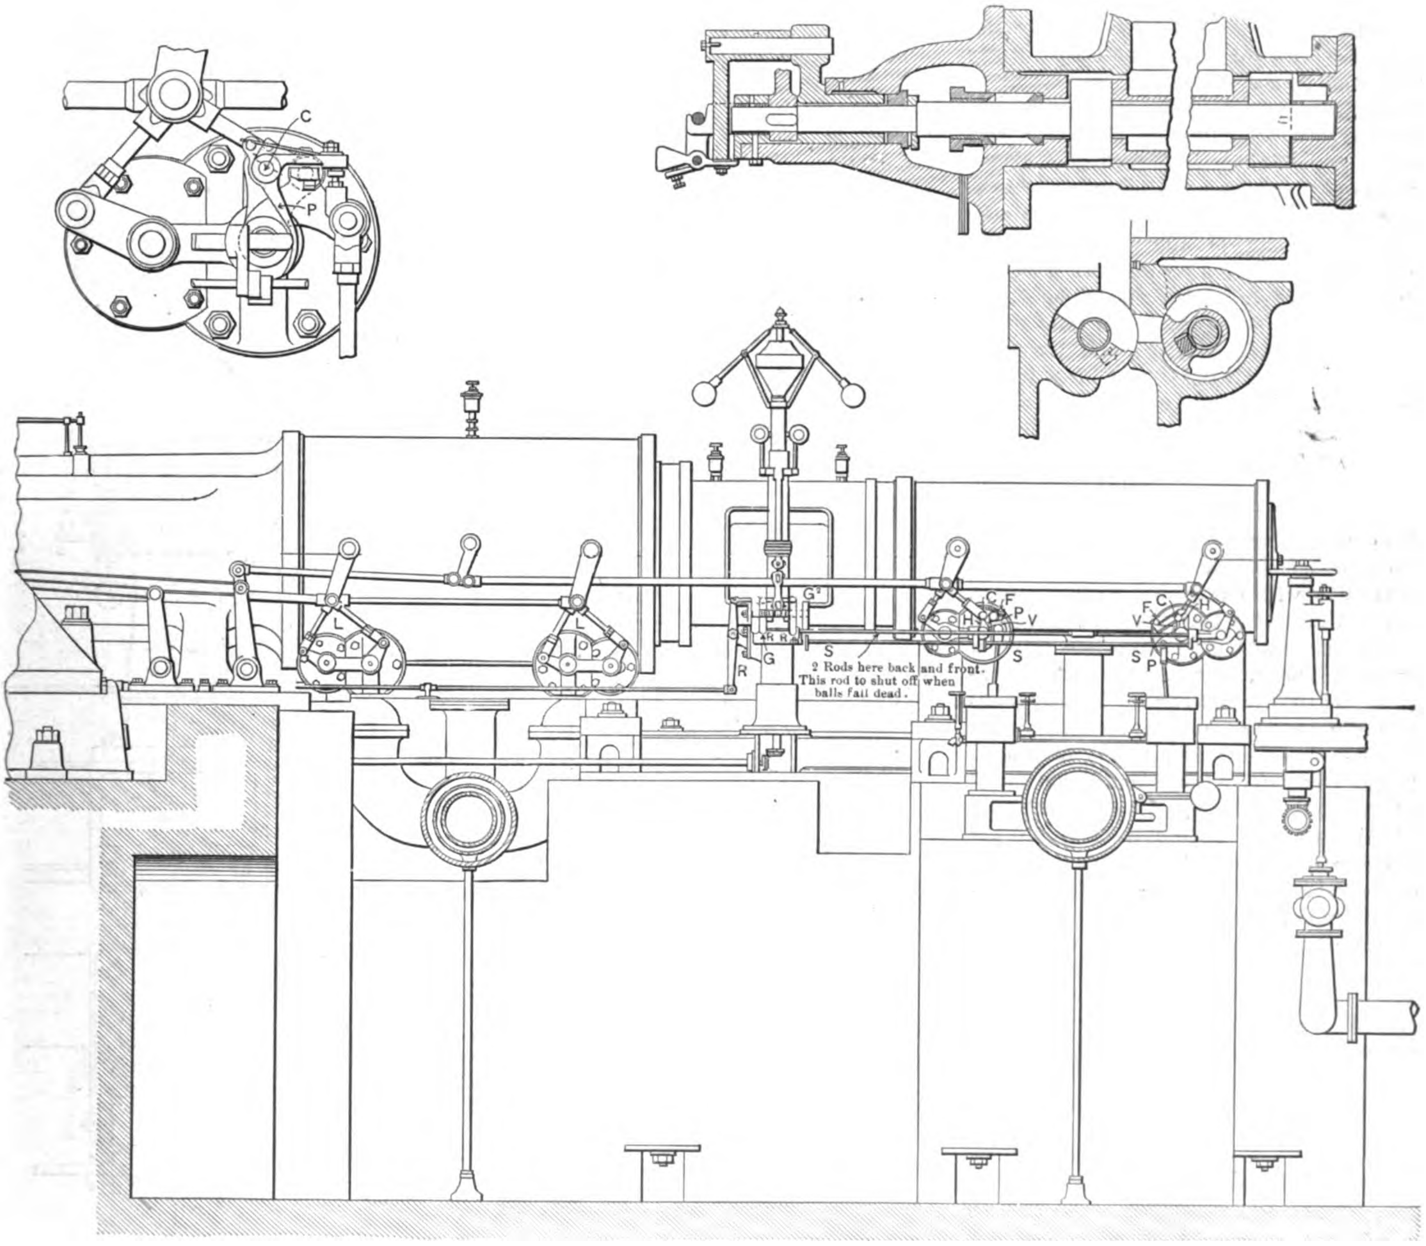

FIG. 2.—PLAN AND DETAILS OF VALVE GEAR.

The trip for releasing one of the admission valves is shown at the upper central part of Fig. 2. The arm, *H*, is oscillated in exactly the same manner as the rocker arm on the exhaust valve stem and the arms on the low-pressure valve gear. The pin, *O*, on this arm, carries a trigger, *T*, and pallet, *P*, cast in one piece. The pallet, however, lies in a plane outside that in which the trigger oscillates. The outer end of the trigger is provided with a hardened-steel lip which engages the arm, *V*; this arm is keyed to the valve spindle, so that the valve is rocked by the arm, *H*, through the intermediation of the trigger, *T*. The release is effected by means of the pallet, *P*, which is curved to a long special sweep. The concave surface of this pallet rests upon a rounded hard-steel head, which is mounted on the end of one of the cut-off rods. There are two of these rods, one serving the trip gear at each end of the cylinder.

The point of trip is varied by means of the right and left-hand spiral gear shown in Figs. 3 and 4. The rocker arm, *R*, is oscillated by the third eccentric, previously referred to, and imparts an oscillating motion through the trip rods, r^1, r^2. The rocker arms to which these rods are pivoted are fulcrumed on two blocks, the distance apart of which is regulated by right and left-hand screw threads on the spindle passing through the blocks. The governor gear is arranged to rock this spindle and thereby vary the distance apart of the fulcrums and consequently the time when the trip rods, r^1 and r^2, actuate the pallets at the valve gear and release the admission valves. The trip rod, r^1, lifts the pallet and trigger at the left-hand end of the cylinders in Fig. 2, and the rod, r^2, actuates the pallet at the right-hand end of the cylinder. The mechanism through which the governor controls the trip gear is shown in Fig. 4. The governor is of the ordinary fly-ball type and rocks the right and left-hand screw through a simple system of levers. A cam, *C*, and weight, *W*, shown more plainly at the left of Fig. 3, are arranged to operate the right and left-hand screw so as to prevent any admission of steam to the cylinder, in case of any accident to the governor. The trip gear is said to give a range of cut-off from 0 to 70 per cent of the stroke, which will be recognized as an unusual range for this class of valve gear.

The valves of the intermediate cylinder are equipped with exactly the same mechanism as that just described for the high-pressure cylinder, except that the point of cut-off is regulated by hand instead of by the governor. Two eccentrics are used on this side of the engine, one to drive all of the valves on both cylinders, and the other to drive the trip mechanism just described in connection with the high-pressure cylinder. The admission and exhaust valves of each cylinder are of equal size. The high-pressure valves are 6.7 ins. in diameter, and all of the other valves are 9.84 ins. in diameter. The areas of the admission and exhaust ports of each cylinder are different, however, the exhaust ports being longer than the admission ports. In the high-pressure admission ports the steam velocity is about 7500 ft. a minute, and in the exhaust ports of this cylinder the velocity is about 6500 ft. a minute. In the intermediate cylinder ports the admission steam has a velocity of about 8500 ft. a minute, and the exhaust steam about 6200 ft. a minute. For the low-pressure cylinder the velocities are 8800 and 5600 ft. per minute for the admission and exhaust respectively.

There are two jet condensers, one at each side of the engine, and each condenser is served by two air pumps. The pumps are vertical, with three sets of suction, bucket and delivery valves. Each pair of pumps is driven from one of the engine cross-heads through the medium of a double bell-crank lever, the long arm of which extends downward from the cross-head link to the lever shaft on each side of which the horizontal arms of the double bell-crank rock up and down, forming a sort of walking beam. From the outer ends of this walking beam are hung the connecting rods of the pumps. Each cylinder is single-acting, but as there is a pair of cylinders the effect is the same as though a single double-acting pump were used, the two cylinders drawing water from the condenser alternately. Each of the air-pump cylinders is 21.65 ins. in diameter and 13.78 ins. stroke, so that the theoretical displacement of all of the pump buckets is 0.0526 of the displacement of both of the low-pressure pistons. The volume of each condenser is 1½ times the

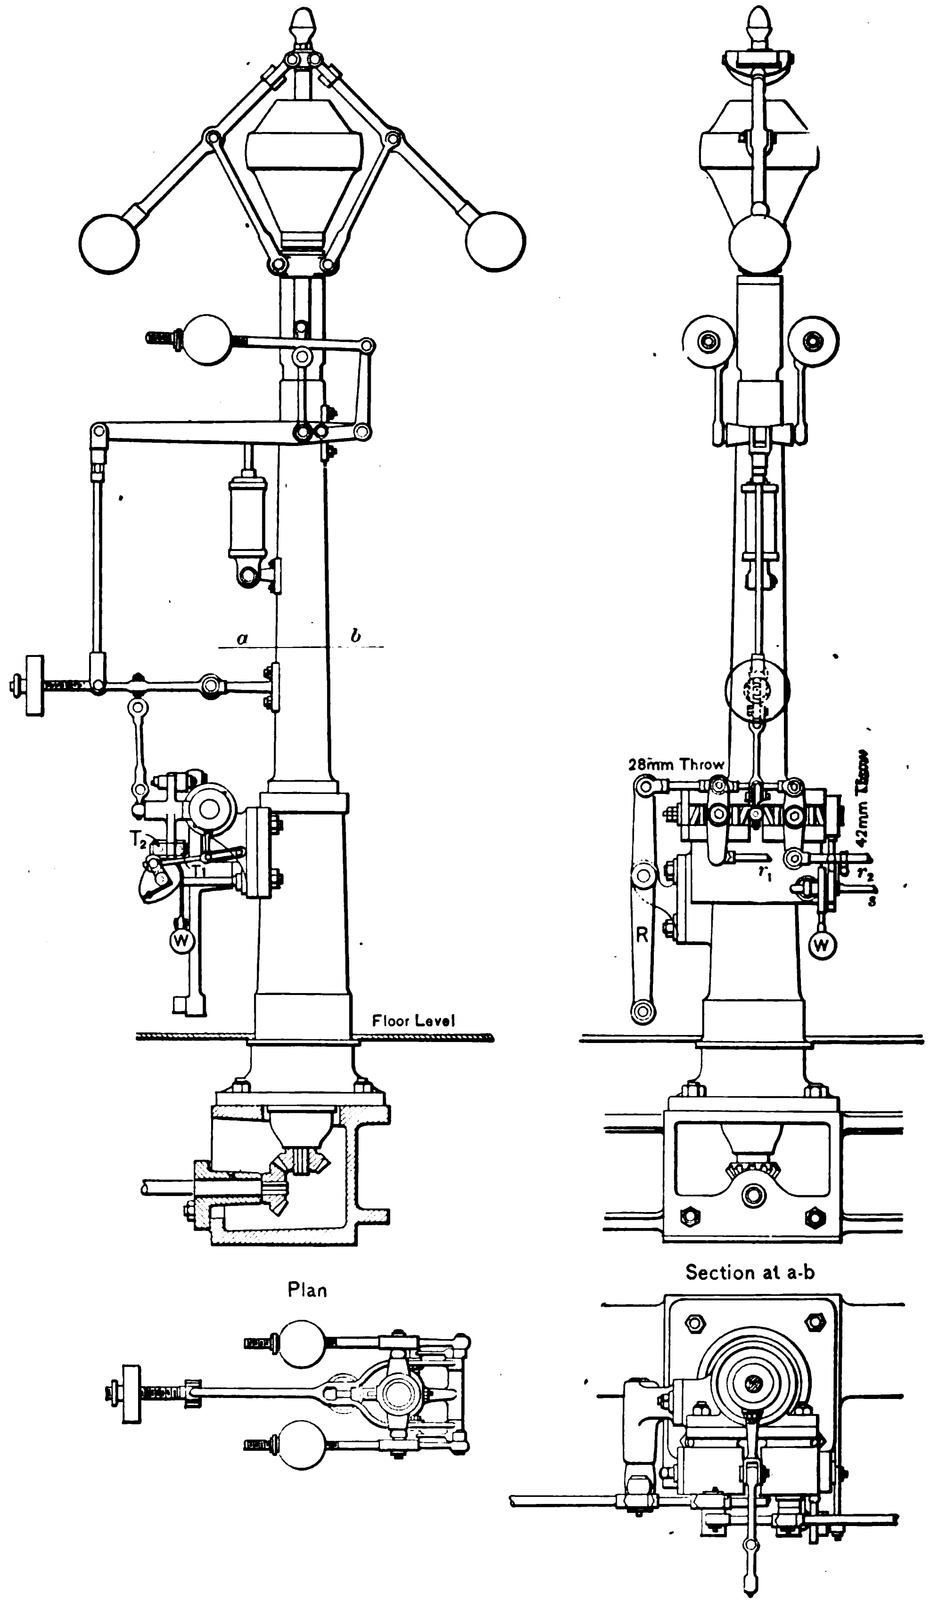

FIG. 4.—PLAN AND DETAILS OF GOVERNOR.

displacement per stroke of one of the low-pressure pistons. One of these engines was exhibited at the Paris Exposition, where it drove a 1000-kw. Schneider alternator supplying three-phase currents at 3000 volts and 50 cycles. The perspective view (Fig. 1) was made from a photograph of this combined generating unit.

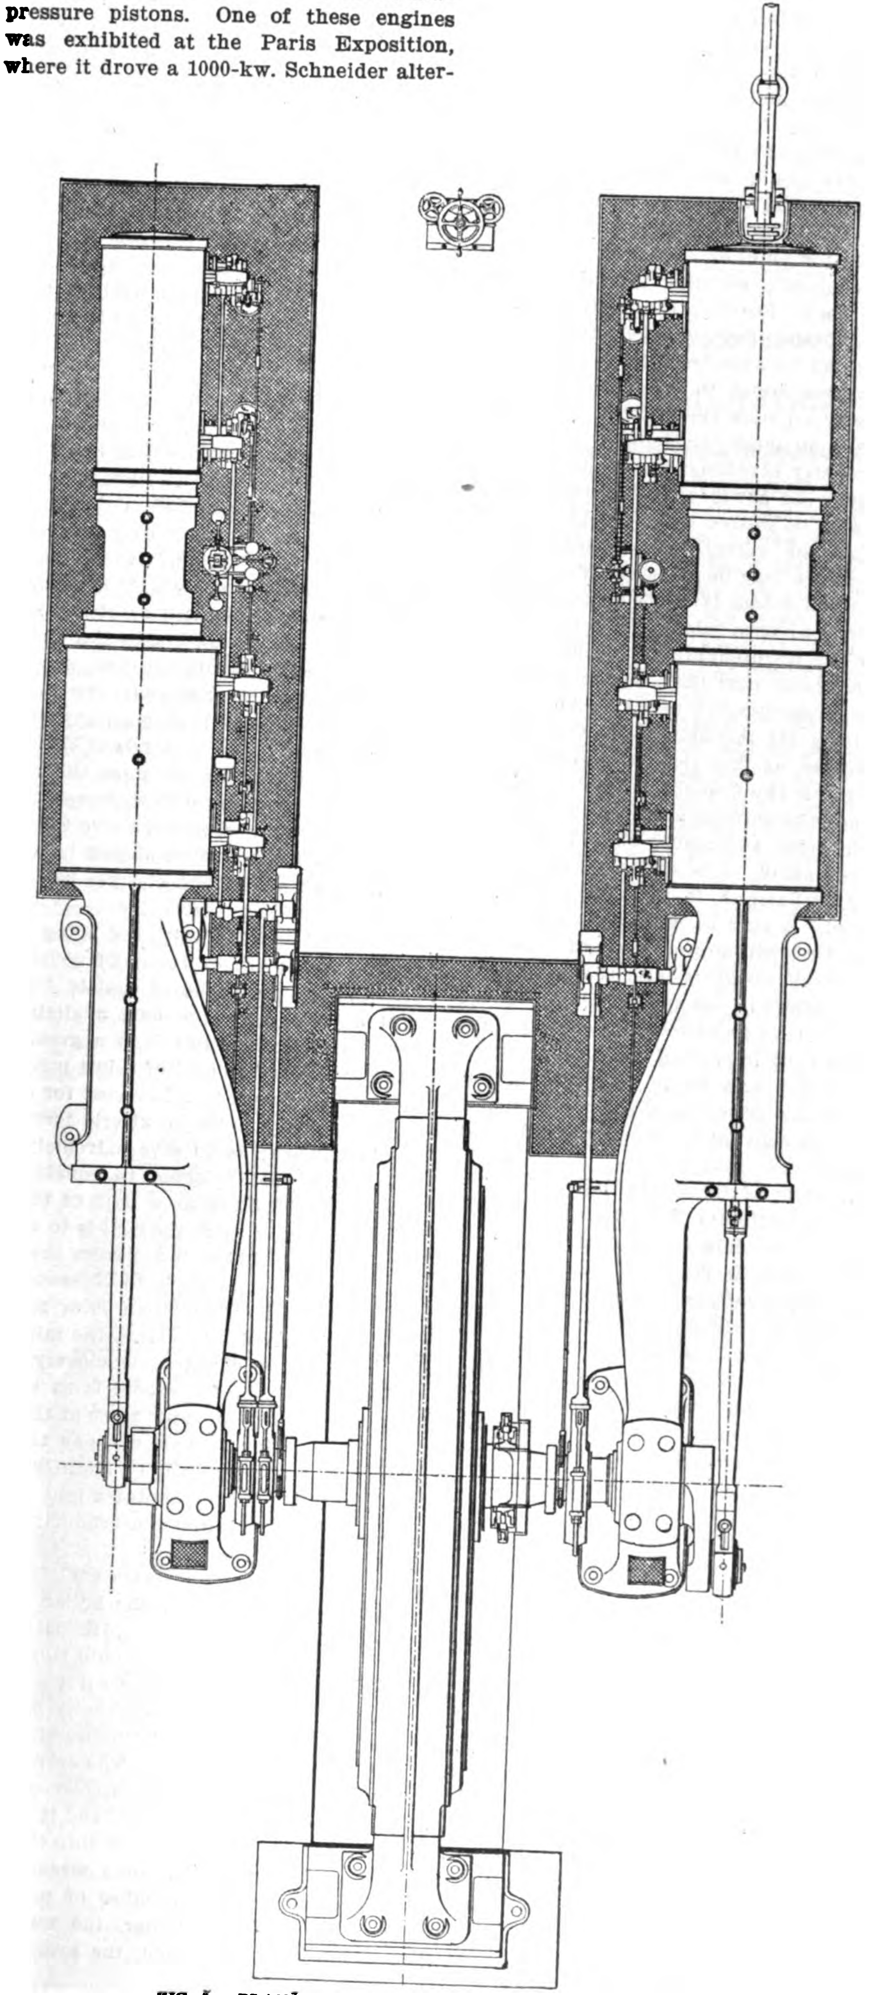

FIG. 5.—PLAN VIEW OF ENGINE AND ALTERNATOR.

ECONOMY IN STEAM PRODUCTION.

BY C. W. OBERT.

Economy in the production of steam is not necessarily secured by installing a modern plant with high-grade boilers, auxiliaries, etc. It depends as much upon the proper handling and care of the machinery as upon its grade; and perhaps more. The highest possible economy is secured only when the apparatus is operated under the very best conditions. The average steam engine, with its perfection of detail and the careful attendance it usually gets, operates under extremely favorable conditions, so that it is not uncommon to find an engine developing a horse-power with a consumption of from 10 to 15 lbs. of steam an hour. But the average boiler, with the lack of intelligent care and dark, dirty surroundings which are regrettably common, usually operates under very unfavorable conditions, and is undoubtedly the most wasteful portion of the power plant—a result which is altogether unnecessary.

The cost of generating steam in a boiler is made up of several factors, each of which involves and is governed by mere details. The location of the boiler has primarily a very important bearing on economical results, and too little attention is paid to it. If it is necessary that the boiler be placed in a cellar or dark room, its surroundings at least should be kept just as clean and bright as possible. The tendency is unfortunately to allow the walls, windows and surroundings to remain dirty and dusty without any more cleaning than is absolutely unavoidable, and the boiler and everything connected with it are sure to follow into that same uncared-for state of inefficiency. Relatively as much exertion should be spent in "shining up" the boiler fittings and cleaning the boiler room as is spent on the engine and engine room. A clean, brightly-painted room lends an incentive to keeping fittings clean and to giving the boiler proper care; furthermore, plenty of light makes it much easier to inspect and clean the boiler and flues thoroughly. Even if a boiler room is necessarily small and dark there is no reason why gauges, valves, injectors, and all other fittings should not be kept polished bright and in good working order, and all important parts and fittings adequately illuminated by means of artificial light.

The internal condition of the boiler is probably the most important factor in the steam-making problem; cleanness is nowhere so profitable as inside a steam boiler. Actual tests have shown an evaporation of from 7 to 8 lbs. of water per pound of coal in a thoroughly cleaned boiler, while with one-eighth of an inch of scale the evaporation was reduced in the same boiler to between 4 and 5 lbs. of water per pound of the same coal; the cost of steam being nearly doubled by the very small accumulation of scale mentioned. Thus, the importance of cleaning the boiler thoroughly and often cannot be over-estimated, although much too frequently it is neglected or cared for by the baneful method of "blowing off hot." In blowing off hot, all scale that is not readily washed out by the outflow of water will dry and bake on the heating surface in cakes which it is difficult to remove when they are once solidified. This pernicious method will also do more harm to the boiler, in the way of straining seams and loosening tubes by the sudden contraction, than would follow from years of service. A boiler should always be allowed to cool down before the blow-off valve is opened. Then, when the manholes and hand-holes are opened, it will be found that the sediment on the flues and shell is soft, sludgy and easily washed off with a hose. If the supplementary washing off is neglected, this sludgy sediment settles upon the heating surfaces and is gradually baked hard, after which it can be removed thoroughly only by chipping out with a scale pick.

The formation of this sludge, which subsequently bakes into scale unless washed out, is unavoidable unless pure feed water can be obtained, and this, of course, is rarely possible. If incrustation forms and it is inconvenient to shut the boiler down for cleaning, it may be advisable to have the feed water analyzed by a reliable chemist, and then treat it chemically to remove the impurities revealed by the analysis; or, better yet, to use a feed-water purifier of the lime-catching type. Such a purifier will remove practically all solids that are present in feed water by simply heating the water to the temperature at which it precipitates all or most of its solid matter.

For the same reason that renders scale objectionable (the impairment of heat-transferring efficiency), the outside of the heating surfaces should receive as much attention as the inner or water side. In practice, the outer surfaces usually receive much more attention than the interior on account of being easier of access, but the cleaning of these surfaces is also too often done indifferently. The soft deposit or coating of soot which forms very rapidly on the fire side of heating surfaces cannot be prevented, but must be cleaned off frequently. The under side of the boiler shell may easily be scraped and then swept off, but it should not be swept only, because sweeping alone may not thoroughly remove the deposit. For the flues a scraper is necessary, even when a "soot-sucker" or blower is used, as a steam or air jet rarely if ever thoroughly cleans a flue. If the fuel is such that the soot is at all tarry or sticky, the soot must be scraped out, as it can be removed in no other way. The arrangements for cleaning the flues should be made as convenient and complete as possible, in order to facilitate the performance of the work in a careful and thorough manner. In many boiler rooms a folding staging is arranged so as to be easily placed in front of the flue door, and this facilitates thorough and rapid work. Too much attention cannot be paid to this matter of cleaning the boiler inside and out, as this is probably the most important factor in steam production from the viewpoint of economy.

The draught is also an important factor in the cost of steam production. A draught suitable for one coal may not be suitable for another; for instance, a fine coal requires a stronger draught than a coarse coal. For this reason the damper in the chimney flue should be arranged so that it can be adjusted from a point near the furnace doors, in order that the fireman may regulate the draught to suit his coal and to meet the demand for steam. By properly checking the draught, much coal may be saved at times that would otherwise be wasted by steam blowing off through the safety valve; moreover, a checked fire may be more quickly "opened out" when steam is needed again than if the fire had been allowed to die down.

For the maintenance of a good draught it is essential that the brickwork about a boiler be maintained perfect. Any cracks admitting air through the setting should be stopped, as they tend to cool the boiler and impair the draught. All brick settings are liable to settling as well as disintegration by heat, and cracks should be looked for frequently. It is well to have the masonry refinished if it has settled or cracked. A coat of whitewash applied to the setting will stop up enough imperceptible cracks to more than pay for the expense. Doors in the setting very frequently give lots of trouble by not closing tightly, and thus impairing the draught greatly, but they can easily be made tight by stuffing the edges with sheet asbestos or any other convenient non-combustible material.

All parts of the boiler not covered by brickwork should be carefully covered with a non-conductor of heat. If the top of the boiler is set so that it cannot be covered by strong cement mortar, it should be covered with magnesia, asbestos, or a cement of some suitable non-conducting material. Exposed steam surfaces may condense from one-third to one-half a pound of steam per square foot per hour or more if exposed to air currents, and thus very materially increase the cost of steam delivered. A good covering 1 in. thick will reduce this condensation loss about 80 per cent. An example of the economy resulting from a covering may be given by considering 100 sq. ft. of exposed steam surface. With condensation at the rate of ½ lb. of steam per square foot per hour, there would be a loss of 50 lbs. of steam per hour, 1200 lbs. per day of 24 hours, or 432,000 lbs. per year of 360 days. Assuming that 1 lb. of coal produces 7 lbs. of steam, this would represent a waste of nearly 31 tons of coal, or $75 to $90. Eighty per cent. of this might be saved with a good covering, so that upon investment of from $15 to $25 for 100 sq. ft. of covering, a saving of from $60 to $70 would be effected in a year. Even if the boiler were fired only 10 hours a day, the covering would save its own cost in a year. This argument applies to steam pipes, valves and fittings as well as to the boiler top and dome.

Another very important factor is that of the firing. Good economy may be obtained in firing by closely watching the steam and water gauges and the judicious use of the damper and boiler feed, in contrast with the too general method of simply crowding in all the coal possible with the least effort. It has been said that the waste due to improper firing is often greater than any other loss in the operation of a steam plant. If the proper conditions of good draught, an even fire, and systematic, even firing be observed, as high economy should result by hand firing as is obtained with mechanical stokers. In marine boiler firing on the Great Lakes the firemen spread their coal evenly over the entire grate at each firing, and they produce steam economically; while firemen on many coastwise steamers on the Atlantic pile up the coal just inside the furnace door, and, as it becomes coked, spread it back over the incandescent fire behind, and obtain fully as high economy as the Lake firemen. These methods of firing are equally good, but in all cases the grate-bars should be kept entirely covered, and the amount of air required above the grate for complete combustion should be admitted from above instead of from below the grate.

Equally important with the firing is the quality and price of fuel. Of course the selection of the grade of coal to be used will depend upon the coal available, as well as its price. But it is a great mistake to think that coal of a low price will necessarily result in a low cost for steam. A cheap coal may be so utterly poor from shale and dirt as to give extremely poor results. It is advisable to consider the question of freight as a part of the coal cost, especially when the coal is to be used at a considerable distance from the mine. A coal that is worth 60 to 75 cents a ton at the mine may be worth $3 or $4 a ton several hundred miles from the mine, due to the freight charges. Obviously, when the actual cost of the coal is so small a percentage of its market price at the point of consumption it does not pay to buy a cheaper coal, as a coal of slightly higher price at the delivery point might mean a coal of double the steam-producing quality.

The best way to select a coal is to test it in actual use under the boiler in comparison with other grades. Sufficient coal of the kind to be tested should be obtained and a ten-hour test made with it under the boiler, which will show exactly what the coal is capable of doing under the actual conditions of operation. The carrying out of such a test is comparatively simple if a platform scale is at hand and it is possible to insert a thermometer into the boiler feed-water pipe. The only measurements necessary are the number of pounds of water fed to the boiler, the number of pounds of coal burned, the average temperature of the feed water and the average steam pressure in the boiler; from these, providing the test is started and stopped with the boiler under exactly the same conditions as to height of water, steam pressure, etc., the actual number of pounds of water evaporated by a pound of the coal on trial may be calculated. Then a similar test should be made with another coal to be compared, care being taken to maintain the steam pressure and feed-water temperature as nearly as possible the same as they were in the first test. This sort of comparative testing will furnish a clear idea as to the relative merits of two or more kinds of coal, and has been used in some places with great economic advantage. In one instance, a coal that was thought to be the best grade obtainable did not show as high evaporation as cheaper coal with shale in it, and in other instances cheap coals have been proven less economical than higher-priced coals.

Abstracts from Foreign Contemporaries

Motor-Driven Feed Pump.—While an electrically-driven pump is superior to a steam-driven pump in point of efficiency, the usual method of motor regulation by rheostat entails a considerable waste of power. In the Mather & Platt pump illustrated by Fig. 1 and described in a recent issue of the London "Mechanical Engineer," the regulation is entirely mechanical, consisting of altering the stroke of the plungers according to the required output; the result being that the electrical power consumed is very nearly proportional to the work done by the pump. The pumps can be driven by either direct-current or polyphase motors; each pump consists of three cylinders mounted radially on a frame at angles of 120° with each other, with plungers driven from a crank pin by connecting rods. The crank pin is arranged eccentrically on a disc fitted into a recess in an internal toothed wheel which engages a pinion on the motor shaft. The rotation of this disc causes the desired alteration of the stroke and it is obtained by gears situated in the hub of the internal wheel operated by a suitable hand lever. An indicator fixed to the regulating device shows the length of the stroke which is in operation and therefore the corresponding output of the pump at the time. Raising the hand lever alters the stroke and when the desired rate of discharge is indicated the lever may be released. The motor is steel-clad with the windings entirely protected from injury.

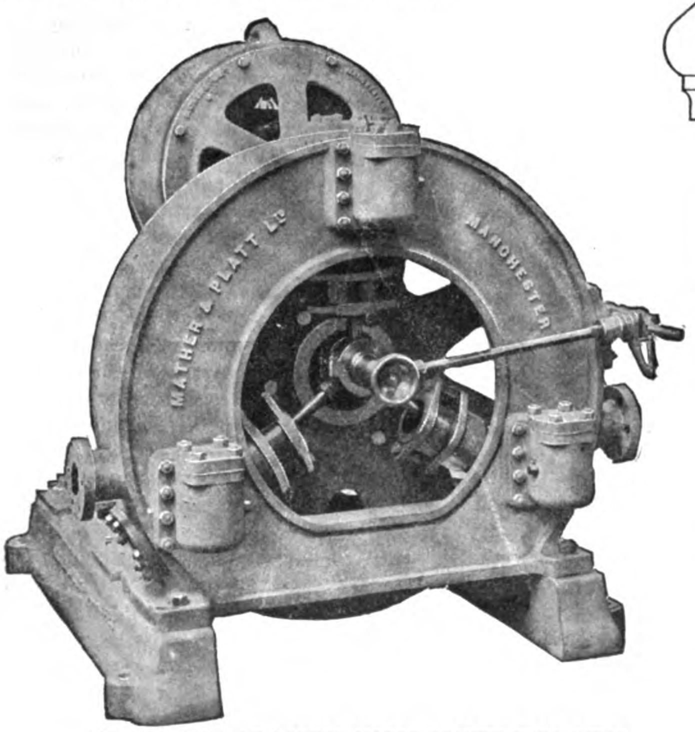

FIG. 1.—CONSTANT SPEED MOTOR-DRIVEN FEED PUMP.

Alternating Arc Lamp for Series Circuits.—A recent issue of the London "Electrician" contains a description of a new alternating-current enclosed arc lamp for series circuits, designed by Frank Lewis, a diagrammatic view of which is shown by Fig. 2. The lamp is of the clutch type, a notable feature being the use of a subsidiary and powerful brake operating on the striking lever, and taking the place of the usual dash-pot. The brake comes into play when the arc is struck and whenever the current exceeds the normal. The lamp circuit is shunted by a choke coil capable of taking all of the current in case the arc should break; the voltage at the terminals of the other lamps remaining fairly constant. The action of the lamp is as follows: Two solenoids, A and B, are in series with the arc. Upon switching on the current, the core, C, is drawn into the solenoid, A, and the arc is struck by the clutch, D. At the same time the core, E, is drawn into the solenoid, B, raising the lever, F, and pressing the shoe, G, against the block, H, on the striking lever. This prevents the core, C, from being raised too quickly and hunting. The act of striking being slow, the arc attains its full length after 30 seconds. When the arc is fully established and the current normal, the core, E, and the shoe, G, drop, the core floating in the solenoid. It is claimed that the light is of a better color, owing to the small inductance and the hard, gritty nature which the ends of the carbons assume. It is also claimed that the candle-power is higher for a given consumption of energy, and that the lamp is not affected by vibration owing to the quickness with which the braking apparatus comes into operation. The total current required is 9 amperes at 80 volts.

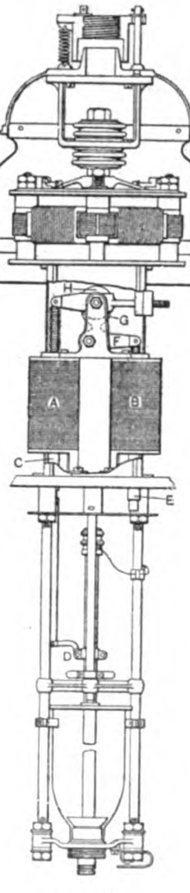

FIG. 2.

Clearance and Compression in Steam Engines.—The study of the effect of compression in the cylinder of an engine upon the steam consumption has received an impetus since the announcements of the unexpected results obtained by Prof. Dwelshauvers-Dery in his experiments on the engine at the University of Liége. The latest of the papers on this subject is one by Mr. H. Dubbel in a recent issue of the "Zeitschrift des Vereines deutscher Ingenieure," giving a review of all the important research work which has been done in Europe and America in connection with clearance and compression. The experiments of Dwelshauvers-Dery showed marked losses with increased clearance and corresponding compression, which is contrary to the accepted statement of Zeuner, who maintained that the injurious effect of clearance could be entirely overcome by compressing the exhaust up to boiler pressure. Experiments by Doerfel upon a Corliss engine using widely varying degrees of increased compression showed that the loss due to initial condensation was diminished by increased compression. Mr. Dubbel gives a tabulated extract of the classic experiments of Prof. Dwelshauvers-Dery and appends the data and results of experiments made by Profs. Barr and Carpenter at Cornell University and Prof. Jacobus at Stevens Institute, all of whom show that for degrees of compression ranging from 11 to 35 per cent bringing the compressed exhaust steam from ⅝ to full initial pressure, the steam consumption per horsepower was not materially altered. Weighing all the conditions carefully, the author concludes that the experiments of Doerfel, Barr, Carpenter and Jacobus are entitled to acceptance, and that there is little or no loss in steam consumption with increased compression. He attributes the results of Prof. Dwelshauvers-Dery to leaky valves and piston.

Insulating Varnish.—Interesting results obtained at the Imperial Physical Technical Institute of Charlottenburg, Germany, with paper coated with "Armacell" varnish and tested to determine its resistance to puncture at high pressures, are given in a recent issue of the London "Electrical Engineer." The paper was coated and baked twice with the varnish, and placed one sheet after another between two round brass electrodes and connected to an accumulator battery system. The voltage was then gradually increased until the paper broke down. In cases where the paper did not break down at the highest direct-current voltage available, which was 11,000 volts, the electrodes were connected to the terminals of an alternating transformer. The results of the test are tabulated in the table herewith:

No.	Thickness in inches.	Resistance between the electrodes at 1000 volts, 75 per cent moisture of air.		Breakdown voltage.	
1	0.00729	29,000	megohms.	10,990	direct.
2	0.00847	27,000	"	8,550	alternating.
3	0.00819	18,500	"	8,850	"
4	0.01072	38,700	"	10,800	"
5	0.00934	167,000	"	10,200	"
6	0.00867	103,500	"	9,750	"

Sheets of copper 0.002 in. thick were also treated in a similar manner and tested with regard to their resistance against temperature, and it was found that at about 750° Fahrenheit the coat of varnish was destroyed, while it only began to crack at 480°, and that when bent at a radius of 0.039 inch.

An Odd Arc Lamp.—Fig. 3 illustrates the "Hackl" arc lamp of Ganz & Co., Budapest, which A. Hausegger describes in a recent issue of the "Zeitschrift fuer Elektrotechnik." The mechanism of the lamp is composed of two racks, one for each carbon, inclined at an angle of about 90°; the racks having a series of pinions and a lever system for insuring the regular movement of the carbons. The mechanism is driven by the weight of the carbons and carbon holders, the movement being controlled by the action of a solenoid. By the use of coreless solenoids the lamps burn without noise, and with the exception of the carbon holders and the contacts connecting them with the circuit, none of the outer or inner parts conduct current. Flatly pointed wick-carbons are used in order to insure a steady arc, and also to prevent the arc from rising in consequence of the heat. The lamps require 10 amperes at a pressure of 28 to 30 volts. Fig. 4 gives curves of the intensity and distribution of light from the "Hackl" and the ordinary arc lamp. The heavy line representing the "Hackl" and the light line an ordinary arc lamp; the right and left half of the curve showing the intensity with and without a globe, respectively. The makers claim that the lamp consumes only 0.52 watt per candle-power, while the ordinary arc lamp requires three times that amount. As will be seen from the curve, the lamp gives higher values all round than the ordinary arc lamp, especially below the lamp. The system is, however, not well adapted for any other than alternating currents, since the greater part of the rays would not be projected vertically downward with direct current, but in the direction in which the positive carbon is placed; besides, the positive carbon would also be twice as thick as the negative one, so that besides other disadvantages, heavier shadows would be produced on the side of the positive carbon.

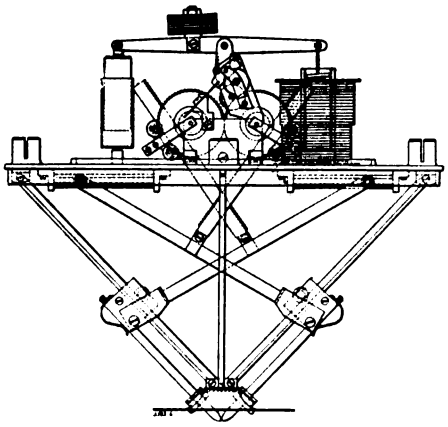

FIG. 3.—"HACKL" ARC LAMP.

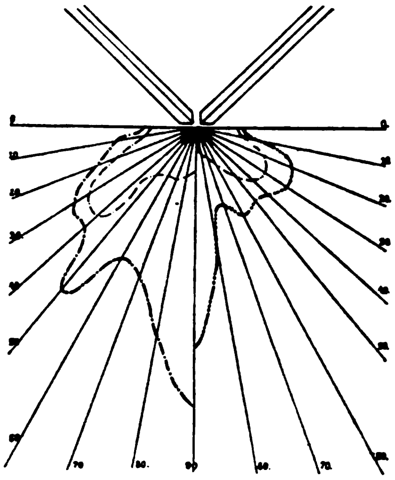

FIG. 4.—CANDLE-POWER CURVES.

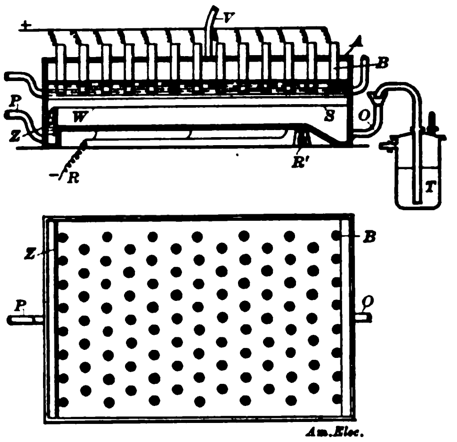
Electrolytic Alkali Cell.—A cell closely resembling that described by Ernest Franke in his article on the "Electrolytic Production of Soda and Chlorine" in the March number of this paper, is described in a recent issue of the London "Electrician." The cell, a sectional elevation and plan of which is shown by Figs. 5 and 6, consists of a closed rectangular vessel, *A*, provided at *Z* with an adjustable "bridge" or weir. The bottom of the cell up to the level of this weir is filled with mercury, which at *R* is in electrical contact with the negative terminals of the dynamos. The pipes, *O* and *P*, supply and withdraw the mercury when the cell is at work. The cell is charged with a concentrated solution of sodium or potassium chloride, and into this dip a large number of carbon or platinum anodes. Pipes are provided, as shown, for the circulation of the electrolyte, and an outlet pipe, *V*, is also provided for the escape of the chlorine gas produced. The cell operates as follows: The sodium or potassium liberated at the surface of the cathode combines with the mercury to form an amalgam. This amalgam floats upon the surface, *SW*, and the circulation of the metal in the bottom of the cell carries it toward the weir *Z*, over which it passes. The amalgam is collected at *P*, the sodium or potassium reclaimed and the pure mercury returned to the cell by means of the pressure vessel, *T*, and the supply pipe, *O*. The drift of the amalgam toward *Z* is assisted by the current of brine passing through the cell in the same direction. The cell is in successful operation in Belgium and in Russia in the caustic alkali and bleach plants of Solvay & Company.



FIGS. 5 AND 6.—SOLVAY CELL.

Formation of Boiler Scale.—Calcium sulphate is probably one of the most obstinate substances found in water with which engineers have to contend, when dealing with feed-water and the formation of boiler scale. Not only is its presence so frequent but the stony scale formed by it adheres so tenaciously to the boiler that it is with difficulty removed. In a recent issue of the "Revue de Mecanique" M. Boyer-Guillon reviews what published information is to be had on the subject, and describes the apparatus and methods of experimental observation employed by him. His observations corroborate in a general way the popular notion of diminished solubility with increased temperature; but his experiments show that up to 392° F. complete solubility is not reached. It also appears that the rate of precipitation is somewhat more rapid at high temperatures than at lower; but in every case several hours were required to attain a fixed degree of solubility for a given temperature. It is often attempted to purify feed-water by heating it in a separate vessel before passing it to the boiler; and while the temperature of the exhaust is usually sufficient to throw down the carbonates, the heat of live steam is required for the more or less complete removal of the sulphates. In view of this it is evident that this method of purification permits most of the sulphate of lime to be carried into the boiler with the feed-water, unless sufficient time be given for it to separate, and is therefore only partially effective.

The Influence of Curve Forms on Measuring Instruments.—Dr.Gustav Benischke in a recent issue of the "Elektrotechnische Zeitschrift" shows what influence the different alternating-current curve forms exert upon measuring instruments. Curves *a*, *b* and *c*, Fig. 7, are taken as typical examples of curve forms met with in every-day practice, and the instruments used were induction voltmeters and ammeters, and Kohlrausch's electromagnetic voltmeters and ammeters. Figs. 8 and 9 are plotted values obtained from the induction instruments, and Figs. 10 and 11, values obtained from the electromagnetic instruments. Figs 8 and 9 show that the induction instruments are not affected by the curve form, while the electromagnetic instruments are. On the other hand, he states, it is known that the latter instruments are not affected by the frequency, which is not the case with the induction instruments.

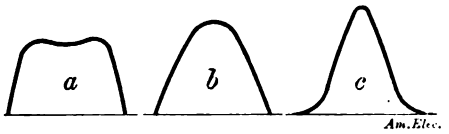


FIG. 7.—CHARACTERISTIC CURVES.

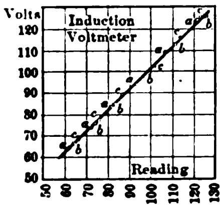

FIG. 8.

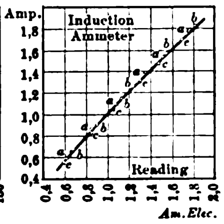

FIG. 9.

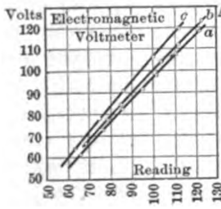

FIG. 10.

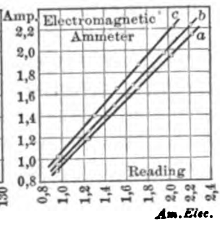

FIG. 11.

Diesel Oil Engine.—An occasion of considerable scientific and industrial importance in Great Britain was the recent exhibition of a 15-h.p. Diesel oil engine built by Scott & Hodgson at Guide Bridge, Manchester, an account of which is contained in "London Engineering." The engine is not only the first of its kind built in England, but the first to be operated on the two-stroke cycle plan, all previous Diesel engines being worked on the four-part cycle system. As is well known, Diesel's invention consists in raising the point of compression far above the limits ordinarily used; and since this could not be done with an explosive mixture in a hot cylinder, he altered the cycle so that instead of drawing in air and oil vapor together and then compressing them, he compresses the air alone to several hundred pounds per square inch and then into this compressed and consequently heated atmosphere he injects oil spray which immediately ignites, the temperature being in the region of 1000° Fahr. The injection takes place when the crank is over the center and the piston begin to travel outward. As will be seen from Fig. 12 no sudden explosion takes place. The oil burns; but not rapidly enough to raise the pressure in the cylinder. When the engine is under full load the top of the indicator diagram is nearly horizontal and shows a distinct cut-off. At this point the pressure begins to fall and drops away in a sweeping curve until the exhaust opens. The air is heated during the burning of the oil at a rate corresponding nearly with the rate of cooling due to the expansion; and after the combustion is concluded the air is expanded down to about 30 lbs. pressure when it is exhausted. The engine that was tested has a power cylinder 7⅞ ins. in diameter, with a stroke of 10¼ ins., and runs at 216 r.p.m. It is horizontal, having in front of the power cylinder and tandem with it, an air pump cylinder 9 ins. in diameter. On one stroke this cylinder draws in air, and compresses it on the other stroke to 4 lbs. per square inch, delivering it into the bed which acts as a reservoir. The discharge valve, however is passed by the piston before the stroke is completed, and the air remaining in the pump cylinder is compressed to 60 lbs. per square inch and delivered to a second stage compressing pump worked by a crank at the end of the crank shaft. This pump has a plunger about 2¾ ins. in diameter, and in it the air is compressed up to 750 lbs. per square inch. On one side of the engine is a secondary shaft driven at half the speed of the crank shaft. This shaft drives the governor by bevel wheels; the governor regulating the quantity of oil injected in accordance with the demands on the engine. The oil is lifted by a pump worked by an eccentric on the secondary shaft; the suction valve of the pump being controlled by a taper piece operated by the governor so as to permit a part of the oil to leak back when full power is not required. The oil is delivered to the inlet valve of the cylinder, and when this valve is raised, the compressed air rushing down through a number of fine grooves drives the oil into the cylinder in the form of spray. The inlet valve, like the exhaust valve, is operated by a cam. The engine is started by means of compressed air, a quantity of which is stored for this purpose in two steel cylinders. Prof. Unwin states that the Diesel engine will convert 37 per cent of the heat in the oil into indicated work and the manufactures of the engine guarantee that the engine of any size will run with .452 lb. of solar oil and crude petroleum per hour per brake horse-power, and that at half load the consumption will not exceed .520 lb. Prof. Meyer, of the Technical High School, Charlottenburg, reports that with raw Tegersee oil of a specific gravity of .789 at 68° Fahr. an engine he tested consumed .467 lb. at normal load, .488 at ¾ load and .567 lb. at ½ load. The engines, it is said, will work with the very cheap tar oils.

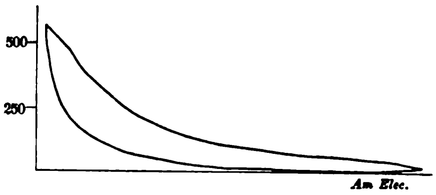

FIG. 12.—INDICATOR DIAGRAM.

Some Recent Electrical Patents

Brush-holder.—One of the disadvantages attendant upon the use of a brush-holder for carbon brushes to which the brush is positively attached is that as the brush wears away and is forced toward the commutator by the holder, the point of contact with the commutator is shifted by reason of the change in the angle between the brush and a line tangent to the commutator. In the brush-holder illustrated by Fig. 1, which has been patented by Wm. D. Pomeroy, this disadvantage is eliminated by a peculiar form of parallel motion. The brush is attached firmly to a holder plate, 12, pivoted to the curved arm, 11; the lower end of the brush-holder plate is attached by means of a flexible laminated conductor, 17, to the arm, 8. To this same arm the curved finger, 11, is pivoted at 10. The two points to which the ends of the laminated conductor, 17, are attached by screws, and the pivots, 10 and 12, of the curved finger, 11, from the corners of a parallelogram, so that the movement of the brush-holding plate is as though it were hung on a pair of parallel links, and the angle between the carbon block and a line tangent to the commutator is maintained unchanged. Pressure is applied in the usual way by means of a spiral spring coiled about the pivot, 10, and having its free end, 16, adjustable in notches along a segment, 15, which is integral with the curved finger, 11. Patent No. 670,059.

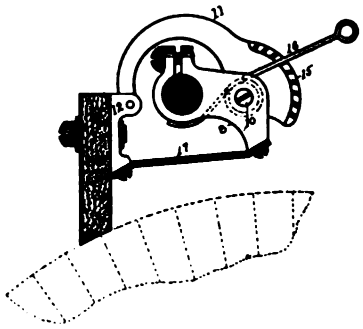

FIG. 1.—BRUSH HOLDER.

Combined Ammeter and Socket Plug.—In order to eliminate the disadvantage of flexible cord connections, Gustav Grabosch has devised an ammeter, the structure of which includes a socket plug for connecting the ammeter to the circuit direct instead of through the medium of flexible cord. Fig. 2 illustrates the arrangement. The ammeter, as illustrated here, is of the magnetic vane type; the exciting coil, *b*, is wound on a bobbin, *a*, having a screw-thread extension, *c*, sheathed with metal, *d*, to which is attached one end of the ammeter coil; the other end of the coil is attached to the tip, *l*. The magnetic vane is mounted in the center of the bobbin, *a*, and the pointer, *h*, and dial are enclosed by a transparent hood, *o*. A spiral spring, *i*, is employed to bring the pointer to zero. Patent No. 670,174.

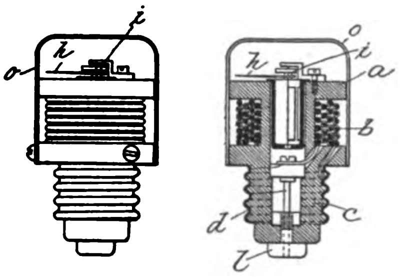

FIG. 2.—AMMETER AND PLUG.

Knife-Blade Switch — In the ordinary knife-blade switch in which the movable blade is forced between two parallel jaws in closing the circuit, a common disadvantage is that if the jaws are set close enough together to give a firm contact, when the blade is forced home the free ends of the jaws are forced apart so far as to put the jaws out of parallel with each other and give insecure contact in the neighborhood of their free ends. Fig. 3 herewith illustrates a form of switch designed by Wm. F. Bossert with a view to obviating this disadvantage. The blade is made duplex so that it embraces the stationary clip instead of being embraced by it. The stationary clip, 32, consists of two thin parallel strips with the upper edges rounded in order to facilitate their entrance between the parallel plates of the knife blade. The knife blades and stationary clips are made of spring material. A vertical cross-section through the clips and blades is shown at the upper left-hand part of the engraving, and a section through the clips alone at the upper central part. Patent No. 670,145.

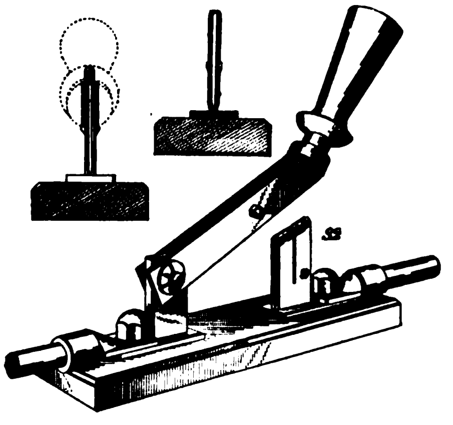

FIG. 3.—KNIFE BLADE SWITCH.

Contact Finger for Motor Controllers.—With the ordinary arrangement of controller contact fingers any change in the adjustment of the finger to compensate for wear is effected by adjusting the tension of the finger; consequently, if the finger springs are at the outset given the proper tension to secure the best operation, subsequent adjustment for wear vitiates the original adjustment and makes the tension either too great or too little. In order to obviate this, Frank W. Garrett provides an auxiliary adjustment, as indicated in Fig. 4 herewith. The usual spring adjustment is provided between the contact finger, *D*, and the end of the arm, *G*, adjustment being made by means of the nuts at *F*. The position of the arm, *G*, however, is adjustable by means of the screw, *H*, which is tapped into the stationary framework of the controller, so that the relation between the tip of the contact finger, *D*, and the controller drum may be adjusted without altering the tension of the spring, *E*. Patent No. 671,079.

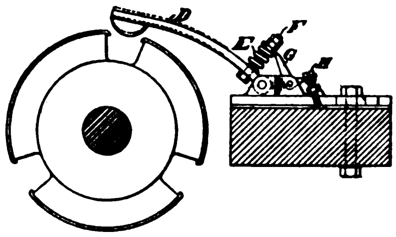

FIG. 4.—CONTACT FINGER.

Anti-Sparking Commutator.—Double-current generators and rotary converters, as generally built, manifest more or less serious sparking at the direct-current commutator because the current in the coils which are undergoing commutation is not uniform throughout a cycle; and the resultant armature reaction also varies, thereby varying the field strength under the pole tips. There is therefore no position at which the direct-current brushes will be sparkless throughout a cycle. The conditions just described require that the brushes should be moved back and forth on the commutator during each cycle, so that the brushes will commutate the current in those coils of the armature which are in position with respect to the field most favorable for commutation. If such a machine were made bipolar, for example, the brushes, during one cycle or complete revolution, would require to have a positive lead, and during other operations a negative lead, corresponding to the generator and motor actions, which alternate in the machine. It is manifestly impracticable to rock the brushes back and forth in accord with the variation in the position of the armature coils with respect to the commutating field and their own reaction; Prof. Elihu Thomson, however, proposes to accomplish the same result by varying the width of the commutator segments, as illustrated by Fig. 5, which shows approximately the gradations that would apply to the commutator of a bipolar machine. In a multipolar machine, of course, what might be termed the "cycles of variation" in commutator width would be increased proportionately to the number of magnet poles. Patent No. 665,486.

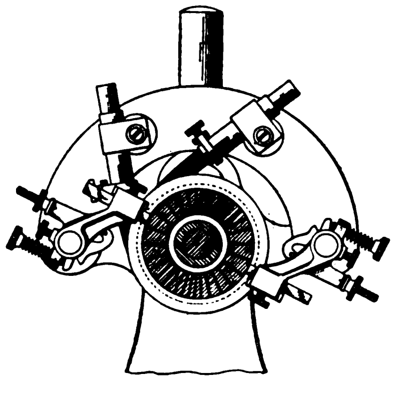

FIG. 5.—ANTI-SPARKING COMMUTATOR.

A Synchronizing System for Alternators.—In coupling alternators in parallel it is customary to bring the fresh alternator into synchronism by regulating the speed of its engine. After the alternator is thrown in, however, it is usually the practice to rely on the engine governor for maintaining the proper speed. With a view to enabling the switchboard operator to control the speed of an engine both at the time of paralleling and after the alternator is in actual operation, H. W. York has devised and patented the electrical controlling system indicated by Fig. 6. A rocker arm, I, is interposed between the eccentric rod and the valve gear, and a sliding block, H, to which the end of the eccentric rod is pivoted, is adapted to be moved back and forth along the rocker arm by means of a screw-threaded rod driven by the motor, M. It is evident that varying the position of the sliding block, H, will vary the throw of the valve and therefore the cut-off. The motor is controlled from the switchboard and pilot lamps are provided which indicate when the block, H, reaches the

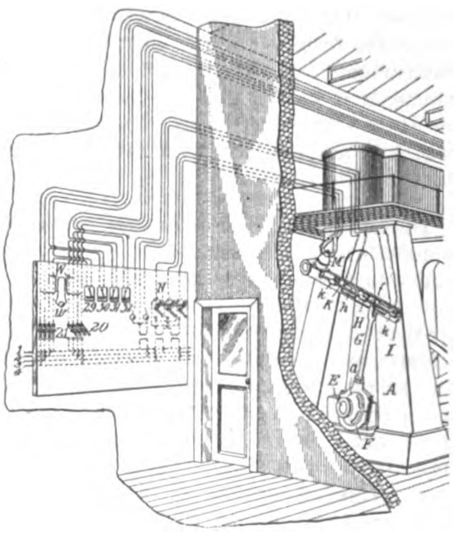

FIG. 6.—ENGINE SPEED CONTROLLER.

extreme end of its travel in either direction. The division of load between the alternators evidently may be controlled by means of this arrangement. This arrangement has been made the subject of three patents, one covering the system, another the apparatus, and a third the method of synchronizing. Patents No. 668,429, 668,430 and 668,431.

Casing for Electric Motors.—The object of the present invention is to provide a casing for electric motors which can be adjusted either to completely enclose the machine or to uncover apertures in the stationary part of the casing and give access to the brushes and commutator. To carry out this object the inventor, Charles A. Eck, provides a rotatable shield exactly similar to the rotating damper of an ordinary stove, and mounted on the end cap of the motor or dynamo concentrically with the bearing. This movable shield is provided with apertures corresponding in shape and size to apertures in the case of the motor, so that it may be turned either to expose the apertures in the stationary part of the machine or to cover them up. Patent No. 669,577.

A Means for Preventing Hunting.—It is frequently the case that an alternator direct-connected to a steam engine, the moving parts of which do not possess sufficient inertia to maintain uniform angular velocity throughout each revolution, has its rate of rotation varied to such an extent during each revolution that the resultant alternating current has a pulsating frequency. Under this condition the operation of synchronous motors or rotary converters from the circuit supplied by such an alternator is usually attended by excessive hunting. Harold W. Buck has found that by varying the field excitation of the synchronous motor or rotary converter, and in time with the engine stroke, the pulsation in the frequency of the alternating-current supply is neutralized and hunting prevented. Fig. 7 represents diagrammatically the apparatus devised and patented by Mr. Buck for this purpose. In the drawing the armature of the synchronous motor is indicated by the figure 8, and the field coils by 9 and 10; the alternating-current supply circuit, 2, 3, 4, is connected to the collector rings in the usual manner, and the field windings are supplied from a direct-current circuit, 11, 12. Connected in series with the field circuit is a resistance, 13, which is periodically varied with relation to the field circuit by means of the reciprocating brush, 17; in shunt with this resistance is a manually-adjustable rheostat, 25. Both of the resistance coils are non-inductive. The reduction of speed in the worm gearing is such that the reciprocating brush, 17, moves to and fro in unison with the rise and fall of crank effort at the engine which drives the generator supplying alternating current to the motor. The variation of the resistance in series with the field winding varies the torque between the field magnet and the armature winding so as to counteract the tendency to hunting. The hand rheostat, 25, is provided for the purpose of adjusting the degree of variation in field strength. The sketch, *B*, in the lower right-hand part of the diagram, illustrates an arrangement of change gearing whereby any desired adjustment may be secured to adapt the machine for circuits having various periods of pulsation in their frequency. The small spur wheel, 26, is driven synchronously with the motor armature and drives the gear, 27, through the medium of an idler, 28. The arm, 30, which carries the small gear and the idler, is adjustable about the center of the gear, 26, in order to allow the gear wheel, 27, to be replaced by another wheel having a different number of teeth, thus varying the reduction of speed between the motor shaft and the eccentric shaft. Patent No. 667,114.

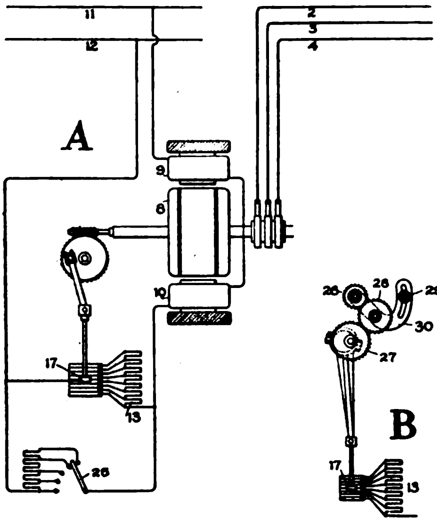

FIG. 7.—DIAGRAM OF CONNECTIONS.

◆

NEW BOOKS.

The Universal Electrical Directory. (J. A. Berly's.) London: H. Alabaster, Gatehouse & Co. Red cloth; 1250 pages, 6 x 9 ins. Price in Great Britain, 7s. 6d.; elsewhere, 8s. 6d.

This, the 1901 edition of the well-known "red book," has been enlarged by 57 pages since last year. The directory is particularly complete and the arrangement of its contents extremely convenient. The American section contains 6160 names and the reviewer has been unable to find a single error in that part of the record which comes within his personal knowledge of names and addresses, which is not of narrow scope.

Electric Lighting. (Vol. II.) By Francis B. Crocker. New York: D. Van Nostrand Company. Cloth; 505 pages, 6 x 9 ins.; 391 illustrations. Price, $3.

This volume of Professor Crocker's work is devoted to all of that portion of an installation outside of the generating plant. This latter part was the subject of the first volume, so that the two volumes cover the entire plant. This volume discusses wiring, systems of distribution, overhead and underground conductors and their installation, arc and incandescent lamps, motor-dynamos, transformers, meters, etc., in a clear and concise manner which is usually explicit enough without being verbose. The book also contains an appendix comprising the National Underwriters' Code for 1901 and another consisting of the report of the Standardization Committee of the American Institute of Electrical Engineers. It is to be hoped that Professor Crocker will be able to keep both volumes up to date by frequent revision, as the subject matter is most valuable and its intrinsic value is enhanced by the style of treatment.

Inventor's Manual. New York: Norman W. Henley & Co. Cloth; 115 pages, 5 x 6½ ins. Price, $1.

This is an interesting little book and one of undoubted value to young inventors. While tending to stimulate inventive ambition, there are no ridiculous statements leading the uninitiated to suppose that the only requisite to untold wealth is the invention of something, no matter what,—anything. The absence of this sort of buncombe raises this book far above the level of those of the more pretentious productions, the chief object of which is to line the pockets of some alleged patent attorney.

Handbook on Engineering. By Henry C. Tulley. St. Louis, Mo.: Henry C. Tulley & Co. Leather, with flap; 792 pages, 4½ x 6½ ins.; fully illustrated. Price, $3.50.

This is a member of the "hand-book" class, and contains a great deal of moderately elementary information concerning steam and electrical apparatus. The principles of dynamos and motors are explained in very clear language and with almost uniform accuracy; the explanation of brush sparking is not quite complete, however, no mention being made of the inductance of the commutated coils. An amount of attention is paid to Brush and T.-H. arc-lighting dynamos which is by no means justified by the present status of these machines with relation to the progress of the art, while very little space is devoted to constant-potential generators and there is not a line concerning alternators or alternating-current apparatus. The steam portion of the book is similarly unbalanced. Considerable space is devoted to Russell, Porter-Allen, Harrisburg, Ideal and Westinghouse engines, with a very moderate amount to the Corliss engine (and this amount devoid of any description of the releasing gear), while the McIntosh & Seymour engine is dismissed with a single page and there is no mention whatever of Allis, Rice & Sargent, Ball and other prominent engines. A considerable amount of space is devoted to refrigerating apparatus, and a practical discussion of the use and management of steam boilers, pumps, injectors, etc., also come in for a good share of discussion, as well as hydraulic elevators and air compressors. The matter contained in the book is excellent, the only criticism one might make being based on the omission of a great deal of matter which logically should have been included.

PROF. HENRY A. ROWLAND.

The scientific world suffered a great loss on April 16 by the death of Prof. Henry A. Rowland, at Baltimore, Md. Professor Rowland was born at Honesdale, Pa., November 27, 1848, and was graduated from the Rensselaer Polytechnic Institute, Troy, N. Y., in 1870, as a civil engineer. The next year found him railroad surveying in Western New York, but his services as a teacher were soon called into requisition at Wooster University. In 1872 he returned to Rensselaer as instructor in physics, and in 1874 he became assistant professor. In the meantime, he had completed his now widely known experiments on magnetic permeability, but at first he was unable to get them published. The scientific journals in America rejected his work, but, confident of its value, he sent his results to Clerk Maxwell, who at once had them published in the "Philosophical Magazine."

When the authorities of the newly founded Johns Hopkins University, at Baltimore, sought for some one to fill the chair of physics and become director of the physical laboratory, Professor Rowland, with his already recognized ability, and with the countenance which Maxwell's recognition of his talents gave, was chosen for the place. This was a year before the University actually opened and he spent the year in Berlin, working with Helmholtz. Here he investigated the effect of static electricity in motion, and later offered the first proof of Maxwell's hypothesis of the identity of electromagnetic and luminous undulatory transmission by demonstrating that a static charge moving with the velocity of light has the effect of a current. Later on, in accordance with an international agreement, Professor Rowland was selected by the United States Government to determine the absolute value of the ohm.

THE LATE PROF. HENRY A. ROWLAND.

While the energies of Professor Rowland were largely devoted to exhaustive researches into the nature and phenomena of electricity and magnetism, his work took a broad sweep through pretty well the whole range of physics. He devised a very exact method for determining the mechanical equivalent of heat, and the value of 778 foot-pounds obtained by him replaced that of Joule (772), which had hitherto been accepted by science. To the public his name is probably even more familiar in connection with his large diffraction gratings, which are ruled by a method of his own directly on concave mirrors, the image of the solar spectrum being thus produced without the aid of lenses. In fact, the photographs of the spectrum obtained with the aid of these gratings far exceed anything else of the kind, and their exhibition before the National Academy of Sciences in 1883 was one of the leading scientific events of the year.

The degree of Ph.D. was conferred upon Professor Rowland by Johns Hopkins University in 1880. As a member of the Electrical Congress at Paris in 1881, and of the jury at the Electrical Exhibition at the same time and place, he received the order of a Chevalier of the Legion of Honor. In 1881 he was elected a member of the National Academy of Sciences. In 1883 he presided over the Physics Section of the American Association for the Advancement of Science, at Minneapolis, and read a memorable address, entitled "A Plea for Pure Science." In 1884, being appointed by the Government on the commission specially formed for the purpose, he presided over the deliberations of the National Conference of Electricians at Philadelphia, and delivered an address. During the same year he received from the American Academy, of which he was an associate, the Rumford medal for his researches in light and heat, and since then other well-merited honors have been bestowed upon him. In 1893 he was elected presiding officer of the International Electrical Congress, sitting at Chicago. During the past eight years Professor Rowland devoted much time to the perfection of a system of rapid telegraphy, a working exhibit of which formed, perhaps, the most interesting feature of the American electrical section of the recent Paris Exposition.

Professor Rowland was the author of many papers of great importance, most of which relate to his far-reaching researches into various scientific subjects. In addition to developing the resources of the physical and electrical laboratories at Johns Hopkins, where, in addition, an electrical testing bureau was established by him, he managed to devote considerable time to many other matters of importance.

NOTES.

A Recipe for Bronze Varnish.—The *Metallarbeiter* gives the following formula for a bronze varnish: Equal parts of good linseed oil varnish and copal or amber varnish, into which is stirred sufficient fine bronze (about 12 ounces of bronze to one pound of varnish) to give a permanent gloss and coloring. A thin application of the varnish is essential for a handsome appearance. The coating has to be baked after being applied.

A Marvelous Process.—According to a contemporary which classifies itself by its own name as a journal of science, a process for treating window panes is used in Germany which consists of painting the panes on one side with a liquid prepared by grinding whiting in a potash waterglass solution. After one or two applications, it is stated the panes are *perfectly opaque*, while the room remains as light as before!

A Substitute for Coal.—According to a press despatch, a workman in a German chemical works has devised a substitute for coal, of which peat is the basis. The fuel is said to cost about $2.50 per ton, and to give out "a great heat." The despatch also states that the fuel "burns with a bright flame and leaves no slag," but it does not state what the calorific value per pound is. The peat is dried, ground up and mixed with chemicals, and the compound is pressed into brick shape.

Dynamo and Motor Discs and Castings.—Those of our readers who have been interested in the descriptions of small motors and dynamos which have been published from time to time in this paper will doubtless be glad to learn that magnet castings and armature core discs for the direct-current machines are obtainable from the American Motor Construction Company, Sip and Olean Avenues, Jersey City, N. J.

The Switchboard Instruments in the Swift Plant.—In the description of the power plant of Swift & Co., which appeared in the April number of this paper, the statement was made on page 152 that "all the switchboard instruments are of General Electric manufacture." This statement, we are informed, is incorrect, the left-hand half of the switchboard, consisting of the arc lighting and incandescent lighting panels, having been entirely equipped by the Wagner Electric Manufacturing Company, St. Louis, Mo.

A Direct-Connected Gas Engine Outfit. —The San Francisco Gas & Electric Company is installing a 200-kw. General Electric dynamo direct-connected to a 300-h.p. gas engine built by the Union Gas Engine Works, of San Francisco. The engine is a four-cylinder machine, and the cranks are set 90 degrees apart, so that the crank shaft receives an impulse twice in each revolution, exactly as in the case of a single-cylinder steam engine. The speed of the shaft is 200 r.p.m. The engine will be supplied with producer gas made on the premises.

Electric Light Consolidation in Maine. —The Sebago Power Company, the Cumberland Illuminating Company, the Deering Electric Light Company, and the Portland Electric Light Company, all of Portland, Me., have consolidated under the Cumberland Illuminating Company's charter, with the corporate name of the Portland Lighting & Power Company. The company is capitalized at $350,000, $100,000 of which is preferred stock and $250,000 common. The officers of the new company are: J. R. Libby, president; M. H. Kelly, vice-president, and E. H. Mather, treasurer and manager.

Electric Traction in France.—Some recently published statistics on electric railways and railroads in France afford interesting reading as an index of the growth of electric traction in Europe. In 1890 the first electric railway was installed in France at Clermont-Ferrand. Since then electric traction in France has developed with wonderful rapidity. The total length of lines in use has nearly doubled during the last year, being 1486.3 kilometers at the beginning of this year against 752.3 a year previous. The total power of the central stations has been tripled in 12 months; the output having increased from 28,308 kilowatts last year to 64,383 kilowatts this year.

The Utilitarian "Chinee."—A new and curious application of electricity, which, however, is not to be taken very seriously, is related by the "Journal d'Electricité." G. A. Wiese who has recently returned from China where he had gone to install an electric light plant in the town of Canton, gives among other interesting items, the following, which takes first place in point of originality. Many of the streets of Canton are so narrow that it was impossible to set poles for the support of the overhead wires; consequently it was necessary to obtain permission from the town authorities to fix supports to the walls of the houses. After the wires were put up an inspection of the line was commenced. The astonishment of the inspectors may well be imagined when they saw the lines liberally garnished with linen which the townspeople had put out to dry. The wires were "alive" with alternating current at 1000 volts, and it is surprising that nobody was killed. When the Chinese had been warned of the danger they smiled in the historic "childlike and bland" manner of Bret Harte, and said that electricity dried their linen better and quicker than the sun, and refused to take in their belongings. Mr. Weise was obliged to resort to the local authorities to put a stop to this novel utilization of the wires.

Telephone Consolidation. —The United Telegraph & Telephone Company, with headquarters in Baltimore, has acquired the Maryland Telephone & Telegraph Company, the Pittsburgh & Allegheny Telephone Company, the West Pennsylvania Long Distance Telephone Company, the Home Telephone & Electric Company, the Allegheny County Telephone Company, and the Harsford County Telephone Company. The aggregate capital stock of these companies is $3,910,000. The West Pennsylvania Long Distance Telephone Company owns a line from Pittsburgh to Beaver, Pa., where connection is made with the United States Long Distance Telephone Company that gives service to Cleveland and other Ohio towns. According to a press despatch, more than 167,000 telephones will be connected by this line with the Pittsburgh and Allegheny plant.

Italian Steam Road to be Changed Over. —The Italian Mediterranean Railway Company has for some time past been studying a project for the adoption of electric traction on its line between Milan and Gallarate, including branches in three directions toward Lakes Majjori, Varese and Lugano, to the towns of Arona, Laveno and Porto-Ceresio. The length of the line from Milan is 25 miles and the three branches are 16, 20 and 21 miles long, respectively. The third-rail system is contemplated. Primary three-phase currents at 12,000 volts would be conducted to the sub-stations and converted by means of transformers and rotary converters to continuous current at 650 volts. The power station would be situated near Tornavento, a fall on the Tessin River being utilized for the development of motive power. Eight large turbines would be installed for the alternators and two small ones for the exciters. According to present specifications the power of each hydraulic unit will be 1,120 horse-power and that of the alternators will be 742 kilowatts each. The line to the sub-station at Gallarate is to be six wires of 7.8 millimeters diameter each, hung on porcelain insulators, on poles. There will be five sub-stations between Milan and Porto-Cenesio. The rolling stock will comprise 20 motor cars and 20 trailers; the former capable of carrying 75 passengers and the latter 93. Each motor car will be equipped with four motors of 75 horse-power and lighted by 20 incandescent lamps.

Laying Cables for the New East River Bridge —On April 7 the first important step was taken in the making and laying of the cables for the New East River Bridge between New York and Brooklyn. The preparation of plans and other preliminary work, as well as the main part of the contract which is to follow, is under the supervision of Mr. Charles G. Roebling, president of the John A. Roebling's Sons Company, who is assisted by Mr. William Hildenbrand. The work done last month was the placing in position of the 2¼-in. diameter ropes which support the temporary foot bridge on which the workmen will stand during the main work of cable laying. Several methods of getting the first line of a bridge across have been employed in the past, and kites, swimmers and other means have been tried, but the method employed on this occasion has, we believe, never been tried before, and appears to be a distinct advance over all previous ones. The drum containing the cable was carried across the river on a float (one end having previously been secured) and the cable was paid out and allowed to rest on the river bed until such time as it could be raised from the water and to the desired height by means of a stationary engine and drum. The first cable was successfully raised on April 11, the time required being only seven minutes, navigation being, of course, suspended during that period.

The Water Power Plant of St. Gall.—The central power station that was installed at the end of last year at Kubel, Switzerland, for the supply of electric light to 14 communes of the cantons of St. Gall and Appenzell, is now in full working order. The station, which is situated about three miles from St. Gall near the Appenzell frontier, is one of the largest in east Switzerland. The plant receives its motive power from the Urnäsch River, which although small, supplies periodically an immense volume of water owing to the frequent heavy rains. To collect this periodic flow a reservoir has been constructed. It is intended, however, with a view to securing a more assured reserve, to utilize also the waters of the Sitter River. A dam has been constructed in concrete which leads the waters of the Urnäsch River into a tunnel bored through rock. This tunnel is 4.6 meters (15 ft.) long, 1.9 meters (6¼ ft.) wide and 2 meters (6 ft. 6¾ ins.) high, and has a declivity of 7½ in 100. It terminates in an artificial lake called the "Gübsenée," created as the reservoir mentioned above. This was formerly the site of a small marshy valley, and has an area of 42 acres; it has a capacity of 1,500,000 cubic meters (52,970,000 cu. ft., or 396,257,000 gallons) of water. The power station is situated on the right bank of the Sitter River. It contains four turbines of 500 horse-power each, and two others of 750 and 1000 horse-power respectively will be installed as soon as the arrangement for drawing from the Sitter is completed.

ESTABLISHED 1889.

American Electrician,

WITH WHICH IS INCORPORATED
Electrical Industries.

CECIL P. POOLE, Editor.
W. H. ONKEN, Jr., Associate Editor.

Published on the first of each month by the

American Electrician Company,

NEW YORK: 120 Liberty Street.
CHICAGO: Monadnock Block.
PHILADELPHIA: 929 Chestnut Street.

Absolute Temperature.

The steam engineer with an ambitious disposition and a studious turn of mind will meet with constant reference to "absolute" temperature in writings relating to heat efficiency, work done by the expansion of steam, etc., and may be somewhat puzzled by the distinction between ordinary and "absolute" temperatures. This may be explained with sufficient accuracy for practical purposes as follows: The two standards of temperature are the freezing point and the boiling point of unconfined water; on the Centigrade scale these are arbitrarily, but rather logically, taken as 0 and 100 degrees, respectively, the scale being simply divided into 100 equal parts between the two standard points. Having thus established a scale, it was a simple matter to extend it in both directions. The Fahrenheit scale is entirely illogical, the starting or zero point being located an arbitrary distance below freezing.

That neither of these scales is literally correct is evident from the meaning of the word zero; zero temperature would obviously be the point at which there would be no heat, and consequently the point below which there could be no further reduction of temperature. And as temperatures below all of the thermometer zero points are of common record, none of these thermometer zeros can be the actual zero of temperature. This point is the one which is meant by the expression "absolute zero;" and "absolute temperature" is the temperature reckoned from absolute zero.

A perfect gas would be one which had no limit to its elasticity, and as the volume of any gas increases and decreases as its temperature increases and decreases, extracting all of the heat from a perfect gas would cause it to shrink to nothing. Now it has been calculated that a perfect gas taken at the melting point of ice would increase and decrease its volume $\frac{1}{492.66}$ for each Fahrenheit degree of temperature increase or decrease. Consequently, decreasing its temperature by 492.66 Fahrenheit degrees, from the melting point of ice, would reduce the volume to nothing; the absolute zero of temperature, therefore, is considered to be 492.66 Fahrenheit degrees below the melting point of ice (32° Fahr.), or 460.66° below Fahrenheit's zero. It follows that the absolute temperature of any substance is 460.66 more than the temperature indicated by a Fahrenheit thermometer. If we use the Centigrade scale, the absolute or true temperature is 273.7° higher than the thermometer shows. In practical computations absolute temperatures are frequently taken as being 461 higher than Fahrenheit temperatures and 274 higher than Centigrade temperatures.

Boiler Room Practice.

The very name "boiler room" is instinctively regarded by all who are in the remotest degree familiar with this part of a steam plant as being synonymous with grime, dinginess and general disreputability, and the place itself is considered as an inevitable eyesore, to be shunned except under stress of dire necessity. As pointed out in an article on economical steam production, which appears elsewhere in this number, not only does this condition of affairs lack valid excuse for existence, but it is a deliberate waste of money to permit it. Of course, coal is not quite so clean as some other commodities one could mention, and no one expects a fireman to maintain a white duck standard of cleanliness; but between this standard and the filthy condition which generally prevails there is a long stretch of intermediate grades of more or less decency and economy. Moreover, coal is not the only factor in steam production; a greater weight of water than of coal has to be handled, and the judicious application of some of it to windows, walls and facings would metamorphose most boiler rooms. Combined with this cleansing should be provided ample light, so that instead of blinking and feeling his way around in murky gloom between or behind batteries of boilers, the fireman can proceed directly to any point or fitting and work conveniently and rapidly anywhere in the boiler house.

It is by no means contended that clean windows and walls and well-lighted corners will directly improve the steaming quality of the boilers. But the application of a small degree of common sense will show that these conditions deprive a lazy fireman of all excuse for neglect and enable a conscientious one to make the best possible showing. Moreover, clean and light surroundings conduce to a better standard of work generally. This point was forcibly exemplified a few months ago at one of the largest stations in America, where mechanical stokers fed through chutes from an overhead bin are used, and not a pound of coal is shoveled. Upon calling a fireman's attention to the fact that all of the fittings were covered with grime, and asking if they were ever cleaned off, we received the following courteous answer, delivered in a surly tone: "What th' ——'s the use in this —— ——. dungeon."

Synchronizing Alternating-Current Machines.

The importance of careful synchronizing in coupling alternators and rotary converters, as differentiated from the haphazard method of throwing tne switch in almost anywhere and depending upon the machines to pull themselves together, can scarcely be overestimated. Notwithstanding that the synchronizing voltmeter is gradually taking the place of the incandescent lamp as an indicator of synchronism, prevailing methods still leave much to be desired, since successful synchronizing depends almost entirely upon the skill of the operator. A nervous or unskilled attendant may, by being a second or so late, cause no little amount of damage, especially after a breakdown when the machines that are running are heavily overloaded and a fresh machine is being thrown in to relieve them. Under such circumstances synchronizing by present methods becomes a difficult operation, because the abnormal load on the engines already running impairs their regulation and the indications of the voltmeter or lamps are so erratic that a "flying shot" is often necessary. This is a risky operation, but the only one possible in such an emergency. Under the conditions cited it is also not uncommon for the voltage to drop so low as to throw out the synchronizing voltmeter entirely, unless it be designed to read accurately for low voltage, and then recourse must be had to synchronizing lamps, which is unsatisfactory because with low voltage the lamps seldom show more than a dull glow. For this reason many stations are provided with a low reading voltmeter in conjunction with the regular instrument. It is, of course, possible to use a voltmeter having a wide range, but such instruments are not so dead beat or so generally satisfactory as those designed to read only over a limited portion of the scale.

Inherent drawbacks in synchronizing by means of lamps are the lag of the light behind the voltage and the uncertainty as to when the lamp reaches its maximum brightness, or if connected up the other way, the lack of indication of perfect synchronism. This latter defect makes it impossible to guard against "short phases." Moreover, a minute or two of flickering light affects the eye so that it cannot readily detect the difference of intensity due to a difference of four or five volts. Switching in on "short phases" is to be avoided, since at best it results in a wrench, and unless the machines are designed to pull in it may easily cause more or less damage. The fault of lagging is not alone confined to the lamps; voltmeters possess it in varying degree. The lag in the voltmeter is of course occasioned by the inertia of the moving parts and also by the damping arrangement. This is manifested in the kick caused by a "quick phase," which results in the momentary indication of a much higher voltage than exists across the terminals of the voltmeter. With a "slow phase" no kick is noticeable and allowance must be made only for the lag of the instrument, which is, of course, a variable quantity depending on the rapidity of the phase.

A strong element of uncertainty is also present in what are commonly known as "standing phases." If the needle slowly drops a volt or two and then comes up again, the switch may be thrown in with safety; but when the needle stands still with perhaps a little quiver, it is risky, as the "phase" may be going back but not be immediately indicated owing to the inertia of the moving parts. Throwing in the switch too late is always worse than throwing it in too early. In the latter case the mechanical action between the machines acts in the same direction as the engine which is bringing them into phase; but in a late "shot" the action is opposed to that of the engine, the motoring current of the fresh machine tending to pull it back into step while the engine is doing its best to pull it farther out of step.

It would seem that the difficulties referred to above might readily be disposed of by means of some form of automatic switching device which would entirely eliminate the personal factor. A differential relay with the two windings supplied from the synchronizing transformers could doubtless be adapted to cause the closure of an electromagnetic switch at the proper moment, reducing the work of an attendant to the mere preparation of the switch and plugging in of the phasing or synchronizing relay. It is true that the inertia of the moving parts of both the relay and the switch might complicate the matter somewhat, but the elements of uncertainty and danger thus introduced would be insignificant in comparison with those inherent in the present rather clumsy methods.

The Rating and Speed of Dynamos and Motors.

The fact that a machine of a given size has one rating and speed as a dynamo and a totally different rating and speed as a motor always appears to the average student to be inconsistent. The explanation is simple enough. The discrepancy in both rating and speed is due principally to the fact that a given machine is operated at a higher voltage as a dynamo than when it runs as a motor. As the speed is almost exactly proportional to the voltage, it will be lower for the motor than for the dynamo; and as the output is directly proportional to the speed, lowering the latter reduces the former. The current-carrying capacity of the machine is practically fixed, regardless of its armature speed; therefore the loss in output due to lower voltage (or the resultant lower speed) when a dynamo runs as a motor cannot be compensated by increasing the current passed through its windings.

For example, a 10-k.w. 125-volt dynamo will have a current capacity of 80 amperes, plus the shunt field current, say 83 amperes total. Assume that its speed is 1300 r.p.m. and its armature resistance 0.06 ohm; the drop in the armature will be $0.06 \times 83 = 4.98$ volts, so that the total e.m.f. generated will be 130 volts, or 0.1 volt per r.p.m. Now if the same machine be put out on the circuit as a motor, under an impressed e.m.f. of, say, 115 volts, the field strength will be about the same as before, as there is no rheostat in the field circuit, and when running at full load the drop of practically 5 volts in the armature leaves only 110 volts of the impressed e.m.f. to be balanced by counter e.m.f.; the speed therefore will be 1100 r.p.m. instead of 1300. The machine will receive from the line 86 amperes (3 in the shunt field winding and 83 in the armature) at 115 volts, or 9.89 kilowatts, and if it has 88 per cent efficiency, it will deliver the mechanical equivalent of 8.7 kilowatts at the pulley. Its ability as a motor therefore would be a trifle over 11 2/3 horse-power. This rough example shows why the speed of a machine is always lower as a motor than as a dynamo, when operated on a given circuit, and why its power-delivering ability is also less when operated as a motor than when it works as a dynamo.

THE CONSTRUCTION OF AN ELECTRODYNAMOMETER.

BY S. M. KINTNER.

One of the best ways to learn about a piece of apparatus is to attempt to build it. This is particularly true of student work where the student has not been doing experimental work for a sufficient length of time to have acquired the habit of examining carefully the instruments with which he works. With this idea in mind it has been the custom at the Western University of Pennsylvania to have students design and build pieces of apparatus which would not only be a great help to themselves, but would supply the laboratory with a set of permanent instruments that could be used in the earlier and rougher work of the student's course, thus saving a great amount of rough usage of the better class of instruments.

It is my experience that students are much more careful in handling the better class of instruments after they have had the practical experience of adjusting instruments of their own make. It shows them the necessity of delicate mountings for accurate work and also the readiness with which such instruments get out of adjustment.

The instruments built this year are electrodynamometers, all of the same general design, but intended for different ranges of current. Ease of construction and repair, as well as sensibility, were points upon which special stress was laid. The accompanying sketches will illustrate how well the first two points were carried out and a test of the instrument given below will show the sensibility. The main frame *F*, and the base, *B*, were made of maple fastened together by glueing and in addition having large screws run up through the base into the uprights, *F*. This gives a very rigid construction. The cross piece, *O*, has a mercury cup for the end, *K*, of the movable coil, *M*. This cross piece, the two clamping strips, *D*, and the core, *E*, complete the list of wooden parts. The other terminal of the movable coil, *M*, dips into a mercury cup in the base of the instrument, at *R*. Each of the mercury cups is made by boring a hole halfway through the wood. These holes are connected by wires to the terminals *T*, *T*. The fixed coil, *I*, is held in place on its core, *E*, by two wooden pieces bolted against the sides of the core, *E*; the desired number of turns being wound in between the clamp pieces. After winding, the coil is boiled in paraffine wax and allowed to cool in it; afterward the wax is cut away with a knife, leaving the coil in its permanent form. As a precaution, thread is usually wound around the coil through holes bored in the core, *E*, in order to insure the coil against unwinding should it become too hot. The terminals of the fixed coil are connected to two binding posts on the other side of the instrument, in a similar position to those shown in Fig. 1; one of these shows in Fig. 2.

The movable coil is made by cutting out a block of wood of the required form and then winding on that the desired number of turns. This coil is readily held in shape by shellac varnish; after the first layer of varnish dries a thread is wound around the coil in the form of a lacing, then another coat of varnish is applied. The top of this coil is clamped by two pieces of hard rubber with a notch cut out to fit the coil. This hard rubber also holds a brass piece which is bent to the shape of a letter U on its side. The brass is attached to the rubber at the point, *V*, by small brass screws which also hold the two pieces of hard rubber together. On the upper side of the U-shaped brass piece, back of the pointer, *P*, is a small piece of 3/16-in. brass rod soldered to the U and having a small hole just large enough to take a small sewing needle, shown at *N*. This small brass rod has a screw secured to its side to which is attached the lower end of the torsion spring. The upper end of the spring is fastened by a small screw tapped into the lower end of the torsion head, *H*. The needle, *N*, is the bearing point and it fits into a small hardened steel hollow cone, *C*, the cone being supported by the brass piece shown. The milled head torsion screw, *H*, is turned from a piece of 1-in. brass rod and has a section in the lower part of ⅝ inch that carries two collars and is of sufficient length in addition to pass through the dial plate, *Z*. One of the collars, *W* (Fig. 1), is simply to clamp the torsion head in place. A leather washer is placed between the collar and the dial plate, *Z*, to increase the friction and at the same time give a certain amount of elasticity to the movement.

The upper collar carries the torsion head pointer, *J*, and is clamped to the torsion head in any desired position by the screw, *A*. A small brass screw with its head cut off, as shown at *G*, makes a good zero stop. Two other small screws at *Y* keep the pointer, *P*, which is attached to the movable coil, from shifting too far.

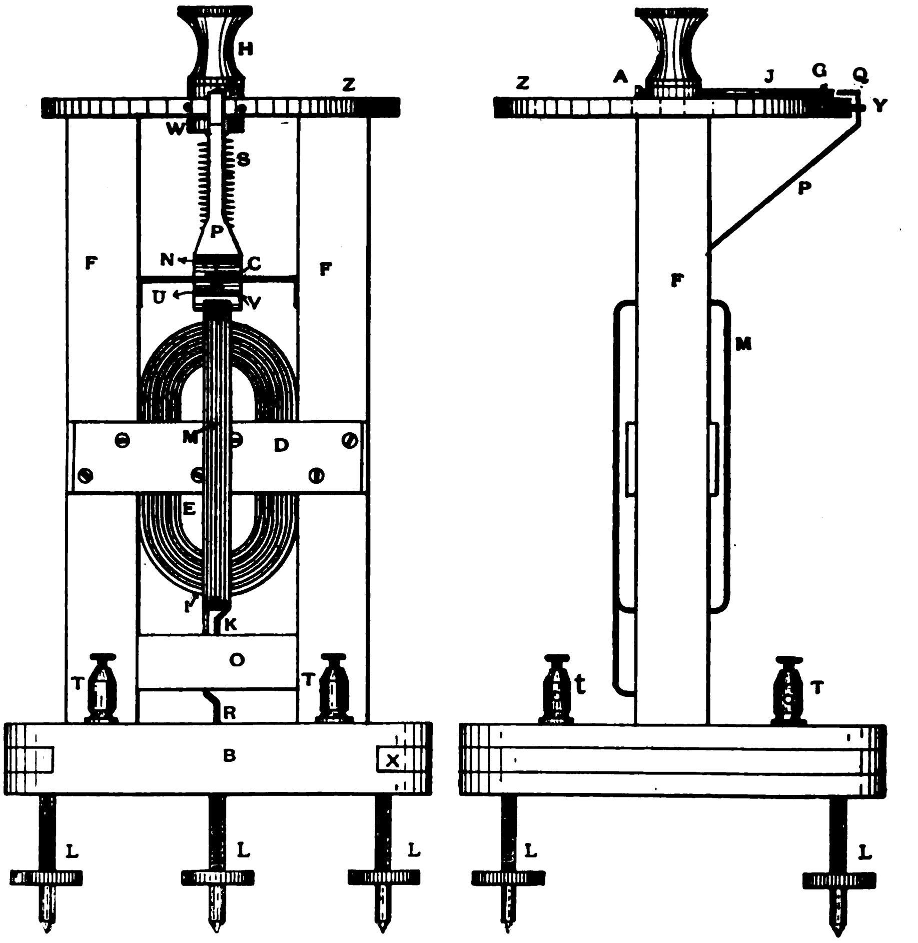

FIG. 1.—FRONT AND SIDE ELEVATIONS OF ELECTRODYNAMOMETER.—FIG. 2.

The dial, *Z*, is made of hard rubber and divided on a milling machine into 360 equal divisions. This hard rubber disc is held in place by two screws passing down through it into the two uprights, *F*, *F*. Three leveling screws, *L*, *L*, *L*, at the bottom complete the instrument. These screws are made by taking ¼-in. brass rod and cutting a cone on one end and a thread on the other. Brass discs are then cut out and soldered on the rods, after which the screws are finished in a lathe.

After assembling the instrument and adjusting all parts until everything looks all right, it is necessary to test for the zero position of the movable coil. The two coils must be at right angles to each other. In order to determine when they are accurately at right angles the following test must be made. The movable coil is short-circuited and an alternating current sent through the fixed coil. As the movable coil will tend to arrange itself in the position of least work, it will tend to turn until its plane is parallel with the lines of magnetism produced by the fixed coil, so that it will enclose no lines of force. This position will be at right angles to the fixed coil and the motion of the movable coil as it attempts to adjust itself will indicate the direction that the torsion head must be turned to bring the coil to the desired position. After a few trials this zero position can be located and the pointer of the movable coil is then fixed so that it indicates zero when the pointer of the torsion head also indicates zero, the instrument being previously leveled.

The following table shows the result of a determination of the constant of the instrument. The comparison was made with a Weston direct-current ammeter having a range of 15 amperes.

Current in amperes.	Deflection, degrees.	Constant of dynamometer.	Difference between const. and average constant.	Per cent variation of constant from average.
1.25	17	.30316	−.00007	.000231
2	43.5	.30350	+.00027	.000890
3	98	.30307	−.00016	.000527
4	174	.30325	+.00002	.000066
5	270	.30430	+.00107	.003529
5.7	356	.30210	−.00113	.003726
Average.........		.30323		.001494

The above values show a close agreement for the constant. The fourth column shows the difference between the average constant and the constant calculated from that particular reading. The fifth column shows the percentage of variation of the constant from the average. The average percentage of variation is a trifle more than 1/7 of one per cent and the maximum variation is less than 2/5 of one per cent. At the time of this test the instrument had been in regular use for over a month and it was tested for the above values without any polishing up of the needle point. This instrument was built for a total cost to the laboratory of less than $1.

COMMON BATTERY TELEPHONE SYSTEMS.

BY W. S. HENRY.

The previous article described the connections of some of the prominent "independent" systems; the present article deals with the system used by the Bell Company. Fig 10 shows the arrangement employed by the Bell Company in its recent common battery systems. The bell, E, should be of high resistance and impedance. It is usually wound to have a resistance of 1000 ohms and the condenser, C, has a capacity of about two microfarads. Enough of the switchboard connections are drawn in this figure to show how the subscriber can call up the switchboard operator and also how the operator can call up the subscriber. When the receiver is on the hook, the contacts, *m* and *n*, are open, and the only path for a current from the battery, B, is through the relay, the sleeve spring of the jack, line 1, the bell, E, the condenser, C, line 2 and the tip spring of the jack. No steady current can flow from the battery, B, through the circuit that has just been traced on account of the condenser, C. However, if the receiver is removed from the hook, enough current can flow from the battery through the relay, line 1, the induction coil primary, the contact, *m*, the hook switch, H; transmitter, T, and line 2, back to the battery to operate the relay. This causes the relay to close a local circuit containing the signal lamp. The lighting up of the lamp notifies the operator that the subscriber desires attention. Hence all the subscriber has to do to call up the switchboard operator is to remove the receiver from the hook, and when the operator answers, to give the number of the other subscriber with whom communication is desired. An annunciator could be used in place of the lamp if desirable. This arrangement of a relay and signal lamp in a local circuit assures the proper operation of the signal so long as the line and subscriber's telephone, when the receiver is removed from the hook, do not offer so high a resistance as to prevent the relay from attracting its armature and so closing the local circuit containing the signal lamps.

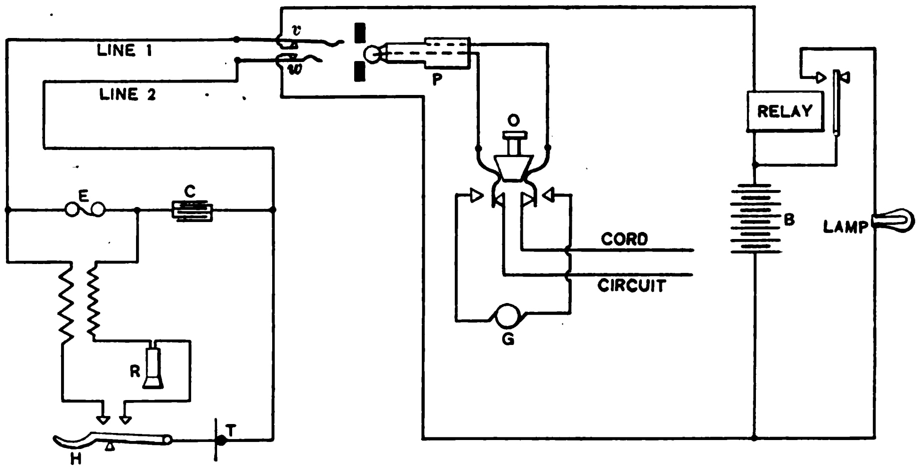

FIG. 10.—COMMON BATTERY SYSTEM OF THE BELL COMPANY.

Suppose that the receiver is hanging on the hook and the operator desires to ring up the subscriber. The operator will insert the calling plug, P, in the jack, thereby lifting the sleeve and tip springs from the contacts, *v* and *w*, and so cutting out the relay circuit. Then by depressing the ringing key, O, the alternating-current generator, G, is connected across the two line wires. This alternating current can flow through the condenser, C, and hence it causes the bell, E, to ring. The path of this current may be traced from G through the sleeve of the plug, P, line 1, bell, E, condenser, C, line 2, the tip of the plug, P, and back to the generator, G.

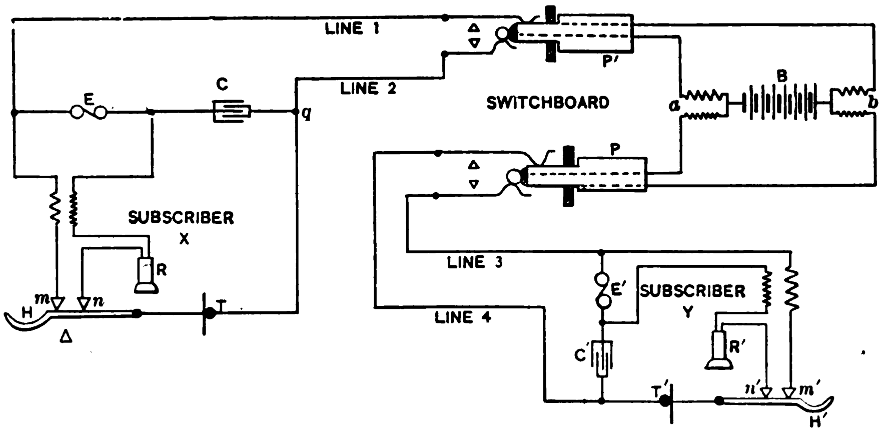

FIG. 11.—DIAGRAM OF CONNECTIONS BETWEEN TWO SUBSCRIBERS.

Suppose that the operator has rung up the subscriber desired by the original calling subscriber and released her listening and ringing keys; then the two subscribers will be connected practically as shown in Fig. 11. When both receivers are removed from their hooks, the contact points, *m* and *n*, make connection with the hook switch, H, and the contacts, *m'* and *n'*, with the hook switch, H'. This connects the transmitter and the primary winding of the induction coil across the two line wires at each station. As explained in connection with the Hayes common battery method in a previous article, the battery, B, supplies current for both of the transmitters, T and T'; the steady current from the battery passes only through the transmitter and the primary winding at each station. To be sure, there is a closed path between the two line wires through the bell, E, the secondary winding of the induction coil, the receiver, R, and the transmitter, T; but the bell magnet, E, has such a very high resistance compared with the resistance of the induction coil primary that only an insignificant amount can flow through it. Nevertheless, the receiver should be connected in this circuit so that this current in circulating around the receiver winding, although it is very small indeed, may tend to help and not oppose the magnetism of the permanent magnet.

The variation produced in the resistance of the transmitter by talking into it transforms the steady current into a fluctuating current that affects the distant receiver in a manner that will be explained. When the receiver is off the hook the latter closes not only the circuit containing the induction coil primary winding and the transmitter but it also connects the primary and secondary windings together at the contact points, *m* and *n*. Starting from the point, q, Fig. 11, there are three circuits to the line 1; one through the condenser, C, and the bell, E; another through the condenser, C, induction coil secondary, receiver, R, and induction coil primary; and the third through the transmitter, T, and the primary winding. It will also be noticed that the transmitter, T, receiver, R, secondary winding, and condenser, C, form a circuit by themselves.

In the induction coil used by the Bell Telephone Company the primary has 2600 turns of No. 24 B. & S. copper wire, and a resistance of 15 ohms, and the secondary has 1300 turns of No. 33 wire and a resistance of 30 ohms. The secondary is wound next to the iron core and the primary is wound over the secondary. The secondary and primary are so wound and connected that a current through the two in series will be flowing in opposite directions around the iron core and therefore the current in the primary winding will partly neutralize the magnetizing effect of the current in the secondary. Consequently, the induction coil does not tend to choke back an alternating current that flows through both coils in series, except in so far as one of the coils, having more turns than the other, is able, with the same current, to magnetize the iron core somewhat. The winding having the larger number of ampere-turns will, of course, have the greater magnetizing effect.

With the hook switches in the position shown in Fig. 11, the battery, B, supplies a direct current for both transmitters. As the resistance of the transmitter, T, is varied by talking into it, the steady current is changed into a fluctuating current. The fluctuations thus produced by the transmitter act on the repeating coil, *a*, *b*, at the central office, and produce in the other line circuit a fluctuating current that actuates the distant receiver, R′.

The talking currents originating at the distant subscriber's station will come over line 1 and pass through the induction coil primary. At the contact, *m*, it will divide; part of it flowing around through the transmitter, T, and part through the receiver, R, the induction coil secondary, and the condenser, C, reuniting at the point, *q*, with the portion that went through the transmitter. The entire current then returns over line 2, to the central office. The condenser, C, neutralizes more or less of the induction of the receiver and the secondary coil, and therefore the impedance of the circuit, *m*, *R*, secondary, *C*, *q*, is probably not much greater than its resistance. Consequently, the choking effect of the circuit just traced is probably very small and negligible.

Such a part of the talking current through the induction coil primary as may flow through the transmitter instead of through the receiver circuit will induce an electromotive force in the secondary winding that will cause an alternating current to flow through the circuit including the receiver, condenser and transmitter. This induced current is in unison with that part of the current from the main line that flows through the receiver circuit. The combined effect of these two currents is sufficient to properly affect the receiver, R. The bell, E, which is wound to have a resistance of 1000 ohms, offers such a high impedance to the rapidly fluctuating talking current on account of its high inductance, that these currents cannot pass through it.

◆

CORLISS VALVE GEAR AND VALVE SETTING.

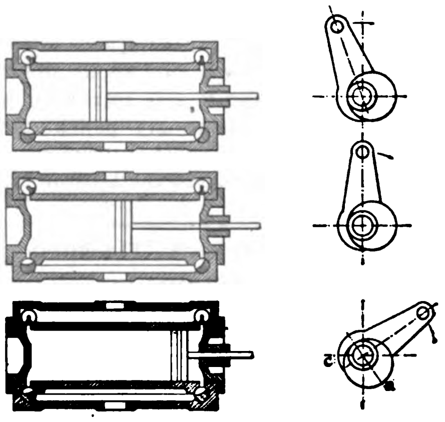
BY C. C. MAJOR.

Owing to the large percentage of power developed by the Corliss engine and its wide introduction in every line of work where economy and close regulation are of any consideration, it is essential that the engineer should understand its operation and especially its valve mechanism and adjustment. The most interesting and important part of a Corliss engine is the releasing mechanism invented by George H. Corliss in 1849. F. E. Sickles patented a drop cut-off in 1841, but as the invention of the steam engine is associated with the name of James Watt, although steam engines were built and operated before Watt's time; so the drop cut-off is most closely associated with the name of Corliss, though Sickles' patent appeared several years earlier.

Just before the appearance of the Corliss engine there was a widespread demand for an engine of superior economy and closer regulation, and as the Corliss filled these requirements to a remarkable degree, its introduction was rapid and it has maintained a commanding position for half a century and probably will not be excelled in simplicity and economy for many years to come.

The valves are four in number, two steam and two exhaust, located at the ends of the cylinder and designed to give maximum port opening with minimum clearance spaces. They usually consist of portions of cylinders oscillating within cylindrical valve-seats. The valve stems are usually of the T form and fit into slotted heads in the valves. This construction allows the valves to be removed without disturbing the stems, upon the removal of the back bonnets. Previous to about 1886 only one wrist-plate and eccentric were used, and as the single eccentric engine is limited to about one-third cut-off, it is not practical to submit these engines to heavy overloads even for short periods of time. Builders first began placing the double eccentric on the low-pressure cylinders only of compound engines, and when the engine was subjected to a heavy load, the receiver was soon emptied, as the restricted cut-off of the high-pressure cylinder allowed only a limited supply of steam to pass through. Builders now equip these engines with single or double eccentrics on both high and low-pressure cylinders, as the purchaser may desire.

The advantage of the double eccentric may be seen by noting the limitation of the single eccentric, as illustrated in Figs. 1, 2 and 3. The ratio of crank length to connecting rod is 1 to 5. Fig. 1 shows the relative positions of valves, piston, crank and eccentric, the eccentric having an angular advance of twenty degrees. The engine is turning in the direction indicated by the arrow and the eccentric has reached the dead center farthest from the cylinder giving maximum port opening as shown at the upper left-hand corner. The valve must be released now or it will not be released at all during the stroke, as the eccentric will change the direction of travel of the wrist-plate and cause the inner member, *H*, of the hook, *K*, Fig. 7, to move away from the knock-off cam, *M*; hence Fig. 1 shows the percentage of stroke traveled by the piston at the point of latest cut-off. Later cut-off can be secured by giving the steam valves a smaller amount of lap, but as the lap is as small as possible without incurring leakage, some other means must be employed. If the angular advance in Fig. 1 were made less, the exhaust valve at the lower right-hand corner would close later in the stroke and the amount of compression would be correspondingly decreased. However, the exhaust valves may be made to close at the proper point in the stroke when the angular advance has been reduced, by adjusting the exhaust-valve rods, *E*, Fig. 4.



FIGS. 1, 2 AND 3.—POSITIONS OF PISTON, VALVES, CRANK AND ECCENTRIC IN SINGLE ECCENTRIC ENGINE.

Fig. 2 shows an engine so adjusted. The eccentric is on the dead center farthest from the cylinder and the steam port has attained full opening as before, but the exhaust valve has not given full port opening, thus interfering with the discharge of the exhaust steam. Since the later point of cut-off as shown in Fig. 2 has allowed an increased amount of steam to enter the cylinder with reduced exhaust passage for its discharge, the back pressure will be increased and compression will be excessive. Fig. 3 shows the exhaust valve at the point of closing the port while the eccentric still has to travel from *a* to *c*. This large travel will give an unnecessary amount of lap to the valve and cause it to open late and prevent a full opening. The effect of shortening the rod, *E*, Fig. 4, is to make the rod and the valve crank approach more nearly to a straight line and thus reduce the travel of the valve for a corresponding travel of the wrist-plate. This trouble is obviated by the use of two eccentrics, as the steam and exhaust valves are operated independently and any desired cut-off may be obtained without interfering with the functions of the exhaust valves.

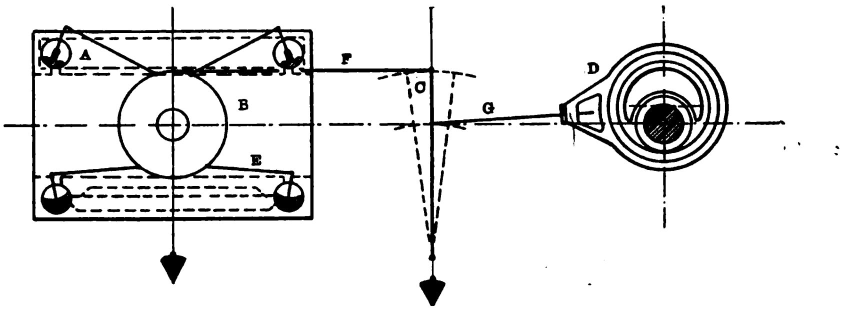


FIG. 4.—RELATIVE POSITIONS OF VALVES, WRIST PLATE, ROCKER-ARM AND ECCENTRIC.

Fig. 5 represents the wrist-plate and stud of a Corliss engine. On the wrist-plate hub will be found the mark, *a*, and on the stud the marks, *b*, *c* and *d*. When the wrist-plate is vertical, the marks, *a* and *b* will coincide, and *c* and *d* represent the amount of travel each side of the vertical. To adjust the reach-rod, *F*, and the eccentric-rod, *G*, Fig. 4, place the wrist-plate vertical, then lengthen or shorten the rod, *F*, until the rocker-arm, *C*, is vertical as shown. Turn the eccentric on the shaft to the center nearest the cylinder and note if the marks, *a* and *c*, Fig. 5, coincide. Adjust the eccentric-rod, *G*, until these marks come precisely opposite each other at the extreme points of travel of the wrist-plate.

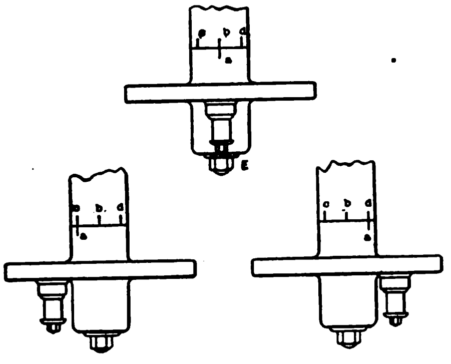

FIG. 5.—WRIST PLATE AND STUD.

If the marks above referred to are not on the stud and the wrist-plate hub, they may be made as follows: Place the wrist-plate vertical with the aid of a plumb-bob. With a chisel make the marks, *a* and *b*, on top of the hub and stud. Move the eccentric to the center nearest the cylinder and make the mark, *c*, very lightly, in line with *a*, then move the eccentric to the opposite center and make the mark *d*. With a pair of dividers measure the distances from *b* to *c* and from *b* to *d*, if they are equal, the marks *c* and *d* should be made permanent; if not, adjust either rod, *F* or *G*, Fig. 4, until they are equal.

To square the valves, that is to give them an equal amount of lap, place the wrist-plate vertical, slacken the nut, *E*, Fig. 5, and place a piece of cardboard between the washer and stud to hold the wrist-plate in position. Hook up the valves by hand and remove the back bonnets. On the valve will be seen a mark which is in line with the edge of the valve face and a similar mark on the valve-seat indicates the edge of the port. The proper amount of lap is found by consulting tables furnished by the builders, and this lap is secured by adjusting the radial rods, *A* and *E*, Fig. 4. This sketch shows the relative positions of valves, wrist-plate, rocker-arm and eccentric.

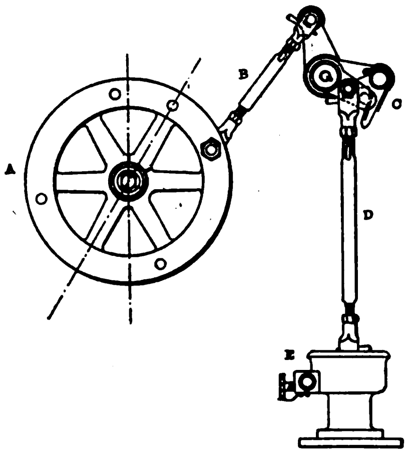

FIG. 6.—TRIP GEAR AND DASH-POT.

When the proper amount of steam and exhaust lap has been secured, the dash-pot rod needs attention. If the rod, *D*, Fig. 6, is too long, the closing shoulder on the hook will come in contact with the hook-block before the wrist-plate has reached the end of its travel and either buckle the rod or break the valve crank. If the rod is too short, the hook will not engage the block and the valve will not be opened. With the dash-pot plunger on its seat and the wrist-plate at its extreme point of travel so that marks *a* and *c* or *a* and *d*, Fig. 5, coincide, adjust the dash-pot rod so that the catch-block, *C*, will have an equal amount of clearance between the die-plate, *D*, and the closing shoulder, *E*, Fig. 7.

To set the eccentric, place the crank on the dead-center nearest the cylinder, hook up the head end steam valve and turn the eccentric on the shaft in the direction the engine is to run till the valve shows the proper amount of lead. Secure the eccentric in this position and turn the engine over to the opposite center and note if the lead is the same. If the work has been done carefully, the lead will probably be the same, but if there is a slight difference, the rods, *A*, Fig. 4, may be adjusted to secure the same amount for each valve.

In setting the exhaust valves for compression, it is difficult to tell at just what point in the stroke the valves should close to give the desired amount of compression. Assuming that the point of closure should be within two inches of the end of the stroke, measure two inches from the end of the cross-head guides and turn the engine in the direction it is to run till the cross-head is in line with the mark on the guides, then adjust the exhaust-valve rod to bring the edge of the valve in line with the edge of the port. The other exhaust-valve should be treated in a similar manner.

The next operation is to adjust the governor to produce equal points of cut-off in the stroke, or rather to allow the same amount of work to be done on each side of the piston. As nearly all Corliss engines are provided with a safety-stop in connection with the governor, it may be well to explain at least one type. Fig. 8 shows the Barclay stop with which the experimental engine at Sibley College, Cornell University, is equipped. This stop consists of a Bourdon tube, similar to that used in a steam gauge, and mounted on the side of the governor shaft. The lower end of the tube is connected to the pipe, *E*, leading to the steam chest of the engine, while the upper end is connected to the finger, *F*, through the link, *M*. When the admission valve is closed and there is no pressure in the tube, the finger will stand vertical holding up the governor by means of the block, *A*, and keeping the knock-off cams in position for latest cut-off,

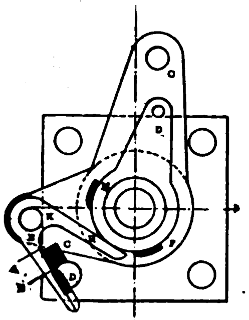

FIG. 7.

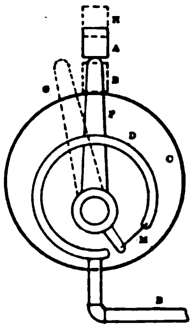

FIG. 8.

which is the most favorable position for starting. It requires from 40 to 50 pounds steam pressure to move the finger so that it will no longer support the block, and this pressure is sufficient to bring the engine up to speed and raise the block to some position such as that indicated at *H*.

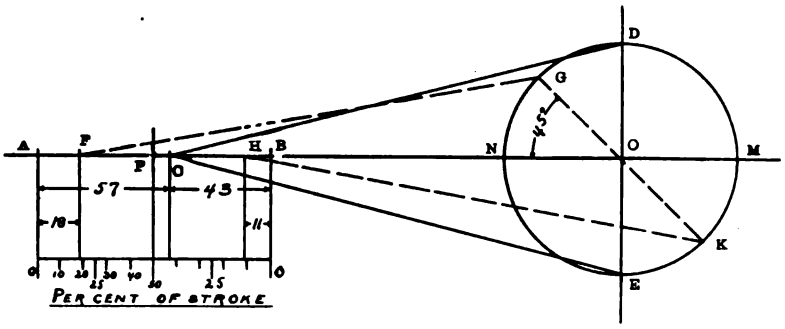

FIG. 9.—DIAGRAM SHOWING EFFECT OF CONNECTING ROD ANGULARITY.

While running under normal conditions the finger will assume the position, *G*, shown in dotted lines where it will remain until steam is shut off. If the governor belt breaks, the governor will fall until the block assumes the position, *B*, and the safety cam, *F*, Fig. 7, will be moved forward under the inner member of the hook, *H*, and throw the hook out so that the die-plate, *D*, will not engage the block, *C*. This will prevent the opening of the valve and the engine will shut down. This stop is perfectly automatic and the safety device does not depend on the memory of the engineer, which is the objection to many safety-stops otherwise quite satisfactory.

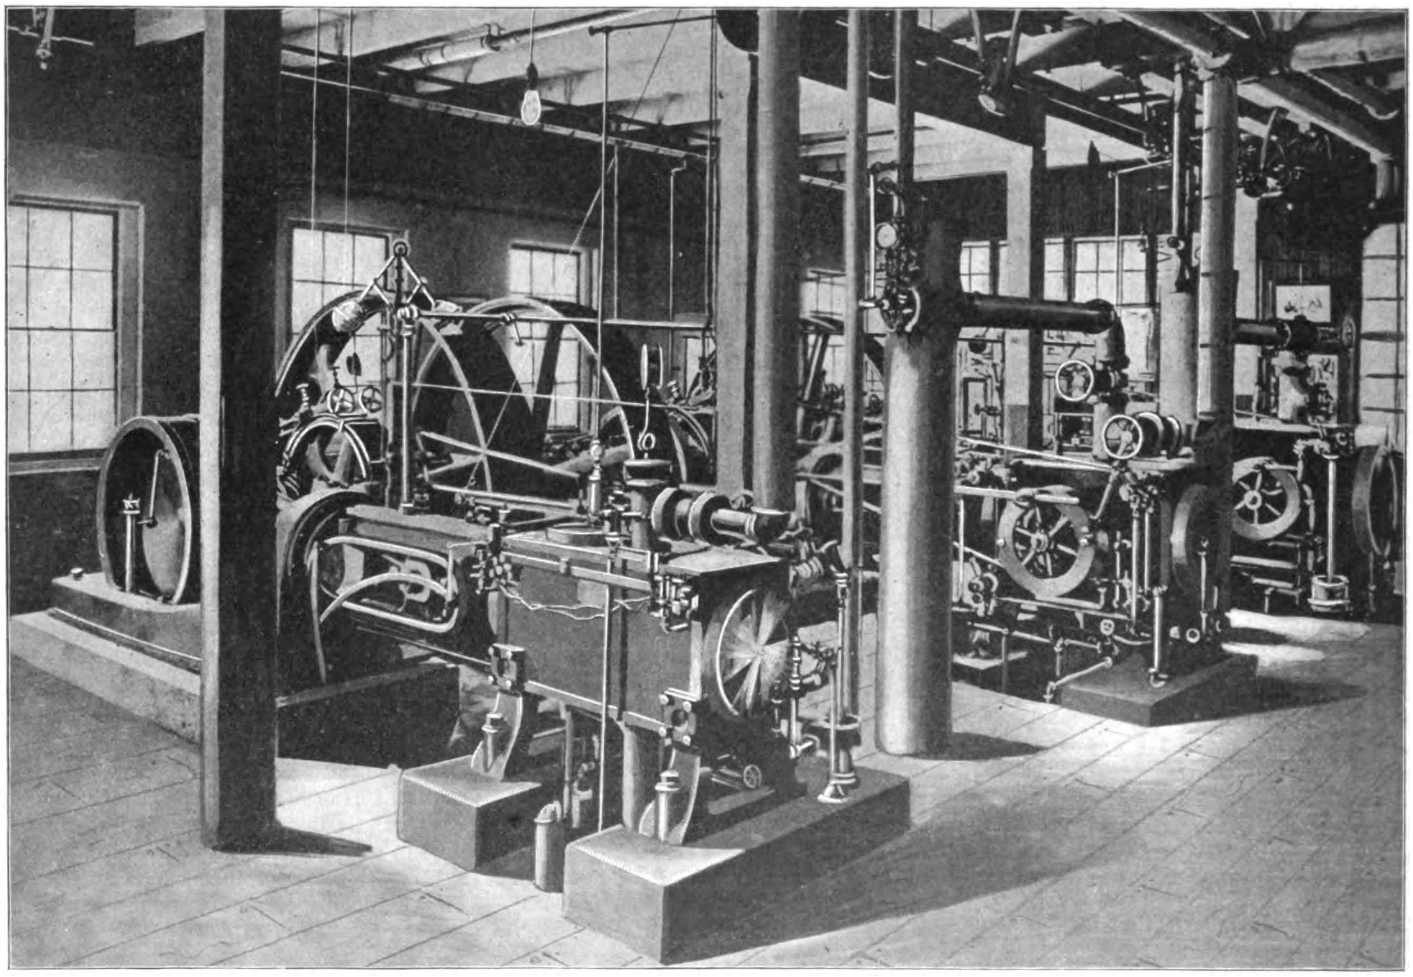

FIG. 10.—EXPERIMENTAL TRIPLE-EXPANSION ENGINE AT SIBLEY COLLEGE, CORNELL UNIVERSITY.

As the stop determines the lowest position of the governor in which the valves should hook up, place the governor on the stop, unhook the wrist-plate and with the hand-bar move the wrist-plate until the lines, *a* and *c*, Fig. 5, nearly coincide. Adjust the head-end governor-rod till the knock-off cam comes in contact with the inner member of the hook so that the valve will be released when *a* and *c* are actually in line. This operation should not be repeated for the crank end owing to the effect of the angularity of the connecting-rod. The effect of angularity is illustrated in Fig. 9. Let *A B* represent the travel of the cross-head and also of the piston, and the circle, *G M E*, the path of the crank-pin. Assume the crank to be on the center nearest the cylinder, as, *O N*; the distance, *A N*, will be the length of the connecting-rod. When the crank travels one-fourth of a revolution, from *N* to *D*, the cross-head will be at *C* or about 57 per cent of its stroke. During the second quarter revolution of the crank, the cross-head will complete its stroke and will move from *C* to *B*, or about 43 per cent of its stroke.

During the return stroke these steps are reversed, hence during the first and fourth quarter revolution of the crank-pin, the cross-head and piston travel farther than they do during the second and third quarters. Assume that cut-off occurs when the crank-pin has made one-eighth of a revolution and is at *G*; the cross-head will have travelled the distance, *A F*. On the return stroke when the crank has gone the same distance and is at *K*, the cross-head will have travelled the distance, *B H*, which is considerably less than *A F*. Under these conditions the head end will do the greater part of the work and the rotative effect given to the belt wheel will not be uniform and the regulation will be correspondingly imperfect.

To correct for the angularity of the connecting-rod when adjusting the cut-off on the crank end, block the governor up to any convenient height and turn the engine over in its direction of travel until the head end valve is released. Measure the travel of the cross-head on the guides and lay off the same distance from the other end of the guides. Turn the engine over till the cross-head is nearly to this mark and adjust the crank end governor-rod so that the valve will be released when the cross-head is even with the mark. This adjustment corrects for angularity and will give equal cut-off at each end of the cylinder, but since the area of the piston-rod diminishes the effective area of the piston on the crank side, the cut-off on that end should be a trifle later to give equal amounts of work done on both sides of the piston. An accurate and final adjustment can only be made by the aid of an indicator.

LAPS, LEADS AND TRIAL COMPRESSIONS.

Diameter of Cylinder.	Wrist Plate Central Position. Lap of Stm. Valve.	Wrist Plate Central Position. Lap of Ex. Valve.	Crank on Dead Center. Lead of Stm. Valve.	Trial Compression.
8	3/16	1/32	1/32	1½
10	3/16	1/32	1/32	1¾
12	3/16	1/32	1/32	1⅞
14	¼	1/16	1/32	2

18	¼	1/16	1/32	2¼
20	¼	1/16	1/32	2¼
22	5/16	3/32	3/64	2½
24	5/16	3/32	3/64	2½
26	5/16	3/32	3/64	2¾
28	5/16	3/32	3/64	2¾
30	5/16	3/32	3/64	3
32	⅜	⅛	1/16	3
34	⅜	⅛	1/16	3¼
36	⅜	⅛	1/16	3¼

A table of laps and leads and trial compressions for engines of various sizes is given herewith and will be found convenient by engineers in charge of Corliss engines.

Fig. 10 shows the experimental triple-expansion Corliss engine in Sibley College. This engine was built by the E. P. Allis Company, of Milwaukee, Wis., from plans prepared by Dr. R. H. Thurston and Mr. Ed. Reynolds, Superintendent for the Allis Company. The main shaft is in three sections, so that the engine may be run simple, compound or triple expansion, with a proper arrangement of the valves in the system of piping shown by Fig. 11. The cylinders and receivers are shown in the center of the engraving, and the piping is so arranged that boiler steam may be admitted to any cylinder. Any one may be run alone or in combination with either of the other cylinders. Both cylinders and receivers are jacketed, and the amount of jacket steam used by each can be determined by means of the traps shown at the bottom of the diagram. The engine is used entirely for experimental purposes.

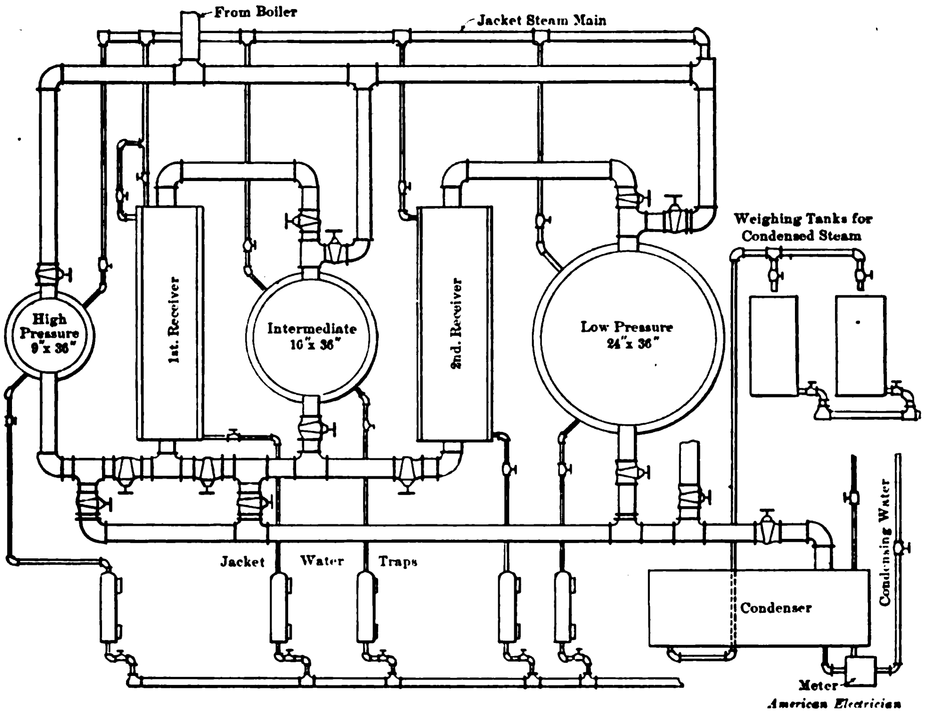

FIG. 11.—PIPING SYSTEM FOR THE EXPERIMENTAL ENGINE AT CORNELL UNIVERSITY.

RAILWAY CAR NOTES.

BY ARTHUR B. WEEKS.

Car truck-boxes are to a street railway company what the man in charge makes them. That they are a neglected part of some systems is self-evident. The securely-fastened journal-cover, like the mantle of charity, covers a multitude of sins. But a car system can as well have good journals as poor ones, if the required care, as well as good material, be given them. Indeed, with proper watching, less care will be necessary, for there will be no hot boxes to call for constant attention. There certainly is no more important part of a street-railway system than this, for it is not merely a question of the cost of brass or babbitt, but the grease and oil bills are enormous where these journals are allowed to run in poor condition. The lubricant runs out at the far end of the box, distributing itself over the wheels and along the tracks, while the box may still run hot and grease may be stuffed in at every trip. Suitable material in the proper hands will count for much. Nor does the writer think that grease that is cheap enough for gears is good enough for truck-boxes.

Some of the old horse-car men used to say: "That old black oil was good enough for horse cars, why is it not suitable for electric cars?" And, strange as it may seem, some men have got no farther than that yet. But note the difference in the conditions—heavier cars, higher speed, greater mileage, with the tendency to even larger cars than ever. There is no possible chance for comparison.

A regular crop of hot-boxes is no credit to the man in charge. Of course, an occasional one is unavoidable. The writer calls to mind a plant where there were several makes of trucks for a system of twenty-six cars. Imagine the number of repair parts necessary, each make having a different size of journal and axle brasses, in addition to other parts of the boxes and the wheel bore. The company did not pretend to carry a stock for all, and that had its drawbacks, also; often cars were compelled to wait for a check brass, or some other trivial repair part. Journals were often badly worn into grooves and ridges, when all that was done was to put in the brass, keep a watchful eye on the hot box, from the first trip out to the last one in, and so on until it was worn out. In some cases, in overhauling trucks the brasses were found worn through lengthwise in the center, and the box itself worn nearly through. In many cases heavy cast-iron dust collars without any retaining spring had worn their way half an inch deep into the journals. With all that lost motion what was to retain grease or oil in the box? The side bars of some trucks were fallen in at the top, 2 to 3 ins. out of plumb, pedestal bolts badly worn and hanging on like ghosts of their former selves; the motor axle brasses had play enough to insert one's thumb in the opening.

As for lubricants, some prefer oil, with good felt and spring attachments; others use grease only. Others, again, use both, while many prefer wool waste and a special grease. Conditions vary to such an extent that one grease cannot be expected to meet all requirements. Either a good oil, with proper attention to the felt, spring and dust collars, or wool waste, is highly recommended. When once the proper lubricant has been secured, keep to it. A reduction in price of one or two cents per gallon or pound on oil or grease is no special recommendation for the brand; quality is what counts. There is no satisfaction in changing from one to another, or in trying everything that comes along. Grease cannot do it all, however; good brasses or babbitt-lined bearings must be used, with careful inspection. Steel shells, babbitt-lined, are very good. Babbitting jigs are essential in any street-railway shop for nearly all bearings.

One word more about wool waste: If one is not familiar with the method of packing a box with it, one should find out from the company supplying it their method of procedure. If it is a failure on first trial, it is probably due to improper packing or to the dust collars being so badly worn that the grease runs out at the farther end of the box. The trouble with felt and grease together is that the felt fills up with grease and a hard surface forms upon it, so that it will no longer feed the oil. Beware of a grease which cakes up after standing awhile, or fills the oilways solidly; it will give trouble. Then, as many have learned, the grease which gives the best service in winter is unsuitable for summer use, and *vice versa.* 'Frequently that which is best adapted to one make of motor will not answer for another style.

In summing up, I can only urge the use of good material, the maintenance of thorough and regular inspection of truck boxes, and renewal of them as often as necessary.

THE SPRAGUE MULTIPLE-UNIT SYSTEM

BY EDWARD CHILTON.

In the accompanying diagram the heavy lines indicate the wires and connections comprising the main motor circuits—that is, the circuits of the motors that drive the car; the light lines represent the wires of the control or pilot motor circuits. Ignoring for the present the pilot motor circuit, and assuming that the main controller, M, is operated by hand, the main motor circuit may be traced as follows: The current comes in at 1, passes through the fuse box or circuit-breaker, 2, thence through the magnetic blow-out coil, 3, coming out at the finger, 4; if the reverser is thrown up, the current passes to 5, thence to 6 connected to 5 (both being drum tips), and to the finger, L3; contacts 4, 5, 6 and L3 are the trolley fingers and drum tips on the reverser.

From the reverser finger, L3, the current goes over to the blow-out coil, 7, on the main controller. From the blow-out coil it passes to the resistance finger, R8; if the main controller is on the first notch, the current passes through all of the resistance coil to resistance finger, R1, and thence to the main drum tip opposite this finger. From the short drum tip, R1, it passes to the heavy tip, 8, connected to it, and thence to the finger +1 opposite the heavy tip, 8; then along the wire +1 the current passes to the reverser finger, +1. Now from the trolley shoe, 1, to the reverser finger, +1, the path, 1, 2, 3, 4, 5, 6, 7, R8, R1, 8, +1, +1, is the same whether the reverser is thrown up or down. That part of the circuit which includes the main drum and the resistance coil remains the same except that each successive controller notch brings into action a new drum tip which engages a new resistance finger and cuts out a new section of resistance.

When the main drum reaches the notch indicated by the dotted line, 00, all of the resistance coil is cut out and the path of the current from 1 to +1 is 1, 2, 3, 4, 5, 6, L3, 7, R8, 0, 8, +1, +1; 00 represents the last series notch. Now from the +1 reverser finger onward, the path of the current depends upon whether the reverser drum is thrown up or down. If it is thrown up, fingers +1, A1, AA1 and F1 engage tips 9 and 10 and fingers F2, AA2, A2 and + 2 engage tips 11 and 12. The path of the current from reverser finger + 1 is then +1, 9, A1, AA1, 10, F1, E1, E1, E1, E1, to main drum tips 0^1, +2, +2, +2, +2, 11, A2, AA2, 12, F2, throttle T, F2, and to the ground at G, and the motor armatures turn so as to move the car ahead. If, however, the reverser drum is thrown down, the fingers +1, A1, AA1 and F1 touch tips 13 and 14 and fingers F2, AA2, A2 and +2 touch fingers 15, 16, and the path of the current is +1, 13, 13, AA1, A1, 14, 14, F1, E1, E1, E1, E1, 0^1, +2, +2, +2, +2, 15, 15, AA2, A2, 16, 16, F2, T and F2 to G. The direction of flow of the current through the armatures has been reversed, so the armatures turn in a direction to move the car backward. It will be noticed that in both positions the current must pass through the throttle coil, T.

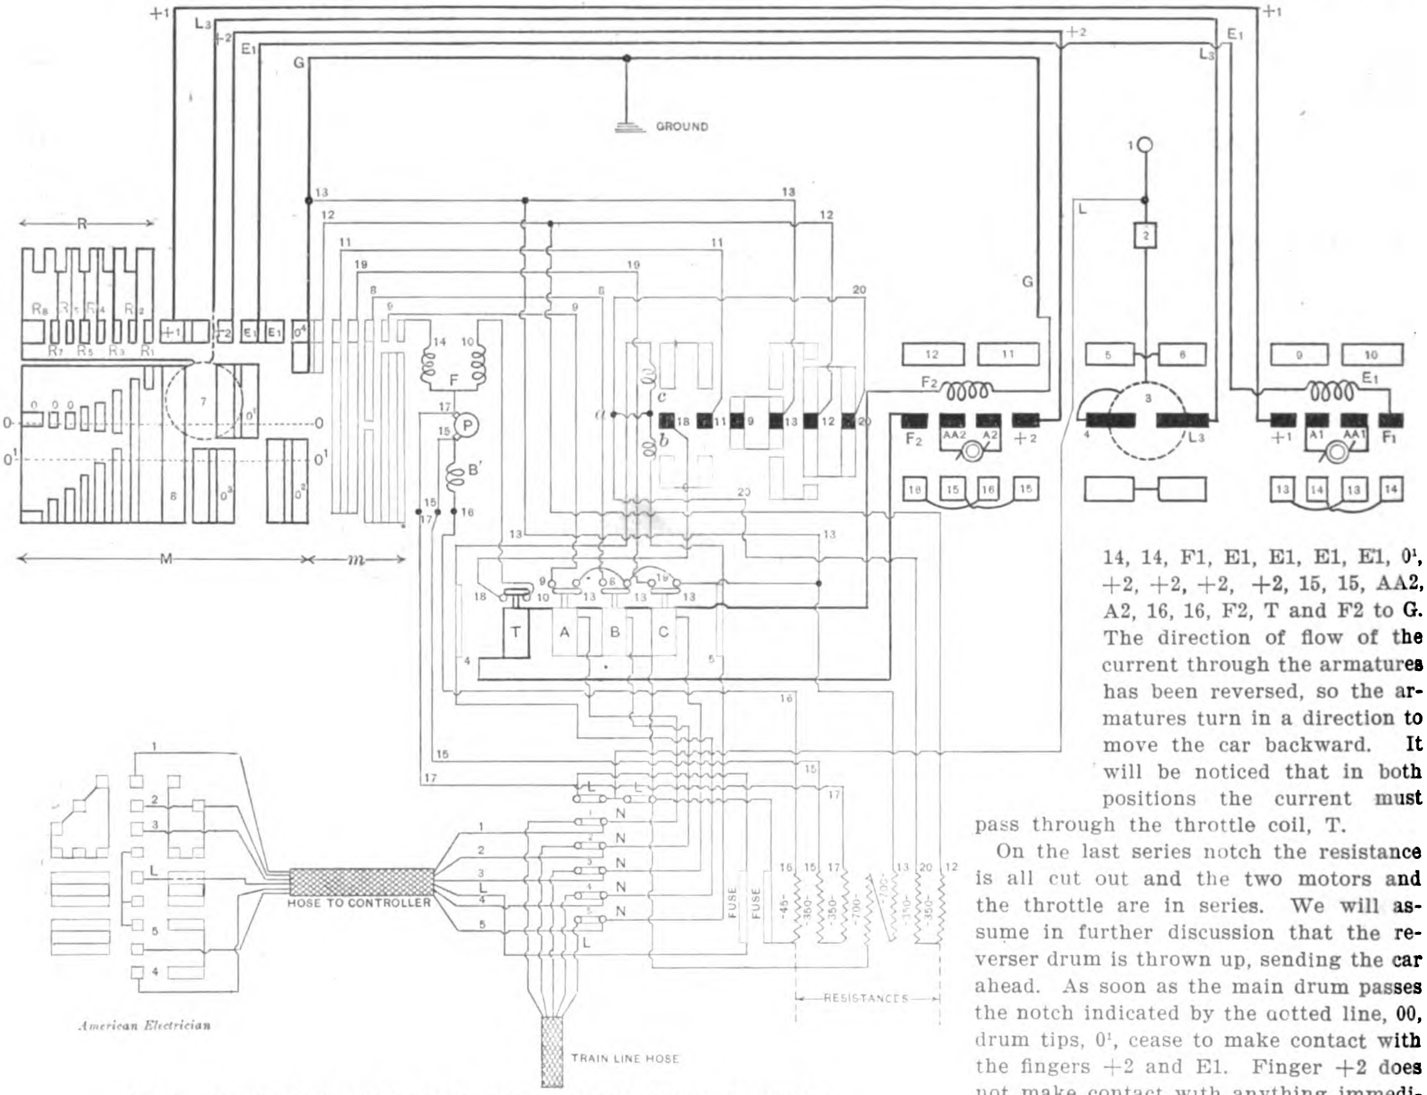

FIG. 1.—DIAGRAM OF CONNECTIONS, SPRAGUE MULTIPLE-UNIT SYSTEM.

On the last series notch the resistance is all cut out and the two motors and the throttle are in series. We will assume in further discussion that the reverser drum is thrown up, sending the car ahead. As soon as the main drum passes the notch indicated by the dotted line, 00, drum tips, 0^1, cease to make contact with the fingers +2 and E1. Finger +2 does not make contact with anything immediately after leaving tip 0^1, but finger E1 touches tip 0^2 at the same time that it touches tip 0 (E1 is a double finger), so that it makes contact with one before it leaves the other, and thereby keeps the circuit intact at that point.

Suppose that tips 0^2 and 0^3 were the same length and that both fingers, E1 and +2, hung in the air after the drum leaves the position of 00. Now remember that the finger, E1, is always the negative terminal of the No. 1 motor and that the finger, +2, is the positive terminal of the No. 2 motor. Therefore, if both of these fingers touch no contact, neither motor can get any current, and the car for the instant is entirely dead. Now, as the finger, +2, is entirely clear of any contact for a moment after leaving drum tip, 0, the No. 2 motor is cut out of circuit just that long, but the current continues to pass through the No. 1 motor by way of path 1, 2, 3, 4, 5, 6, L3, L3, 7, R8, 0, 8, +1, +1, +1, +1, 9, A1, AA1, 10, F1, E1, E1, E1, E1, 0^2 and 0^4, to G. In order to put the two motors in multiple, it is necessary first to drop at least one of them from the circuit entirely. As soon as finger + 2 touches the tip, 0^3, which is very soon after it leaves tip 0^1, motor No. 2 can get current, and the two motors are then in multiple. On the dotted line, 0_1, 0_1, which indicates the first multiple position, the path of the current from 1 to the double finger, +1, is 1, 2, 3, 4, 5, 6, L3, L3, 7, R8, R7, R6, R5, R4, R3, to the drum tip opposite the finger, R3, then to 8 and to double finger. At this double finger, +1, the current divides; part of it takes the path +1, +1, +1, +1, 9, A1, AA1, 10, F1, E1, E1, E1, E1, E1, 0^2, 0^4, G, through the No. 1 motor and the other part takes the path + 1, 0^3, + 2, + 2, + 2, + 2, 11 A2, AA2, 12, F2, T, F2, G, through motor No. 2.

It will be seen that on the first multiple notch the two motors are in multiple, but there is in series with the two all of the resistance coil included between the fingers, R3 and R8. It will also be noticed that the throttle coil, T, is in circuit with only the No. 2 motor. As the main controller drum continues to advance, the resistance fingers, R4, R5, R6, R6, and R8, come into action successively, and by degrees cut all of the resistance coil out, so that on the last main controller notch the two car motors (or four, as the case may be) are in full multiple across the line. The current path is the same as at the dotted position, $0_1 0_1$, except that the fingers, R7, R6, R5, R4 and R3 may be left out.

In the present case it is assumed that the main controller is being operated by hand, just like any other car controller, thereby eliminating the multiple-unit feature, which involves only the pilot motor and its circuit. The pilot motor simply takes the place of a man on each car. It will form the subject of a future article.

The Pan-American Exposition.—Owing to the recent storms and heavy snowfall throughout the lake regions the Pan-American Exposition will only open in an informal way on May 1; the regular full-dress exercises having been deferred until May 20.

DISPOSING OF THE WATER OF CONDENSATION.

BY C. W. OBERT.

As water of condensation accumulates in a receiver, or in the chamber of a separator, or in "pockets" in the steam piping, it will need to be drained out from time to time according to the rapidity of accumulation. When such drainage is accomplished by drain cocks simply tapped into lowest points, it requires considerable attendance and care to keep the water properly drained out, and if the condensation happens to accumulate very rapidly it may become necessary to leave the drain cocks wide open to provide against emergencies when close attention cannot be given to them owing to duties elsewhere, even though this procedure will inevitably cause a great waste of steam by its blowing out with the drainage. Some engineers in meeting this contingency have endeavored to reduce the amount of steam blown out with the drainage by connecting a pipe or hose to the drain cock and running it to the bottom of a barrel of water, and then leaving the drain cock wide open all the time. This method keeps the reservoir or "pocket" drained of water very successfully, of course, and steam will not appear to be blowing to waste, but it is very questionable whether as much or more steam does not go to waste by passing down the pipe or hose with the drainage and being condensed by the coolness of the surrounding water in the barrel, than if the drainage blew out into the open air direct.

The frequent attention required to keep the accumulating condensation drained out by repeatedly opening the drain cocks and to prevent waste of steam by not leaving the drain cocks open too long may be done away with by connecting these drain cocks to some kind of self-discharging device, such as a steam trap. An improvised steam trap is sometimes adapted after the fashion of a simple plumber's sewer trap, by connecting to the drain cock one of the ends of a long pipe bent into the shape of the letter U. Free passage through this pipe is obstructed by a water seal, produced by filling the bend to some depth with water, and then the weight of the column of water forced up by the steam pressure into the outer or open leg of the U will, if properly proportioned, balance the pressure of the steam in the inner leg. As the condensation water drains down into the bend in the steam leg it will merely mingle with the water in the bend, increasing its volume and thus increasing the height of the water column in the open leg until it runs over and flows to waste. This is a very simple and easily applied device, but it is limited to very low pressures of steam on account of the great length of outer leg that would be required to get a sufficient height of water to balance high pressures. Thus, to balance a steam pressure of 90 lbs. per square inch, the water column in the open leg would need to be 208 ft. high.

For high pressures the ordinary steam trap will accomplish the discharge of the drainage automatically and very efficiently. The regular steam trap consists of a tank or receiver into which the condensation is drained, provided with a mechanism designed to open a discharge valve after the water has collected to a certain extent and to close after it has been discharged. There are several very successful steam traps on the market, among the simplest of which are those in which the discharge-valve mechanism is operated by a float. Figs. 1 and 2 show two traps that work on this principle. As the condensation accumulates in this type of trap its float rises with the water level, and at a certain point opens a discharge valve at the bottom, allowing the water to flow out. Then, as the water is discharged, the level falls and the float falls with it, eventually closing the discharge valve just before the trap is entirely emptied, so that the live steam cannot have access to and escape through the discharge outlet.

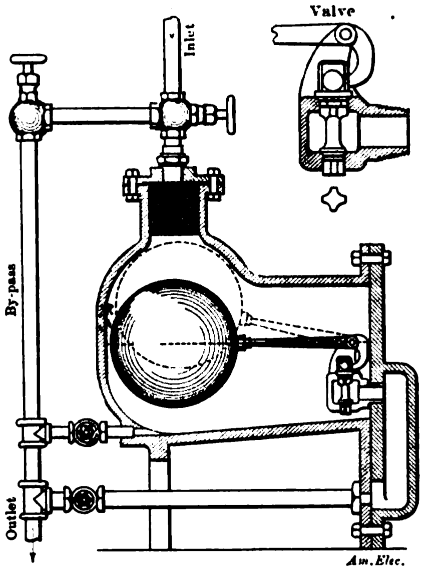

FIG. 1.—FLOAT STEAM TRAP.

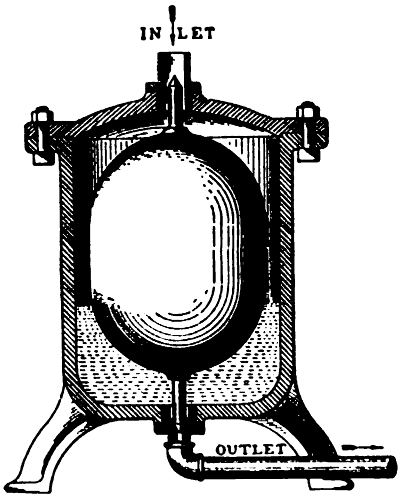

FIG. 2.—FLOAT STEAM TRAP.

In another type of steam trap the discharging mechanism is operated by the weight of the drainage water as it fills a movable bowl, or bucket, integral with the trap. These traps, two of which are shown by Figs. 3 and 4, are so arranged that the water as it enters is directed into the movable bowl or bucket until the weight of the accumulating water is sufficient to carry the bowl downward against the pull of counter-balancing weights. The downward motion actuates a mechanism which opens a valve admitting steam to the trap directly from the boiler; this steam drives the water of condensation out through a siphon or a discharge-valve opened by the mechanism. After the water is discharged, the bowl rises to its former position, thereby closing the steam and discharge valves and restoring the former conditions, ready for a repetition of the process. These traps possess the advantage of being able to discharge against a head of water, or even directly into a boiler under pressure, if the boiler is lower than the trap. The admission into the trap, during each discharge, of steam at boiler pressure makes the pressure inside the trap equal to that in the boiler, so that if the trap is on a slightly higher level than the boiler its discharge outlet may be connected to the boiler and the water will flow into the boiler by its own weight. This feature is valuable on account of the saving derived by returning the hot condensation water directly into the boiler instead of wasting it, or allowing it to cool as is usually done.

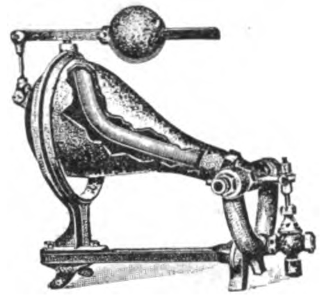

FIG. 3.—BOWL STEAM TRAP.

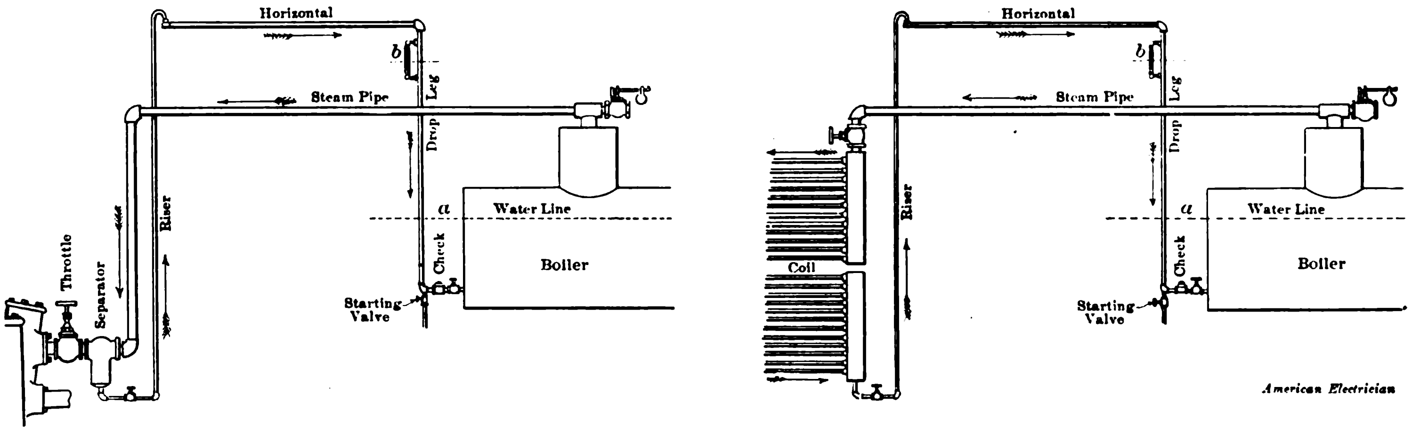

FIG. 7.—ARRANGEMENT FOR RETURNING WATER OF CONDENSATION TO BOILER WITHOUT TRAPS—FIG. 8.

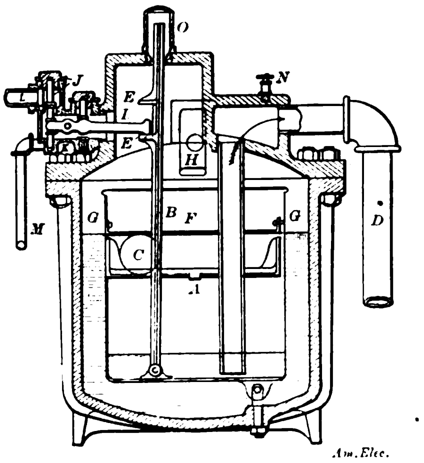

FIG. 4.—BUCKET STEAM TRAP.

A very interesting type of steam trap is one whose discharge valve is controlled thermostatically by the expansion and contraction of metal plates or rods. In this type, of which two are shown by Figs. 5 and 6, the discharge-valve is normally open at all temperatures below the boiling point of water, so that all condensation water may discharge freely; but as soon as the trap is emptied and steam begins to rush through, the higher temperature of the steam raises the temperature of the metal plates, or rod, causing them or it to expand and close the discharge-valve.

However, in spite of the ingenious designs of these steam traps, they all have one inherent and unavoidable disadvantage—the discharge-valve will inevitably corrode or wear away due to the action of the hot water of condensation and will need reseating and renewal from time to time. Attempts have often been made to reduce this trouble by using composition metals for the valves and seats, with the result that certain compositions wear much longer than others, but that none are immune from appreciable wear.

There is an extremely ingenious substitute for the steam-trap which is designed to return condensation water direct to the boiler. It combines the advantages of the boiler-return steam traps with the advantage of having no valves or mechanism to wear out. Figs. 7 and 8 are diagrams of this device, which is known as the "steam loop," and consists chiefly of a special arrangement of piping. There are three pipes, two of which are vertical and the other horizontal. One of the vertical pipes, which is called the "riser," is connected at its lower end to the reservoir, or the point of steam piping to be drained, and the other, which is called the "drop-leg," is connected at its lower end to the boiler feed pipe just outside the check. The upper ends of these two vertical pipes, which are carried up to a considerable distance above the top of the boiler, are connected by a horizontal pipe, so that this so-called "steam-loop" is simply a system of piping connecting the drip connections to the boiler-feed pipe. In starting the action of the steam loop, the starting valve, shown next to the boiler-feed check, is opened long enough for the entire loop to be filled with steam and drainage, commingled, by blowing through the loop from the drips, and thereafter, the following action takes place automatically. The steam which has been blown into the loop is condensed by the coolness of the exposed piping, thereby producing a slight drop in press-

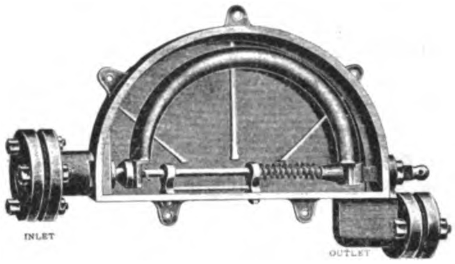

FIG. 5.—THERMOSTATIC STEAM TRAP.

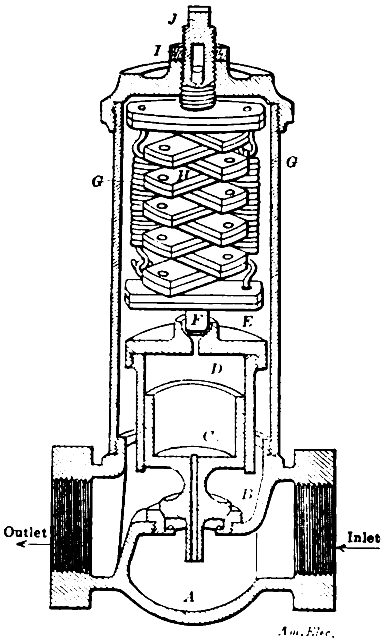

FIG. 6.—THERMOSTATIC STEAM TRAP.

ure from point to point throughout the loop, whereupon the steam pressure from the boiler will tend to rush in to make up this drop. But pressure cannot act from the boiler direct on account of the boiler-feed check next to the boiler, so it is compelled to act through the separator or drip connections, and, in doing so, it forces drainage, mixed with steam up into the riser, through the horizontal pipe to the drop-leg. This mixed steam and water becomes cooled in its passage through the pipe, thereby condensing the steam and causing another incipient vacuum, allowing more mixed drainage water and steam to be forced up the riser and into the drop-leg. When the drop-leg is filled to a sufficient height above the water line of the boiler, the weight of the water overcomes the back pressure on the check valve and it feeds into the boiler. This device is admirable for its extreme simplicity and high efficiency.

DIRECT-CURRENT DYNAMOS IN PARALLEL.

BY ALTON D. ADAMS.

Two or more shunt-wound dynamos operated in parallel at the proper speeds tend to divide the external current between them in the correct proportion, if the shunt field circuit is so adjusted that the e.m.f. generated in each armature equals the voltage at the common connection plus the "drop" in that armature when passing its correct share of current. A change of speed or poor adjustment of the magnet strength of one of several shunt-wound dynamos operating in parallel results in an incorrect division of the total current between them and in some change of line voltage. In an extreme case one of the shunt dynamos may generate an e.m.f. lower than the line voltage and thus take current and operate as a motor, doing work on its engine or driving shaft. No serious results necessarily follow, however, the polarity of magnets is not reversed and normal conditions can be at once restored by suitable adjustment of speeds and the rheotats in shunt windings.

There are two properties by reason of which shunt dynamos are operated in parallel, without any special connections. One is that, however much any one machine may lower its e.m.f., no matter whether it acts as a generator or as a motor, the magnets remain constant in polarity; the other is that changes of armature e.m.f by one dynamo does not tend to produce further change in the same direction, because the voltage at the field winding terminals cannot fall below that at the bus-bars. It is impracticable to operate series-wound dynamos in parallel with no special connection between them.

If the two dynamos are exactly alike in every way and are operated at constant speed, all will go well, but if a change of speed or some other cause lowers the e.m.f. generated in the armature of one dynamo to a point a little below that necessary to maintain its share of the current flow, the field winding of this dynamo being excited by only its reduced current, the magnet becomes weakened and reacts to further lower the e.m.f. generated in the armature. When its e.m.f. becomes less than the voltage delivered by the other machine, current will be forced through it backward by the stronger machine, and it will be driven backward as a motor, its field magnet polarity having been reversed by the reversal of current through the winding. The result of this reversal of rotation would be the throwing off of the belt and a runaway on the part of the "motoring" armature.

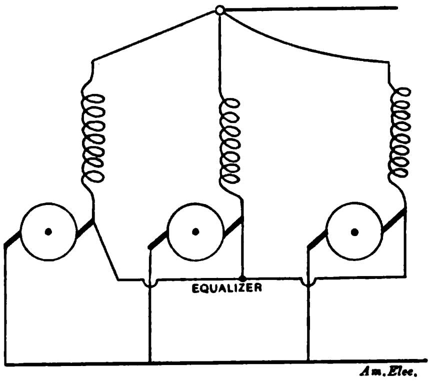

FIG. 1.—PARALLEL CONNECTIONS FOR SERIES DYNAMOS.

To prevent this reversal of current in the magnet coils of series dynamos connected in parallel, and the consequent reversal of armature rotation, the terminals of the magnet coils next to brushes must be joined, as shown in Fig. 1. The result of this third connection, commonly known as the equalizer, is that the magnet coils are all connected in parallel independent of the armatures, so that the total line current divides between the coils inversely as are their resistances, and the direction of its flow is constant. Should the e.m.f. generated in any armature in Fig. 1 drop below the voltage delivered to the common brush cables by the other armatures, the low-pressure armature would take current as a motor, but would continue to rotate in the same direction as before, since the polarity of its magnets remains constant.

Compound dynamos, having both shunt and series coils on their magnets, combine, to some degree, the properties of both shunt and series dynamos. When operated in simple multiple, they are very unstable as to the division of load between them. The same causes which produce a reversal of current through a series dynamo will produce the same result in the armature and series winding of a compound dynamo when two or more machines are operated in simple multiple. As the shunt-field winding continues to be charged at the full voltage of the system, however, the reverse magnetizing action of the series coil, when a dynamo takes current from the others as a motor, weakens but very seldom reverses the polarity of the field magnet, so that, while a machine may run as a motor, its direction of rotation is not likely to be reversed. To counteract the tendency to an unequal or disproportionate division of the load between compound-wound dynamos, recourse is had to an equalizer connection between the inner terminals of the series coils on all of the dynamos, putting them all in multiple, exactly as in the case of purely series dynamos and with practically the same result. Neglecting the resistance of the cables that form the equalizing connection, the voltage across the terminals of all series windings is the same and the current flowing through the several coils varies inversely as their resistances.

The series coil of a compound-wound dynamo is, of course, intended to produce at the dynamo terminals either a constant pressure or a certain rise in pressure as the current output increases. The effect of the series winding varies nearly with the amount of current flowing in it, and is calculated on the assumption that the amperes in the dynamo armature and in its series coil are always equal, except as to the small current of the shunt coil when this connects directly with both sets of brushes, as in Fig. 2. As the equalizer connection for compound wound dynamos renders the current in any particular series coil entirely independent of the current in its armature, the actual compounding current will correspond with the calculated current only when each of the several dynamos in parallel furnishes current in inverse ratio to its series field resistance. The ultimate effect of the series winding depends not only on its ampere-turns, but also on the magnetic density in the field magnet and armature core. As is well known, a certain magnetizing force, measured in ampere-turns, produces a much greater increase of magnetic flux when the magnet frame to which it is applied is at a low, than when it is at a much higher, stage of saturation.

Dynamos are commonly stated to be either compounded for constant pressure at their terminals or over-compounded for a certain per cent of their no-load voltage, but these particular compounding effects can only be correct for given combinations of speed, no-load voltage and position of the rheostat lever, for each dynamo. Owing to these inherent properties some care as to armature speed and shunt-field excitation is necessary to get the rated effects from the series winding

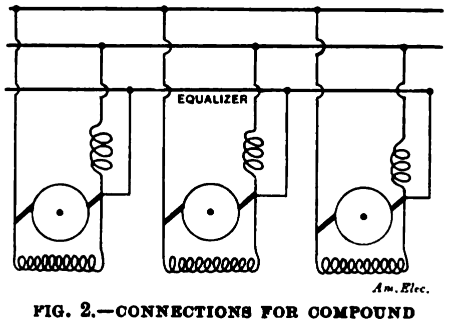

FIG. 2.—CONNECTIONS FOR COMPOUND DYNAMOS

with a single dynamo, and when several dynamos of different capacities and makes are operated in multiple, with equalizer connections, it is almost impracticable to secure the predetermined compounding effect in each machine. It is true that such dynamos are regularly operated in parallel with good results, but this is accomplished more by manipulation of rheostats than by the predetermined effects of compounding coils.

Lessons in Practical Electricity

EFFECT OF SELF-INDUCTION IN THE ROTOR OF AN INDUCTION MOTOR.

As intimated in previous Lessons, the armature, rotor or secondary, as one may choose to call it, is subject to self-induction, just like the armature of a direct-current motor. This effect, however, is greater in degree and more disadvantageous in the induction machine, as will be shown in due course.

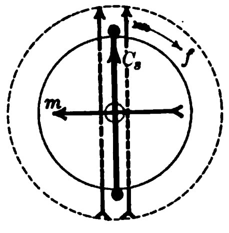

FIG. 17.—CURRENT IN PHASE.

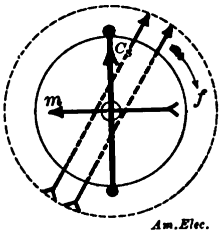

FIG. 18.—CURRENT LAGGING.

The current induced in the rotor conductors by the rotating magnetic field alternates at a low frequency, as explained last month, and as the conductors form closed circuits about an iron core they possess considerable inductance, which results in not only reducing the volume of current flowing, but in throwing that current out of phase with the induced e.m.f. that forces it through the rotor conductors. This phase displacement is illustrated by the diagrams, Fig. 17 and 18, in which a single turn or loop of the rotor "winding" is shown. (It is much easier to follow the actions in the rotor by considering a single loop, and the result is practically as accurate as though the whole squirrel cage were considered. It also simplifies matters to study a bipolar field, and this will be done throughout the Lessons on this subject. The only difference in the actions of bipolar and multipolar fields is in the rotative speed.)

In Figs. 17 and 18, a rotor core is represented having two conductors joined at the ends by wires across the heads, thus forming a closed loop. The inner edge of the stator ring is indicated by the dotted circle, the air-gap being exaggerated in order to show the position of the rotating field flux; the plane of this flux, as well as the position of its central or densest part, is indicated by double arrows across the air-gap, and the direction of rotation by the curved arrow, *f*. The e.m.f. induced in the loop will have its maximum value when the central zone or densest part of the flux, indicated by double arrows, passes across the conductors of the loop, and with no self-induction the current would do likewise, as indicated in Fig. 17, where the arrow-head, C_s, indicates the flow of induced current in the rotor loop. This current induces a cross flux in the rotor core, as indicated by the arrow, *m*, and the pull or torque between these two fluxes is greatest when they are a quarter of a mechanical cycle apart, as shown; consequently, the torque is maximum when there is no lag in the current. Self-induction, however, produces a lag in the current (the phase of the induced e.m.f. remains coincident with the mechanical phase of the field flux) and then the current in the loop does not attain maximum value until the rotating flux has passed the conductors, as indicated in Fig. 18; then the angle between the field flux and the cross flux is greater, as shown, and the torque is less. The exact relation between the current lag and the torque may be shown by the use of a few simple formulas. As it is awkward to compare the current phase with the position of the field flux in space, the phase of the induced e.m.f., which rises to maximum in unison with the passage of the flux, will be taken as the basis of comparison.

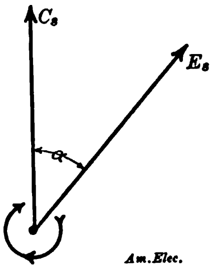

FIG. 19.—ILLUSTRATING LAG ANGLE.

If the difference of phase between the current, C_s, and the e.m.f., E_s, which forces it through the loop be represented by two vectors, as in Fig. 19, the angle, α, between the vectors will be such that its cosine is equal to the resistance of the loop divided by its impedance; thus,

$$R_s + Z_s = \cos\alpha.$$

As stated previously, the torque is maximum when the current is in phase with its e.m.f., and it decreases directly in proportion to the cosine of the angle between the two vectors representing the difference of phase between the current and the e.m.f. Thus, if there were no lag in the current. the torque exerted on one loop, in pound-feet, would be equal to $.707 \times \Phi \times C_s \times k$. In this expression, Φ is the number of magnetic lines in the rotating field flux; C_s is the current in the conductor loop, and k represents the constants necessary to reduce absolute units to practical ones. As there is always a current lag, however, the torque can be represented by the expression: $T = .707 \ \Phi C_s k \cos\alpha$. As the cosine of the angle of lag is equal to the resistance of the loop divided by its impedance, the last equation may be changed to read:

$$T = .707 \ \Phi C \frac{R_s}{Z_s} k.$$

Furthermore, as the current in the loop is equal to the e.m.f. divided by the impedance, $C_s = E_s + Z_s$, and as the e.m.f., E_s, is equal to $4.44 \times n_s \div 100{,}000{,}000$, the current, C_s, is equal to $4.44 \times n_s \div 100{,}000{,}000 \times Z_s$, and the equation for pound-feet of torque may be again changed to read thus:

$$T = \pi \Phi^2 n_s \frac{R_s}{Z_s^2} k \ldots\ldots\ldots (5)$$

in which k now includes the numerical divisor 100,000,000 (or more accurately its reciprocal) in the expression for e.m.f., and n_s is the frequency of the current in the rotor loop. This formula shows that increasing the resistance of the rotor loop will increase the torque, while any increase in the impedance of the rotor loop will decrease the torque. Now, as impedance consists of resistance and reactance combined, the resistance cannot be increased without increasing the impedance also, but it must be remembered that the increase is not directly proportional. Separating the impedance into its component parts, formula (5) develops into

$$T = \pi \Phi^2 n_s \frac{R_s}{R_s^2 + X_s^2} k \ldots\ldots (6)$$

A rough example will serve to show that if the resistance equals the reactance, a change in either direction will reduce the torque; consequently, increasing the rotor resistance will increase the torque only up to the point where the resistance and reactance become equal—beyond that, it decreases the torque. Example: Resistance = 2; reactance = 2; as the impedance, Z, is equal to $\sqrt{R^2 + X^2}$, in this case its value is $\sqrt{4+4} = 2.8284$, and the fraction, $\frac{R_s}{Z_s^2}$, in formula (5) has a value of $\frac{2}{8} = 0.25$. Now, suppose the resistance were increased to 2.1; then the impedance would be 2.9 and the fraction $\frac{R_s}{Z_s^2} = \frac{2.1}{8\text{-}41} =$ 0.2497. Again, suppose the resistance reduced to 1.9; then the impedance would be 2.759, and the fraction $\frac{R_s}{Z_s^2} = 0.24968$. In both cases, the value of $\frac{R_s}{Z_s^2}$ is less than when the resistance and reactance are equal, and the torque increases or decreases directly with an increase or decrease in the value of this fraction.

Formulas (5) and (6) also show that if the other factors remain unchanged, any increase in the frequency, n_s' of the rotor current will increase the torque. This confirms the explanation in the April Lesson of the increase in torque due to increase in "slip," the rotor conductors being "cut" by the magnetic field at a higher rate as the difference between their rotational velocities increases. Following out this line of reasoning, the torque would be maximum when the rotor stands still, as the conductors would be "cut" at the full frequency, *n*, of the magnetic field.

This would be true if the rotor had no

inductance (L_s) and consequently no reactance (X_s). ($X = 2 \pi n L$). But it has, and at standstill the reactance is about twenty times as high as at full speed. This great reactance throws the rotor current so far out of phase with its e.m.f. as to decrease the torque to a very small value, notwithstanding the great rush of current due to the high e.m.f. induced in the rotor by the high rate of "cutting" between the rotating field and the conductors. Another rough example will serve to illustrate this point. Formula (6) shows that the torque is directly proportional to

$$n_s \frac{R_s}{R_s^2 + X_s^2}.$$

Now suppose that the resistance, R_s, of the single loop is 0.005 ohm and its inductance, L_s, 2½ millihenrys, or 0.0025 henry. Now with a primary frequency of 60 cycles and a 5 per cent slip at full speed, the rotor frequency will be .05 × 60 = 3 cycles, and the reactance ($2 \pi n_s L_s$) of the one loop will be $2 \pi 3 \times 0.0025$, or 0.0047124 ohm. Substituting these values in the above expression, we get

$$n_s \frac{R_s}{R_s^2 + X_s^2} =$$

$$3 \times \frac{0.005}{.000025 + .0000222} = 317.8,$$

so that the torque is $317.8 \pi \Phi^2 k$ at full speed. Now at standstill the rotor frequency is the same as the primary frequency—60 cycles. The reactance then will be $2 \pi 60 \times 0.0025$, or 0.94248 ohm, and

$$n_s \frac{R_s}{R_s^2 + X_s^2} =$$

$$60 \times \frac{0.005}{.000025 + .88827} = 0.33765.$$

Consequently, the torque at standstill will be only $0.33765 \pi \Phi^2 k$ pound-feet, the difference between this torque and the full load torque being in the ratio, roughly, of 318 to 0.338. It is because of this effect that the rotors of large motors are provided with coil windings and slip rings whereby an external resistance may be inserted in the rotor circuit. Suppose, for example, that the terminals of our single loop were led to two slip rings (like the collector rings on an alternator) and the brushes of those slip rings connected to a resistance of 0.935 ohm; then the total resistance would be 0.94 ohm, the reactance at standstill, 0.94248 ohm, and the starting torque, $32 \pi \Phi k$ pound-feet, or nearly 100 times the standstill torque without external resistance.

Letters on Practical Subjects

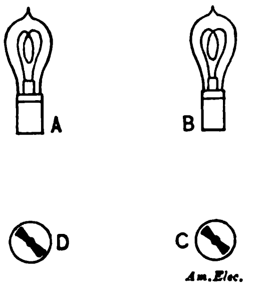
A Problem in Connections.

To the Editor, American Electrician;

Sir:—I would like to ask if any of your readers can solve the following problem: In the accompanying diagram, A and B are incandescent lamps; C and D are switches. The problem is to arrange the connections so that the lamp A can be lighted by means of the switch D, and when this is done the lamp A may be cut out by the switch C. Now it is desired that the switch C will either relight the lamp A alone or light both the lamps, A and B, at the same time, and with both of these lamps lighted they may be turned out by the switch D and the series of operations just described carried through again. I have not been able to solve the last part of the problem, and will appreciate it if some of your readers will suggest a solution. The switches are represented as snap switches, but it is not intended to limit the form of switch to be used.

George Moutonnet.

Saumur, France.



LAMPS AND SWITCHES.

Boosting Transformer Switch Connections.

To the Editor, American Electrician;

Sir:—Referring to Mr. C. C. Webster's letter in your March issue, I beg to disagree with the statement that in the case of Fig. 4 the e.m.f. would rise in the primary, due to an increase of current in the secondary during the time when the switch is being thrown from one position to the other. A moment's study will show that the secondary carries the full line current whether working as a booster or during the change of position, so that in no case would the primary e.m.f. rise above normal. Fig. 3 in Mr. Webster's letter, and Fig. 5 in Mr. Wood's letter, in the same issue, are both open to the very serious fault that they open the line during the change of position. This fault is not possessed by Fig. 4, which seems to be the correct connection.

Chelsea, Mass. E. W. Lothrop.

DIAGRAMS OF SWITCH CONNECTIONS FOR THROWING OUT BOOSTER DURING LIGHT LOADS.

Operation of Engine-Driven Alternators in Parallel.

To the Editor, American Electrician;

Sir:—It has been said that the varying crank impulses of an engine at different angles cause "pumping" or hunting by an alternator, but the writer's observation leads to the conclusion that this is not serious in itself, because engines will sometimes run for an hour or more without indications of cross-currents and then apparently without reason the alternators will begin to pump. If the variations of the crank effort during one stroke cause the disturbance it ought to exist at all times; otherwise, such a conclusion is illogical.

In throwing one alternator in parallel with another it is found necessary to throttle the engine until its speed corresponds to the speed of the active machines and then throw in the switch. Under these conditions it is impossible to make the speed of the fresh engine exactly like that of the loaded engines, but the variation is so sluggish that there is plenty of time to couple the alternators at the proper moment; not, however, without causing some cross-currents. However this may be, when they are once in operation and it is desired to uncouple one from another, the machine to be thrown out is gradually slowed down by throttling until the load is nearly off and then the switch is pulled, and this operation causes no disturbance whatever. From these facts it seems reasonable to assume that the tendency of an engine to slow down under these conditions is not detrimental to the operation of alternators in parallel, but that the trouble comes from the tendency, due to variations of steam pressure or other causes, to go beyond normal speed.

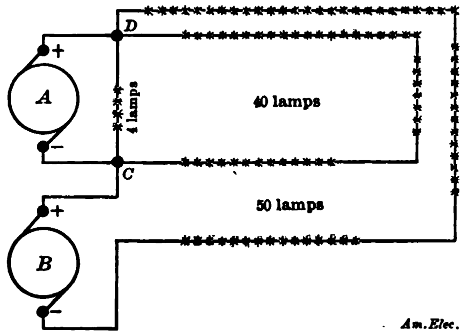
It was with this idea in mind that a dash-pot was designed in such a way as to offer great resistance to the tendency of the cut-off to lengthen and only the very slightest resistance to the tendency of the cut-off to shorten. Such an arrangement, while not adapted to rapidly fluctuating loads, is suggested as a solution of the problem of hunting or pumping. Ralph J. Patterson.

Woburn, Mass.

An Arc-Lighting Problem.

To the Editor, American Electrician;

Sir:—The accompanying diagram illustrates a curious accident which occurred some time ago on two of our arc lighting circuits. The dynamos shown in the diagram are Brush machines of the ordinary type; the dynamo, *A*, supplies 40 light and the dynamo, *B*, supplies 54 lights normally. The accident referred to consisted of a cross between the two circuits, as indicated by the dots, *C* and *D*, where the line from the positive pole of the dynamo. *B*, crosses both of the line wires of the other circuit. Four lamps were caught in between the two crosses, as indicated in the diagram. It may be interesting to some of your readers to figure out what happened when the cross occurred. The lamps take 50 volts each and the line current is 10 amperes. What is the distribution of the current; what is the action at the dynamos, and what happens to the four lamps between the points *C* and *D*?



CROSSED ARC LIGHTING CIRCUITS.

Waterbury, Conn. F. M. Swalm.

Bucking of Railway Generators.

To the Editor, American Electrician;

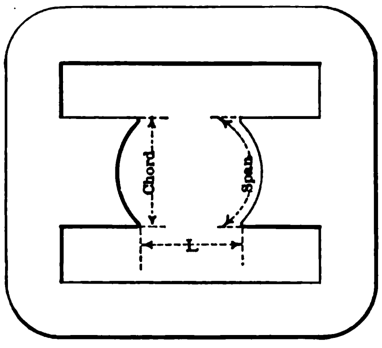
Sir:—In Mr. Parham's interesting article on the "Bucking of Railway Generators," which was printed in your February number, one part of the explanation of this trouble seems to be incomplete, and the other part at variance with common practice. In all small railway power houses there are prolonged periods when the load is zero and in such cases the load fluctuates violently between zero and maximum and even considerable overloads without any bucking whatever on the part of the generators. The writer has operated machines under these conditions for several years and never had the slightest trouble from bucking. A more plausible explanation would seem to be that the magnetic characteristics of the two dynamos are so different that they cannot be made to divide the load properly under different loads, and although they may have been adjusted to give the same e. m. f. when they were thrown in together, the station attendant will almost always re-adjust the fields afterward so that the load is divided equally under average load. If the magnetic characteristics of the machines differ very greatly the e. m. f. of one of them will be considerably higher than the other at no load if they are adjusted to divide the load equally at average or full load, and the action which Mr. Parham describes will take place. Mr. Parham is evidently wrong, however, in supposing that the series fields of the dynamos have anything to do with the bucking; series field windings are always connected in parallel by the equalizer bus-bar, so that it is impossible for the armature of one machine to back current in the demagnetizing direction through the series field coils of another. Ed. S. Morgan.

Denver, Colo.

Pole-Piece Dimensions.

To the Editor, American Electrician;

Sir:—Having occasion to calculate the span of pole-pieces and the chord of the tips (distance straight across) I recently prepared the accompanying table to save time and trouble in figuring out each case. I submit it in the hope that it may be of service to some of your readers who are engaged in drafting or similar work.



BIPOLAR FIELD MAGNET.

The figures in the body of the table give the chord, span, etc., in inches per inch of polar bore for various percentages of polar span. For example, an armature chamber is to have a bore of 12 ins.; the field is four-pole and the pole-pieces must cover 74 per cent of the armature surface. What is the chord? The table gives 0.549 in. as the chord per inch of diameter for four poles covering 74 per cent; 0.549× 12 = 6.588 ins. Of course, 6.6 ins. would be near enough.

Per cent of Armature Covered by Pole Pieces.	2 Poles.			4 Poles.			6 Poles.			8 Poles.		
	Pole Chord.	Pole Span.	Coil Leng'h L.	Pole Chord.	Pole Span.	Coil Depth T.	Pole Chord.	Pole Span.	Coil Depth. T.	Pole Chord.	Pole Span.	Coil Depth. T.

80	.951	1.257	.308	.588	.628	.11	.407	.419	.18	.309	.314	.145

To ascertain actual dimensions multiply the figures in the body of the table by the bore of the pole-pieces.

The column headed "L" contains the maximum length of coil that will go between opposite poles of a bipolar ironclad field, per inch of polar bore. Those headed "T" contain the maximum *thickness* of coil that can be put on a multipolar field magnet which has no removable pole-shoes, such as Fig. 2. The sketches serve as a key to all of the table headings.

Adjusting an Electrodynamometer.

To the Editor, American Electrician;

Sir:—In your March issue I notice a note on the use of electrodynamometers; I would like to add a simple test. After having performed the manipulations stated in the article, short-circuit the movable coil at the mercury cups and pass a not too strong alternating current through the instrument. If the adjustment is correct the pointer will remain stationary. If the adjustment is not correct the pointer will be deflected owing to currents being induced in the movable coil. The current passing through the movable coil owing to its being shunted across the short circuit is too small to affect the instrument.

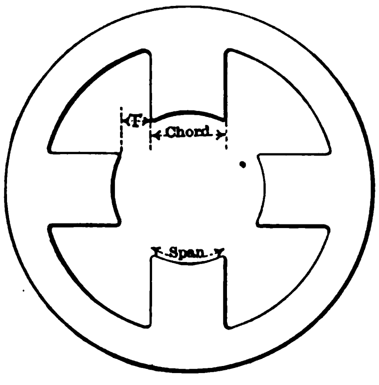

FIG. 2.—FOUR-POLE FIELD MAGNET.

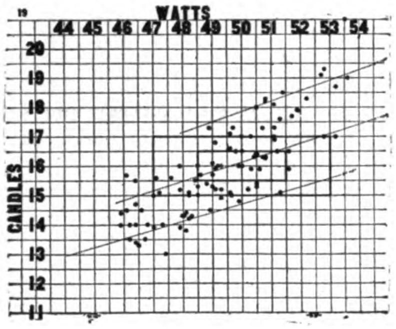
Allegheny, Pa. P. M. Gallo.

Electrical Catechism

593. What is meant by a target or shot-gun diagram?

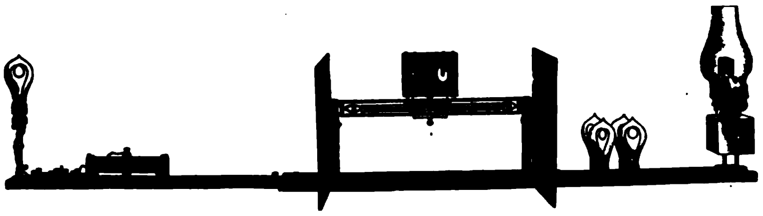
A target diagram shows the watts absorbed and the candle-power of a number of lamps which are tested for uniformity. Such a test should be made for each lot of new lamps bought. The lamps are each placed on a photometer and subjected to the voltage marked on the lamp case, and the watts and candle-power measured at the same time. The readings for each lamp are recorded and also plotted on a sheet. The record of a test of a poorly sorted lot of lamps is shown in the accompanying target diagram.



TARGET DIAGRAM.

594. What is a photometer?

The photometer is an apparatus for measuring light. The lamp to be tested is placed at one end of a bar, a standard lamp of known candle-power is placed at the other end, and each is subjected to the voltage specified. A movable screen or "sight box" is then moved along the bar between the two lights until its two sides are equally lighted by the two lamps. When a balance is found, the strengths of the two lights are inversely as the square of the distances from each light to the sight box screen. At the same time the volts and amperes are measured for the lamp under test, and the watts are calculated by multiplying volts by amperes.



PHOTOMETER.

595. What is the temperature of the filament in an incandescent lamp?

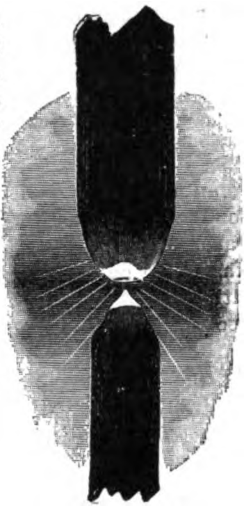
The temperature is from about 3092 to 3812° Fahrenheit. If the voltage is too high the lamp takes too much current, and the temperature of the filament becomes so high that it becomes soft and droops until it may touch the glass bulb, which then cracks and allows air to enter and burn the filament. An abnormally high temperature also causes disintegration of the filament and causes its candle-power to drop off rapidly.

596. How many incandescent lamps are in use?

It is difficult to estimate closely. There are from 15,000,000 to 20,000,000 lamps sold yearly in America, and the European demand probably increases these figures to about 25,000,000. The total number of lamps in service is probably several times the latter figure.

597. What is the electric arc?

The electric arc is a phenomenon discovered by Davy about 1800. He sent a strong current through two carbon pencils and then separated them. The current continued to pass, raising the temperature of the ends of the carbons to a high degree, while a vapor of carbon passed between the carbon pencils. By reason of the rising currents of air the stream of incandescent vapor between the pencils assumed an arched form, and Davy named it the electric arc or arch. Later experiments show that the end of the positive carbon is raised to the temperature of volatilization, that of the arc itself being higher and that of the negative carbon being lower.



ELECTRIC ARC.

598. What is the source of the light from an arc?

Almost all of the light comes from the end of the positive carbon, which is heated by the current. In the case of alternating-current arcs the light comes equally from the ends of both carbons. In most lamps the carbon pencils are together at the start, but are immediately separated by the lamp mechanism. The current meets great resistance as the carbons separate, and the energy absorbed heats the ends of the carbons until the end of the positive carbon begins to vaporize and furnish a path of incandescent vapor between the two pencils. The end of the positive carbon assumes a cup shape, which is called the crater, and from this proceeds a clear white light. The purple or violet light that sometimes becomes prominent, comes from the arc itself.

599. Does the light of an arc come from the combustion of the carbons?

The light comes principally from the positive crater and to a small extent from the arc itself. The carbons burn so slowly that the light from ordinary combustion is negligible except under abnormal circumstances. When the arc is too short or the current too large, or the carbons too soft, a flame plays around the arc and burns the carbons rapidly. This flame is not so luminous as the arc or the crater, and it actually reduces the amount of light.

600. How rapidly do the carbons burn ordinarily?

A positive carbon 12 ins. long and 0.5 in. in diameter will burn from 7 to 12 hours. The negative carbon lasts from one to three and one-half times as long as the positive, varying with the voltage of the arc. The life increases as the diameter increases. When the arc is enclosed the carbons last much longer, a single pair lasting from 50 to 150 hours. The life of the carbon depends upon the current, the pressure, the condition of the air, the manufacture of the carbon and the amount of plating on its surface.

601. What are enclosed arc lamps?

With the enclosed arc lamps a small glass globe surrounds the arc and fits the carbon pencils so closely that the air inside the globe can change only slowly. This reduces the rate of combustion of the carbons, so that they last longer. This not only reduces the frequency of retrimming (re-carboning) the lamp, but also reduces the demands upon the feeding mechanism of the lamp. The gas within the globe seems to glow and increase the apparent amount of light more than the glass diminishes it. The enclosed lamps are so much more satisfactory in their operation that they are rapidly replacing the open arcs for interior illumination and are being used to some extent for outdoor lighting. They are the cause of a large increase in the total amount of arc lighting furnished.

602. What currents are used in arc lamps?

The standard current for a street arc lamp is 9.6 to 10 amperes, or 6.8 amperes for "half arcs." Enclosed arc lamps take from 2 to 10 amperes. Arc lamps of the open type take as high as 15 amperes. Searchlights take as high as 200 amperes.

603. What voltages are used in the arcs?

The smallest pressure that will maintain an arc is about 18 volts. Arc lamps for alternating currents are often operated on 28 to 33 volts. Ordinary open arc lamps such as are used for street lighting take from 40 to 60 volts. Enclosed arcs take from 60 to 160 volts at the arc.

604. On what kind of circuits are arc lamps operated?

Arc lamps were formerly operated almost exclusively on series circuits in which a dynamo maintained a constant current. Arc lamps are now operated upon any kind of circuit giving 28 volts or more. The general tendency is to simplify the machinery in electric stations and to use the same dynamos for furnishing current for all purposes, consequently the arc-light machines does not command the attention it did a few years ago.

Queries and Answers

IMPORTANT.—No attention will be given to inquiries which do not give the full name and address of the inquirer.

How can two alternators connected in series be brought into phase with each other?
E. A. W.

Two alternators cannot be operated satisfactorily in series for the reason that they will not stay in phase.

What is meant by the expression "circular mils?"
E. M. S.

A circular mil is the unit of circular area of the cross-section of a wire. It is equal to the diameter of the wire in mils multiplied by itself. A mil is 1/1000 inch.

Can a 110-volt direct-current ceiling fan motor be charged to run on a 104-volt 60-cycle alternating-current circuit by exciting the fields separately?
W. P. P.

Not satisfactorily; the sparking at the brushes would soon destroy the commutator; moreover, the speed would be absurdly reduced by the high self-induction of the armature.

Why will not a 110-volt direct-current fan motor, driven as a dynamo by an alternating-current fan motor give any e.m.f. at the binding posts?
W. T. S.

Because the direct-current machine is series-wound and the fields are not excited until the full-load current passes through.

Is the carrying capacity of a wire affected by the length of the wire? (2). What determines the voltage of a dynamo or motor?
G. I. B.

Not unless the wire is wound into a coil. (2). The number of wires on the armature, the strength of the magnetic field and the rate at which the armature revolves.

What is the effect of using a cored upper carbon instead of a solid carbon in an alternating-current arc lamp?
C. G. H.

The core being softer than the shell, it is burned away more rapidly and forms a slight crater in the upper carbon, increasing the effectiveness of the illumination below the lamp. This also centers the arc between the carbons and prevents it from traveling around erratically.

How many square inches of surface are required on the positive plates of a storage battery per ampere of current? (2). How many circular mils of cross-section should be allowed in the wire of an armature winding per ampere of current? (3). How is the drop in voltage through a known resistance found?
F. M.

About eighteen. (2). From 400 to 800 circular mils, according to the radiating surface of the armature and its speed. (3). By multiplying the resistance in ohms by the current which passes through it.

What size plates should be used for a storage battery to discharge one ampere for six hours? (2). How can I tell when the battery is charged without inspecting?
E. F. W.

Use two positive plates 2½ x 4 ins. and one negative plate the same size. Apply the paste only to the faces of the positive plates next to the negative plate. (2). By connecting a voltmeter to the terminals. When the e.m.f. exceeds 2½ volts the battery is near enough charged for practical purposes.

Does compression increase the economy of a steam engine, and why is higher compression used with high-speed engines than with the Corliss type?
E. B. L.

This is an unsettled question; some builders claiming that high compression increases the economy and others disputing that claim. Some compression is necessary in order to cushion the piston at the end of each stroke and make the engine run smooth, and the higher the speed the more compression is required for this purpose.

Can an alternator be installed in place of a direct-current generator for lighting purposes without changing the wiring?
H. J.

As a general rule, no. This depends, however, upon what plan of wiring has been used in connection with the direct-current machine, and also upon the voltage of the alternator that is to be put in. If the voltage of the latter machine is the same as that of the direct-current machine then, of course, no change in the wiring is necessary; this would be a very unusual case, however.

Please explain why a magneto will ring through the secondary core of an induction coil when the primary coil and core are removed, and will not ring when the primary coil and core are in place unless the primary coil is short-circuited.
W. R.

Because the inductance of the secondary coil when the core is in it is so high that the counter e.m.f. of the coil opposed to the magneto e.m.f. reduces the magneto current to a value too small to ring the bell. When the primary coil is short-circuited; the mutual induction between the primary and secondary reduces the counter e.m.f. of the secondary coil and the magneto is enabled to ring through it.

Should the block across the upper ends of the magnet cores of an Edison bipolar dynamo be called the yoke or the keeper? (2). Is the "neutral" point on a commutator the point of commutation or the point midway between the brushes, where the e.m.f. is zero? (3). Is the "commutation" point the point on which the brushes actually rest, or the point on which they would rest if there were no field distortion?
J. E. B.

The yoke. (2). The term "neutral" has been applied to both of these points, but it is most commonly applied to the point on which the brush would rest if there were no field distortion. (3). The commutating point is invariably the one upon which the brush actually rests.

What is meant by "wattless current?" (2). How can I construct an automatic damper regulator for a 75-h.p. boiler? (3). Would the horse-power of a boiler be doubled by doubling the heating surface?
G. L.

There is no such thing as wattless current; the wattless component of a current is the component which is out of phase with the e.m.f. by 90 degrees. (2). We cannot undertake to furnish designs for apparatus; moreover, you would not be able to build a satisfactory automatic damper regulator unless you had excellent shop facilities. (3). Yes, provided it is the effective heating surface that is doubled.

Does it make any difference in telephone work which terminal of the induction coil is connected to the positive pole of the battery? (2). If not, why is it that in a singing test of a telephone receiver reversing the battery makes quite a difference in the result?
H. R. E.

Not a particle. (2). Because the telephone receiver magnet cores are polarized by the permanent magnet, so that the vibration of the diaphragm tends to amplify the battery effect if the battery is connected one way, while it tends to diminish it if it is connected the opposite way.

Can I cut out a damaged armature coil in a revolving-field three-phase alternator, or should the coil be taken entirely out of the slots? (2). Can a damaged field coil be short-circuited, or should it be removed in order to continue running?
H. E.

The damaged coil may be disconnected from the armature circuit and its place bridged over with a piece of wire; the safest plan, however, is to remove the coil entirely, as the e.m.f. induced in it may damage it still further and extend the damage to neighboring coils. (2) The field coil may be simply short-circuited and left on the pole in order to maintain the mechanical balance until a perfect coil can be substituted.

What is meant by the "duty" of a pumping engine?
P. P. W.

Formerly the duty of a pumping engine was the net foot-pounds of work delivered per 100 lbs. of coal burned under the boiler, and some persons still adhere to this definition. As the quality of coal varies widely, however, the American Society of Mechanical Engineers recommends as the unit of duty the number of foot-pounds of work delivered per 1,000,000 heats unit supplied to the steam cylinders of the engine. Put in formula shape this would read as follows:

$$\text{Duty} = \frac{1,000,000 \times \text{net foot-pounds}}{\text{B. T. U.}}.$$

How can I equalize the clearance in a cylinder without taking off the cylinder heads?
A. R. T.

Disconnect the connecting-rod from the cross-head and push the cross-head back until the piston strikes against the back head of the cylinder; then scratch a mark on the cross-head guide opposite a mark on the cross-head itself. Pull the cross-head forward until the piston strikes the front cylinder head and make another mark on the cross-head guide opposite the mark on the cross-head. Then couple up the connecting-rod and turn the engine over, adjusting the piston rod in the cross-head block until the mark on the cross-head comes within the same distance of each of the marks on the cross-head guide at the ends of the strokes. This assumes that the back surface of the piston corresponds with the inner surface of the back cylinder head to exactly the same extent that the front side of the piston corresponds with the front head; consequently, if the two facing surfaces do not correspond in the same ratio this method will not be entirely accurate, but it will ordinarily be sufficiently accurate for all practical purposes.

A QUICK-CLOSING WATER GAUGE.

Fig. 2 herewith illustrates a quick-closing water gauge manufactured by Paul B. Huyette, of Philadelphia, and Fig. 1 is a sectional view of the valve which is used on this gauge. It will be observed that the stem of the valve is provided with a screw thread of coarse pitch so that instead of requiring several revolutions to close or unclose the orifice connecting the water gauge with the boiler only a partial turn is necessary. This motion is given to the valve stems through the medium of chains hanging within convenient reach of the fireman, as indicated in Fig. 2. It will be entirely obvious that the gauge may be shut off from the boiler in the event of the breakage of the water glass or other accident without the slightest danger of injury to the fireman. Even in the event of the blowing out of the pet cock, usually located at the bottom of the water glass but not shown in the illustration, the fireman can shut off the gauge at a safe distance by using a piece of stout wire with a hook in the end of it, by means of which he can catch the chain and pull it without standing directly beneath the water gauge.

S. K. C. FREQUENCY CHANGER.

A machine for changing the frequency of alternating currents is usually somewhat complicated both in construction and operation. Built of the ordinary type it consists of an induction motor with a wound rotor, the rotor circuits being connected to slip rings and delivering currents at a different frequency from that of the currents supplied to the stator winding. The induction motor is direct-driven by a synchronous motor, so that it really becomes an induction generator; its rotor is driven in the opposite direction to that which it would take if it were allowed to run as a motor.

The inductor type of generator, however, lends itself to frequency changing with beautiful facility, as is exemplified in the case of the S. K. C. machine illustrated herewith. It is doubtless well known to all of our readers that the S. K. C. alternator comprises two stator rings or crowns on which are wound armature coils, and which are excited by a single field coil concentric with the shaft and located between the two stator rings, a revolving wireless rotor serving to perform the changes in the magnetic circuit necessary to induce an e.m.f. in the stationary armature windings. In converting this machine into a frequency changer it is only necessary to employ one set of the stator windings as a motor armature and the other set as a generator armature, and to make the number of rotor projections which are situated within the generator half of the machine different from the number of projections which revolve within the motor half; the machine thus becomes a motor-generator with a single field winding, separately excited, of course. The windings being stationary, they may be readily connected up in a variety of ways, so that a single machine can be connected to give two-phase or three-phase currents of various voltages. The frequency, of course, cannot be changed without changing the pitch of the armature coils and the rotor extensions or poles.

Frequency changers, as a rule, are employed to change a low frequency into a higher one for lighting service, although, of course, this function may be reversed. The machine here shown is designed to transform 25-cycle three-phase currents of 1800 volts into 50-cycle two-phase currents of either 1125 or 2250 volts, according to the manner of connecting up the generator winding. Fig. 2 is a diagram of the windings, motor connections and generator terminal board and Fig. 3 is a diagrammatic end view of the two stators and the corresponding halves of the rotor. It will be noticed that the half of the rotor in the motor side of the machine has six poles, while the half which revolves in the generator side has 12 poles, and that the pitches of

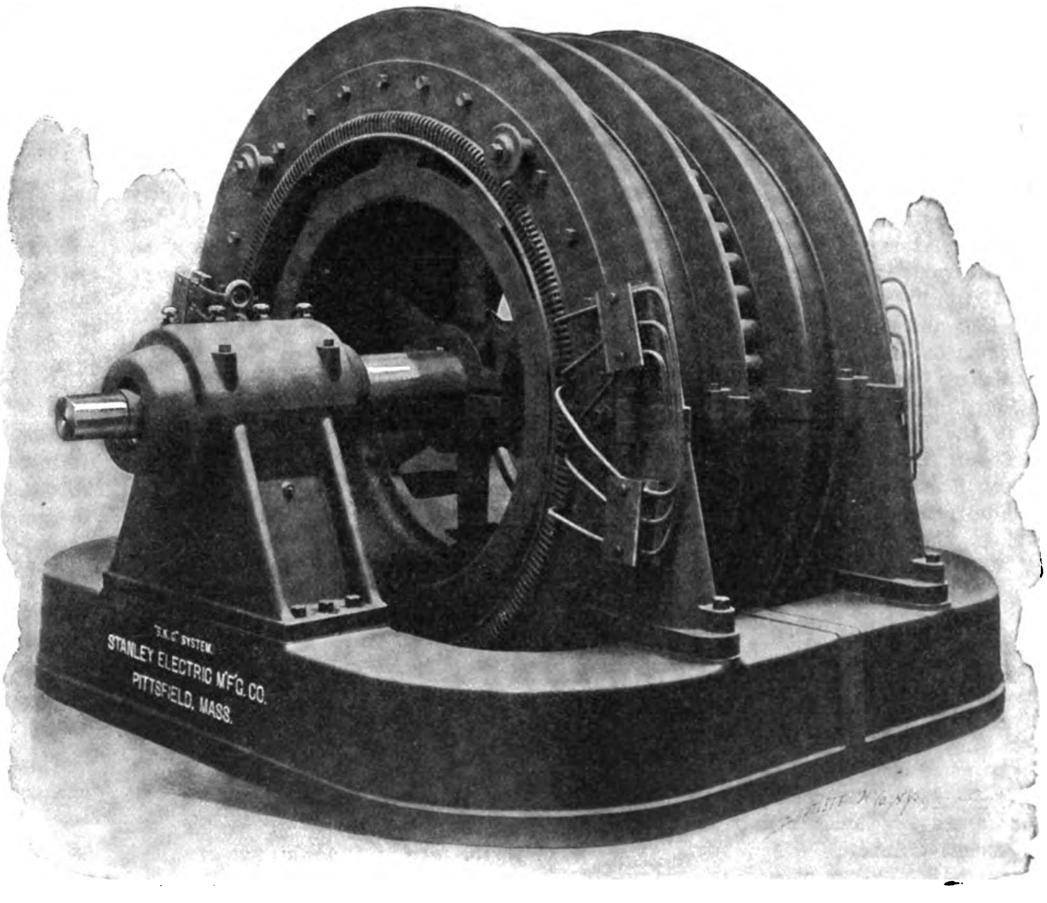

FIG. 1.—S. K. C. FREQUENCY CHANGER.

the stationary coils on the two sides differ correspondingly. The generator side of the machine is provided with a terminal board, the connections of which are shown in the upper part of Fig. 2; the two semi-circular arrangements resembling rheostats are the faces of two inductive voltage regulators, one regulator being inserted in each phase of the generator winding. By this means the e.m.f. of each phase may be regulated independently of the other and also independently of the field excitation. These auxiliary regulators provide a range of 10 per cent variation in the e.m.f. of each phase. In the winding diagram the letters, *A*, *B* and *C* indicate the coils of the three phases of the motor winding, and the figures referring to the generator winding indicate the terminals which are led to the connections on the terminal board which are indicated by the same figures. The motor winding is connected up delta-fashion, as indicated by the diagram in the upper left-hand corner of Fig. 2.

SWITCHBOARD SHUNTS AND TRANSFORMERS FOR ELECTRICAL MEASURING INSTRUMENTS.

A plan has been devised by Machado & Roller, New York, in connection with the instruments of the Whitney Electrical Instrument Company, which is of great convenience to users of shunted instruments. It consists of proportioning all instrument shunts so that the drop between terminals at rated load is the same. and building all ammeters whatever their capacity, so that the same difference of potential in milli-volts will cause the needle of any one of them to swing to full scale. All the ammeters on a given board may therefore be readily compared without interfering with the shunts or bus-bars, by disconnecting the leads of each meter from their several shunts, and supplying them in parallel with current from a single test cell of dry battery; sufficient resistance, of course, being interposed to cut down the voltage to a point where the meters show full scale. If any of the instruments does not show full scale it is evidently out of calibration, by the percentage that the indication bears to the full indication; and the meter must be either run with a correction factor or sent away for adjustment. In such an event it is not necessary to remove the shunt, since the drop it gives across the contact studs is a standard and known quantity.

Where a milli-voltmeter is at hand, a shunt may be readily attached to it and its readings compared with the station instrument, enabling the former to act as a check on the latter and perchance take its place when emergency requires. It is claimed that the shunts themselves will never vary as they are specially made by milling out solid blocks so as to obviate the soldered contacts usually employed and which are sources of possible error. As shown by Fig. 1 herewith, the terminals on the shunts to which the instrument leads are attached, are exceptionally heavy in order that contact errors at that point, which are a source of difficulty with shunted ammeters, may be minimized. Other features of the devices such as the temperature coefficient of the shunt material have been the subject of much thought and investigation and the final form arrived at is said to be conducive to high commercial accuracy.

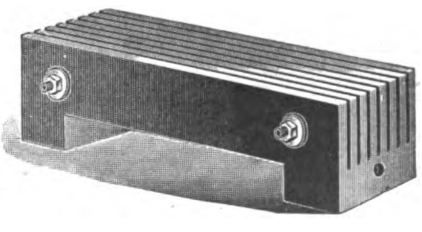

FIG. 1.—SWITCHBOARD SHUNT.

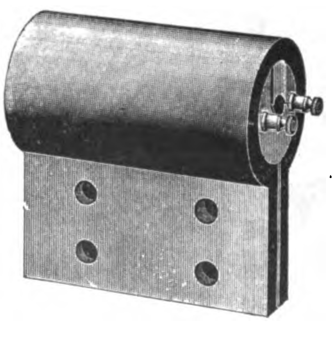

FIG. 2.—TRANSFORMER.

Fig. 2 illustrates a device which serves the same purpose for alternating-current instruments that the shunt-block does on direct current. It is a small transformer having a one-turn primary with very heavy terminals bolted directly to the bus-bar connection. The secondary is wound on a split aluminum spool which fits inside of the primary; in this coil is induced a small current which is carried to the instrument by means of suitable leads. The advantages accruing from the use of this device are of course that heavy conductors need not be carried to and from the instruments and that the secondary potential is almost nil, obviating any possibility of danger from the high voltages usually carried on the main busses. These transformers are made with capacities as high as 15,000 amperes.

New Apparatus and Appliances

ENGINE-LATHE MOTORS.

The accompanying illustration, Fig. 1, shows a Commercial double-commutator motor geared to a heavy engine lathe. By a specially constructed saddle casting, the motor is mounted upon the standard head stock casting, thus requiring no change in the lathe patterns. The motor drives a simple sleeve which replaces the ordinary step pulley or cone in the head stock of a belt-driven lathe. It is of the semi-enclosed type, and is said to be so designed that the greatest torque is secured at the low speeds. By means of various combinations of windings with gearing, 12 different speeds of the spindle are secured, ranging from 2½ r.p.m. to 450 r.p.m., without the use of any external resistance in the armature circuit. When set for a given speed, that speed is maintained practically constant, it is asserted, whether a light or heavy cut is being taken by the lathe tool. The starting and stopping of the lathe is accomplished at the apron of the carriage. The controller is constructed with an interlocking mechanism which is said to make it impossible to form two combinations of circuits simultaneously, or to start the motor without the speed-governing lever being locked in its correct position. The manufacturer claims that by the use of this system of motor propulsion heavier cuts can be made and greater pulling force exerted than can be secured with the ordinary belt-driven lathe, for the reason that the capacity of the latter is limited by the driving power of the belt. In addition to this the use of all belting and shafting is eliminated, the advantages of which are obvious. The motors are built by the Commercial Electric Company, of Indianapolis, Ind.

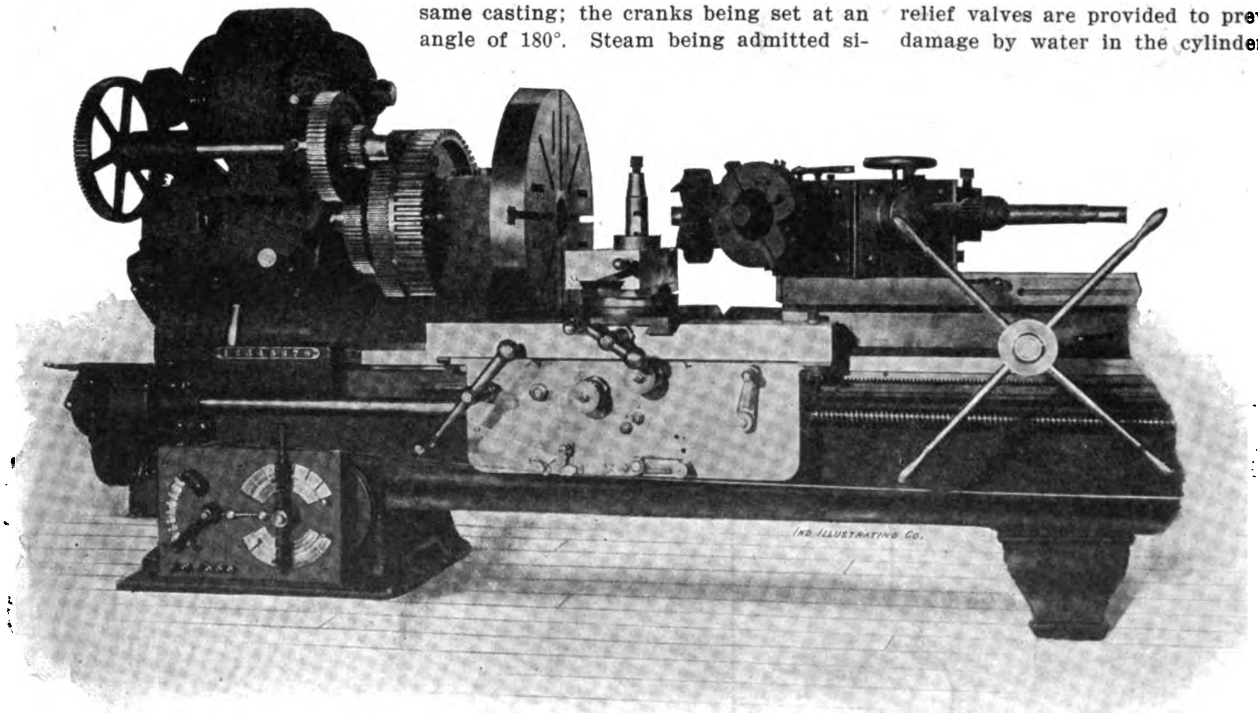

FIG. 1.—MOTOR DRIVEN ENGINE-LATHE.

COMPACT GENERATING SET.

Fig. 2 depicts a 5 x 4-in. enclosed double upright engine and standard 12-kw. 4-pole generator built by the B. F. Sturtevant Company, of Boston, Mass. The engine is of the type originally designed for the work of forced draft fan propulsion on the vessels of the United States navy. The cylinders are placed side by side in the same casting; the cranks being set at an angle of 180°. Steam being admitted simultaneously to the top of one cylinder and the bottom of the other, the reciprocating parts are balanced in their movements and high speed is made possible. The cylinders are of large diameter as compared with the stroke, in order that the power may be developed at high rotative but moderate piston speed. The steam admission to both cylinders is regulated by a single piston valve, under the control of a shaft governor. All moving parts subject to friction are of steel and the bearings of ample size. Automatic relief valves are provided to prevent any damage by water in the cylinder. Complete sight-feed oiling arrangements from a single oil tank connect with all of the bearings, and the frame is so constructed as to enclose all running parts, while still

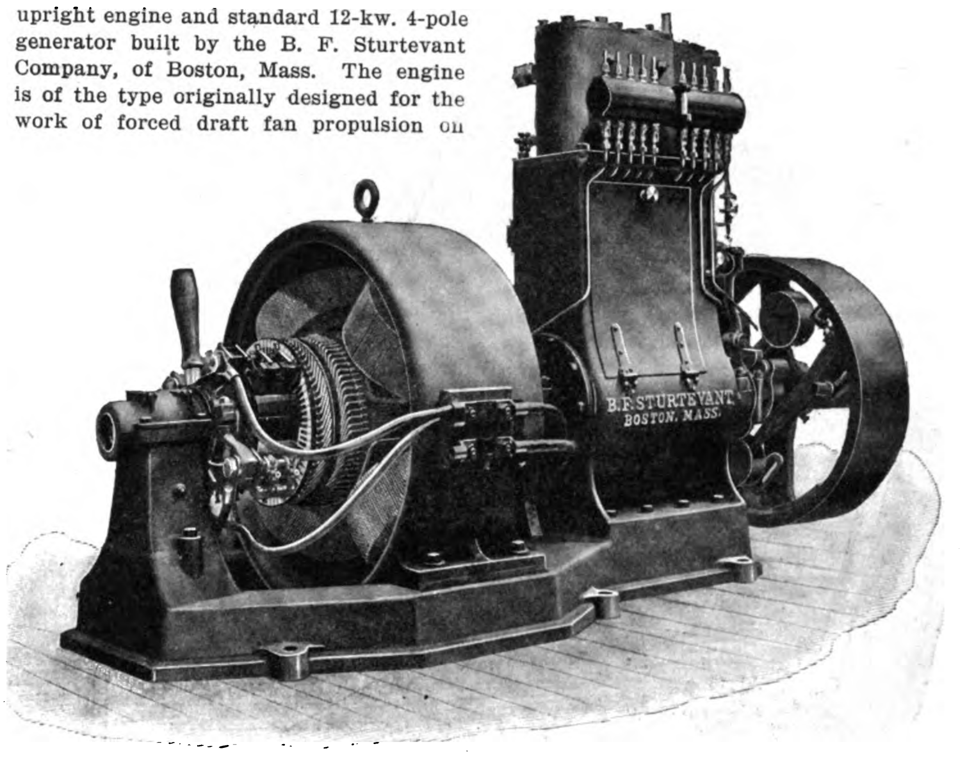

FIG. 2.—DIRECT-COUPLED 12-KW. GENERATOR.

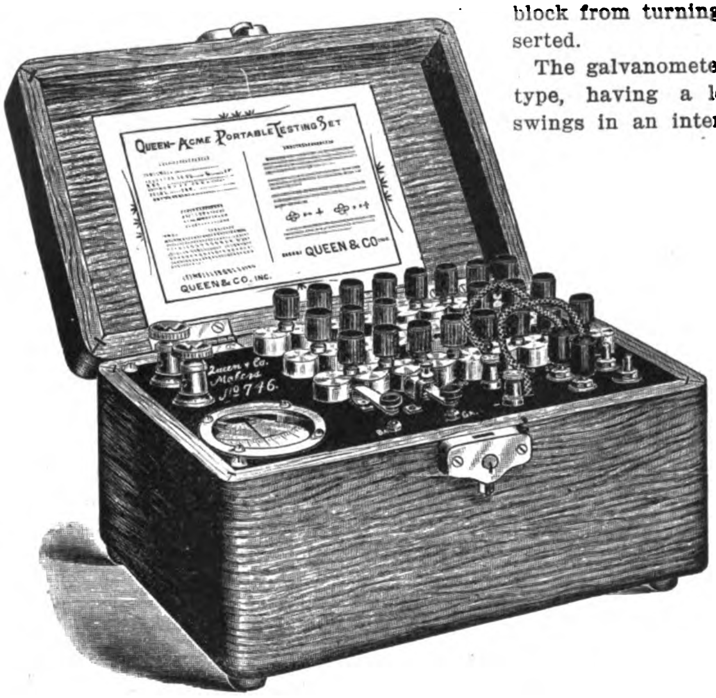
leaving them accessible by opening a door. The magnet frame of the generator is of cast steel, and the shape of the pole-pieces and proportions of magnetic field and armature are said to insure sparkless operation under all changes of load. The armature is of the barrel-wound type. The cast-iron flange, bolted to the armature spider at each end of the core, forms a support for the projecting ends of the coils. Ventilation is effected by the use of specially constructed vanes, forming air ducts between the laminations of the core. Carbon brushes are used exclusively and are mounted in holders of the sliding socket type, arranged for easy adjustment.

ACME PORTABLE TESTING SET.

The latest form of the Queen Acme Portable Testing Set, illustrated herewith, embraces many important changes in construction and detail. An improvement in the construction of the metal blocks of the Wheatstone bridge and rheostat is shown in Fig. 4. Ordinarily the block is held to the rubber plate by the threaded end of the small rod screwed into the block and the threads being liable to oxidation, a poor contact ensues. In the construction used by Queen & Co., Philadelphia, this objectionable feature is overcome by using part of the block itself extended through the rubber plate to take the check nut below. A small rod, to which the end of the wire comprising the resistance coil is soldered, is also soldered into the bottom of the brass block. This gives a complete soldered circuit from the plug contact through one block and rod with its resistance coil, back through the end rod and block, and succeeding plug contact. The bottom of the metal block is also provided with a knurled surface as shown at K, so that the little corrugations will be forced into the rubber plate, securely fastening it, and preventing the block from turning when the plug is inserted.



Queen-Acme Portable Testing Set
Queen & Co.
Queen & Co. Inc.
Queen & Co. Makers
No 2746.

FIG. 3.—ACME PORTABLE TESTING OUTFIT.

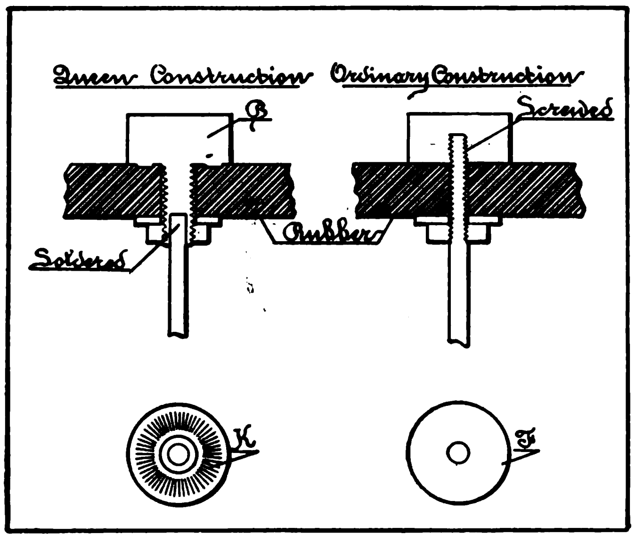


FIG. 4.—DETAILS OF PLUG BLOCKS.

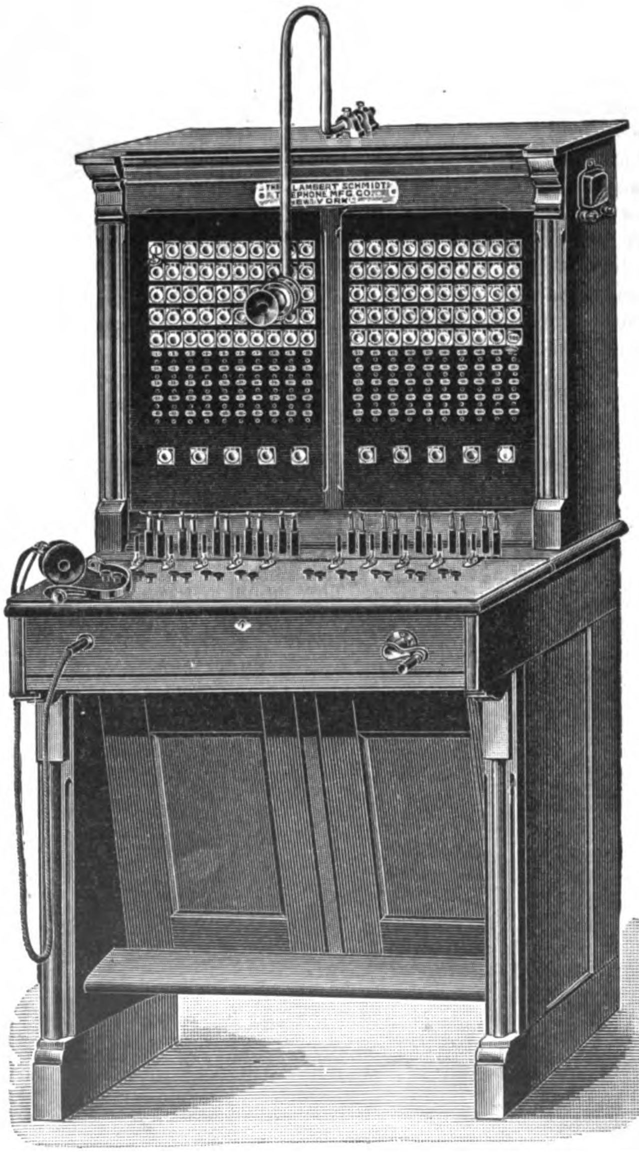
The galvanometer is of the D'Arsonval type, having a long, light coil which swings in an intense magnetic field, resulting in a high degree of sensitiveness. The system is so balanced that the set can be used in any position without impairing the accuracy of the indications. It is deadbeat and has a uniform scale which can be calibrated, so that the instrument can be used in insulation tests, the scale reading representing the insulation resistance. The battery consists of four special dry cells, any or all of which may be used as desired. The batteries have a large current capacity and a high e.m.f. and are said to give better results than the silver chloride cells heretofore used. The makers furnish this set enclosed in a finished oak case, and it is accompanied by a special circular describing the various details of the set and the different measurements which may be made with it.

PRIVATE TELEPHONE SYSTEMS.

The Manhattan Hotel, New York City, is elaborately equipped with labor-saving devices, not the least of which is the telephone system installed by the Lambert-Schmidt Telephone Manufacturing Company of New York City; which consists of wall and desk telephones connected by a common battery system to the 100-drop switchboard shown by Fig. 5. The method of calling is to remove the receiver from the hook, which automatically raises the line drop at the switchboard, this drop staying in that position until the operator



The Lambert Schmidt Telephone Mfg Co. New York

FIG. 5.—100-DROP TELEPHONE SWITCHBOARD.

at the switchboard inserts an answering plug in the proper line jack. The operator then throws down the listening cam, ascertains the connection desired, inserts the calling plug in the jack of the desired number, throws down the ringing key connected with this calling plug and signals the telephone. When through talking, hanging up the receiver at either station raises the clearing-out drop corresponding with the pair of plugs in use and this drop remains in that position until the correct pair of plugs is withdrawn. In the basement is located a battery closet for supplying current for the entire telephone system and an alternating current motor-generator, also in the basement, is used in signalling the telephone stations from the switchboard. The wall telephones consist merely of a transmitter, double-pole receiver, polarized ringer and automatic switch-hook, mounted in a hardwood box. The desk telephones are of the all-metal portable type.

ALCOHOL AND GASOLINE TORCHES.

Figs. 6 and 7 show a torch which the Clayton & Lambert Manufacturing Company has recently added to its line. The company also manufactures an alcohol torch of pocket size, somewhat similar in appearance to the one shown, the tank of which is drawn from heavy brass and is free from seams, having an adjustable blow pipe screwing up or down on the burner tube, together with a screw cap for making the torch air tight when not in use. The torch illustrated by Fig. 7 burns either alcohol or gasoline. An air blast is passed through a chamber charged with gasoline or alcohol, which is said to yield a much stronger fire than the usual type. This torch is also of pocket size, and is provided with a hook so that it may be hung up and used as a lamp when the blow pipe is not used. Both torches are nickel-plated and polished.

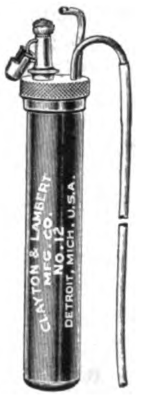


FIG. 6.

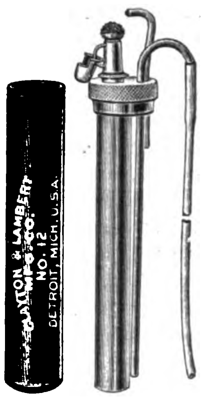

FIG. 7.

ELECTRICALLY-DRIVEN BENDING ROLLS.

The bending rolls illustrated by Fig. 8 are made of solid wrought iron forgings arranged in pyramid form and have a capacity for bending plates up to 12 ft. in width and ⅝ in. thick. The lower rolls are geared together while the upper or bending roll is revolved by the friction of the plate in passing through. It has a hinged bearing at one end which may be turned down out of the way, while the other end has a long shank extending to a third support which retains the roll in position for the removal of rings or flues. The machine is firmly tied together by a heavy cast-iron bed plate, and is very strongly geared. Suitable levers and clutches are conveniently placed for the quick and easy control of all the operations. The rolls are driven by an 18-h.p. reversible, constant-speed motor built by the Bullock Electric Manufacturing Company, of Cincinnati, Ohio. The field magnet consists of a circular yoke of special steel, and pole-pieces built up of soft sheet steel stampings securely bolted to the yoke. The shape of the punchings is said to be such as to produce saturated pole-faces resulting in sparkless commutation. The field coils are machine wound and are slipped over the poles before they are bolted to the yoke. The armature core discs are annealed and then japanned. They are held firmly together by malleable iron end plates. For controlling the motor, an automatic rheostat is used which prevents the operator from throwing on the full current too quickly.

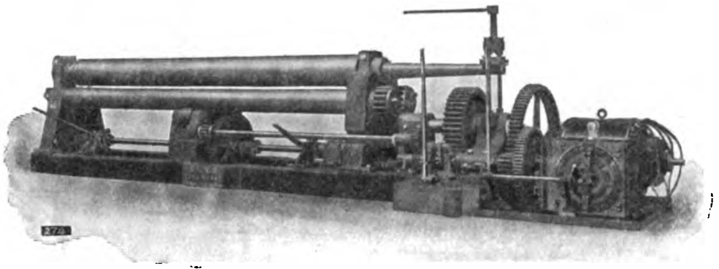

FIG. 8.—MOTOR-DRIVEN BENDING ROLLS.

A NEW ELECTRO-MECHANICAL SWITCH.

Fig. 9 illustrates a substantial electro-mechanical switch recently brought out by the General Incandescent Arc Light Company, New York.

This switch is designed to control a number of electric lights or motors, etc., from one or a number of distant points, without running the heavy mains to the points of control. Essentially the switch consists of a pair of solenoids held firmly in an iron frame, which acts as a return path for the magnetic lines of force and thereby increases the "pull" during the opening or closing of the switch. As the switch begins to move, the pull continually increases in strength until it reaches its maximum at the end of the stroke. This feature is advantageous in closing the switch, as the magnetism has to overcome the fraction of the contacts, and any hesitancy on the part of the switch to continue its motion at this moment would produce excessive arcing and pitting, thereby further hindering the entrance of the switch blades into the clips.

The lower core has a "lost motion" which is first taken up by the solenoid, producing a heavy hammer blow which opens the contacts and is followed by the strong accelerating pull of the magnet until the final position is reached. There is no danger, therefore, of the switch stopping or even hesitating after it has once started to close or open. The contacts are made very flexible so as to avoid danger of their sticking; they are also self-adjusting and give a perfectly flat rubbing surface. It will be seen from the illustration that the current is broken in two places on each pole, making six breaks in a three-pole switch. The illustration shows a 100-ampere three-wire switch such as is used on the Edison three-wire system, but the switches are also made single, double and triple pole for any capacity, voltage or system, either direct or alternating. The switch automatically cuts the solenoids out of circuit after its operation, so that there is no danger of their burning out and there is no arcing at the push-button. Secondary circuit-breaking contacts are provided to take the arc on each one of the contacts, so that the main contacts will not be burned or their temper reduced.

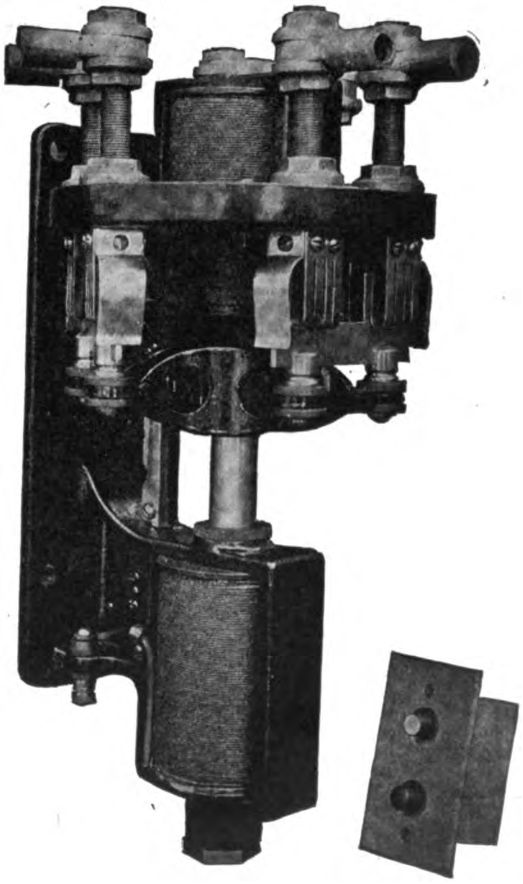

FIG. 9.—ELECTRO-MECHANICAL SWITCH.

As the coils can be wound for any voltage, batteries may be used to operate the switch if it is not desirable to use the lighting circuit for that purpose. The solenoids require from 150 to 200 watts to operate them. This method is often employed when it is desired for any reason to cut the lighting or power service entirely out of the building. The push-button switch is made in a very substantial manner and will fit into any flush receptacle. The buttons are made one black and one white, as usual, so that one may tell at a glance which to press in order to open or close the switch.

HOTEL TELEPHONE EQUIPMENTS.

Telephones have become almost as much of a necessity in model hotels or apartment houses as elevators or mail chutes. For this reason the new Hotel Essex in New York city has been equipped throughout with telephones and a switchboard, giving rapid communication between the office and every suite and hall; and placing the management within easy reach of every patron. The Ericsson Telephone Company, of New York, installed all of the apparatus. The room telephones are all of the hand microtelephone pattern shown by Fig. 12. Each is fitted with a flexible cord sufficiently long to enable a person to use it without rising from the bed. The office is called by pressing a contact in the handle of the microtelephone which throws the drop at the switchboard. The operator connects in the usual manner and if the person desires to converse with a patron in another part of the hotel the connection is made and the operator calls the party desired by ringing a small musical gong placed near the ceiling of the apartment. The halls are furnished with wall telephone sets of the type shown by Fig. 11. The telephone is fitted with the Ericsson receiver and transmitter and the office operator is called by merely removing the receiver from the hook. The switchboard is shown by Fig. 10. It embodies the finest mechanical construction and occupies very little space compared to its capacity. The system is operated by central batteries and is so arranged that when desired, a motor generator can be used instead of the battery for calling.

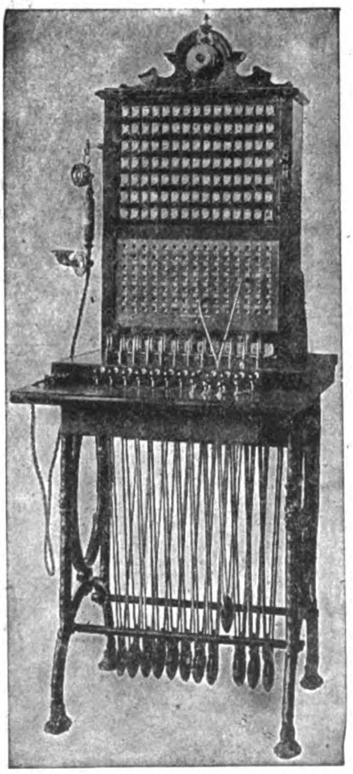

FIG. 10.—TELEPHONE SWITCHBOARD.

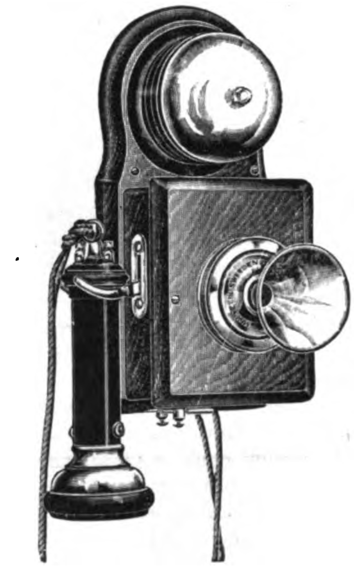

FIG. 11.—WALL TELEPHONE.

INTERRUPTER FOR X-RAY COILS.

A modified Wehnelt interrupter designed jointly by Dr. P. H. Cunningham and Elmer G. Willyoung, of New York, and manufactured by Mr. Willyoung is shown by Fig. 14. It is especially adapted for Roentgen ray coils, and is said to reduce the time of exposure necessary for photographing through the trunk or pelvis to about four minutes. Reversing the connections is said to make a rectifier of it for use in operating induction coils on an alternating current circuit. Its construction is clearly shown by Figs. 13 and 14. A glass jar 9 ins. deep by 6 ins. in diameter rests in a heavy base and carries a hard fiber cover in which are held the anode and cathode. A platinum wire, *P*, is brazed to the end of a brass rod, *R*, and passes through a lava tip, *T*. An adjusting screw, *A*, is provided which serves to expose a greater or less area of platinum beyond the lava tip. All the metal parts are enclosed in a hard rubber tube, *K*, which fits tightly into the central disc of the cover. The lead electrode is insulated in practically the same manner as the platinum although not as readily detachable, it being possible to remove and replace the latter very quickly. A worm of ⅜-in. lead pipe has a current of cold water circulating through it which serves to keep the apparatus cool when in operation. A vent in the cover permits the escape of the generated gas.

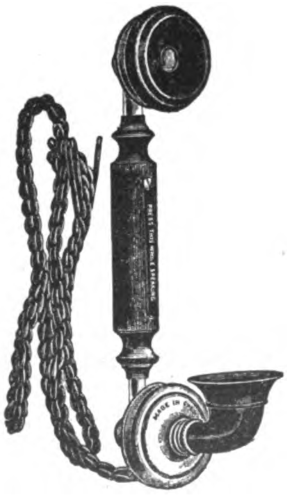

FIG. 12.—MICROTELEPHONE.

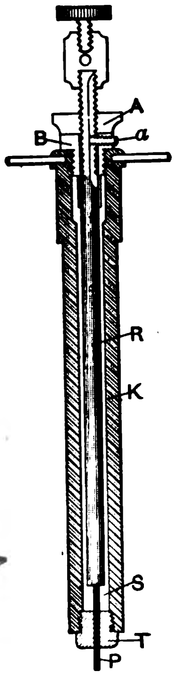

FIG. 13.

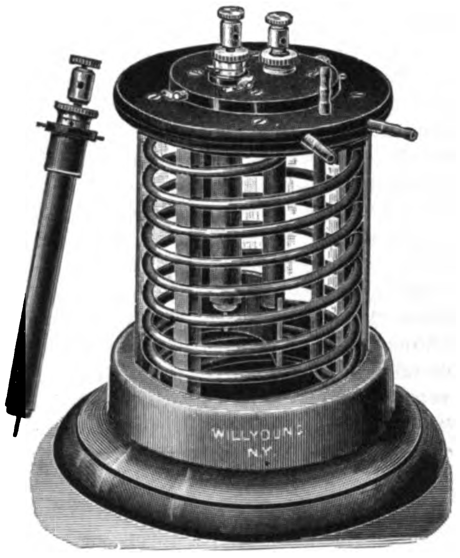

FIG. 14.—THE WEHNELT INTERRUPTER.

AN INSTRUMENT FOR TEACHING TELEGRAPHY.

An instrument designed to simplify instruction in telegraphy and to impart in a comparatively short time a knowledge of the Morse alphabet is illustrated by Fig. 15. The Omnigraph, as this instrument is called, consists of a baseboard on which are mounted an ordinary key and sounder and between them a disc furnished with teeth which are engaged by a spring contact adjacent to the disc. The disc is rotated by means of a small crank shaft geared with the disc shaft, while the spring contact being forced outwardly by the teeth and returning by its own elasticity makes and breaks the circuit, and an experienced telegrapher will immediately recognize in these makes and breaks the

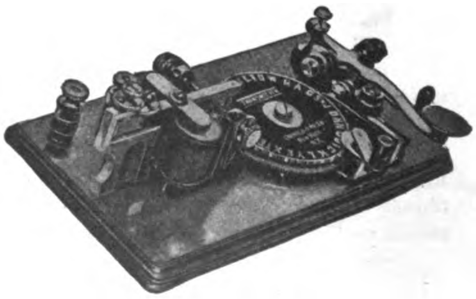

FIG. 15.—THE OMNIGRAPH.

dots and dashes of the Morse alphabet. An inspection of the disc shows that the teeth are arranged to spell the sentence "John quickly extemporized five tow bags" which includes all the letters of the alphabet. This message is transmitted slowly or rapidly and with a distinctness and faultlessness not attainable with the key in ordinary practice. When the student has learned to distinguish the different letters with sufficient proficiency he can learn to transmit messages by the key which forms part of the apparatus. This apparatus is manufactured by the Omnigraph Manufacturing Company, of New York City.

A NEW GATE VALVE.

The accompanying engravings illustrate the principal features of a gate valve made by the Darling Pump & Manufacturing Company, Limited, of Williamsport, Pa. The valve is interchangeable and is said to differ from other gate valves in that it has compound equalizing wedges, parallel seats and double revolving gate discs—three distinct advantages which the manufacturer claims are not embodied in any other single gate valve. The wedging mechanism operates between the gate discs; the discs themselves being capable of revolving independent of each other and of the wedging mechanism. A sectional view of a bronze mounted iron water valve is shown by Fig. 17, in which *A* is a clamp nut; *B*, a bonnet; *D*, a follower; *E*, a packing plate; *G*, gates; *K*, follower bolts; *M*, the upper wedge; *N*, gate rings; *O*, the bottom wedge, and *P*, the case rings. Opposite lateral guides, or grooves (shown by white lines above the part, *G*, Fig. 17), are provided upon which the peripheries of the gate discs roll, either up or down, in or out, in opening or closing the valve. Fig. 16 shows the parts of the wedging mechanism. The upper wedge is provided with a threaded hole to receive the stem, from which it receives motion to raise or lower the gate discs in opening or closing the valve; it is also provided with two lateral rounded bosses, or bearing lugs, upon which fit loosely the bearing sockets in the inner surfaces of the gate discs. The lower wedge hangs loosely upon the boss on one of the gate discs, and is provided with inclined faces co-acting with those upon the upper wedge. The operation of the valve in closing is as follows:

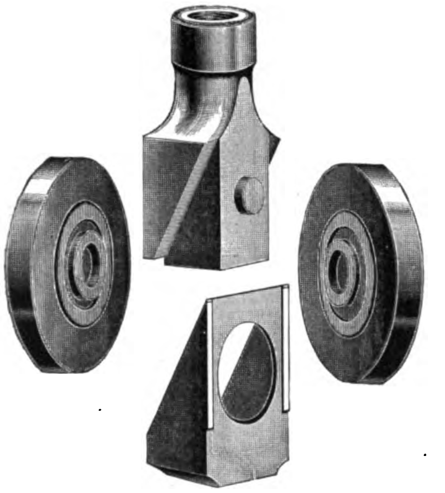

FIG. 16.—DETAILS OF VALVE GATE.

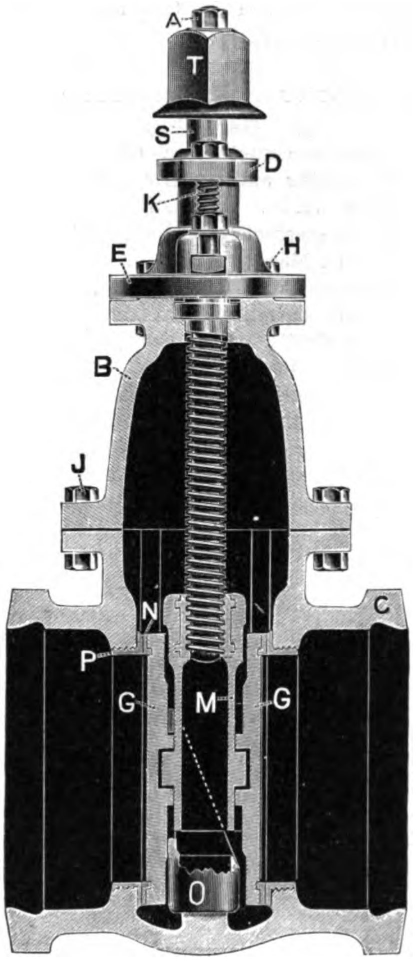

FIG. 17.—SECTION OF GATE VALVE.

The valve being open, the parts hang loosely upon the upper wedge; the wedges are extended or are in alignment and hence the gate discs are arranged with their outer faces at an interval less than the distance between the valve seats. The stem is turned and the parts descend free and clear of the seats until the lower wedge reaches the bottom of the case and its movement is checked; then the gate discs are in proper position opposite the ports or pipe openings of the valve; the further downward movement of the upper wedge causes the inclined surfaces of the upper and lower wedges to slide upon each other and thus contract the wedge block longitudinally and spread it laterally (bringing the pressure to bear over almost the entire surface of the gate discs instead of just on one small part), thereby forcing the gate discs firmly against the seats. In opening the valve a quarter turn is sufficient to release the upper wedge and a further movement of the stem raises the parts free and clear, leaving a straight passage through the valve.

The valves are said to work equally well with pressure on either side of the gates, and each valve is tested before shipment. These valves are at present made in sizes for pipe 2 ins. to 16 ins. diameter; with either hub ends, spigot ends, screw ends or flange ends; either iron body, bronze mounted; or all brass or all iron and for test pressures of 300 lbs. to 2200 lbs., depending upon the service required.

IMPROVED SIGN-LAMP RECEPTACLE.

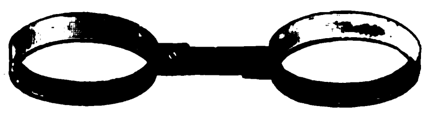

FIG. 19.—CLAMP HOOKS.

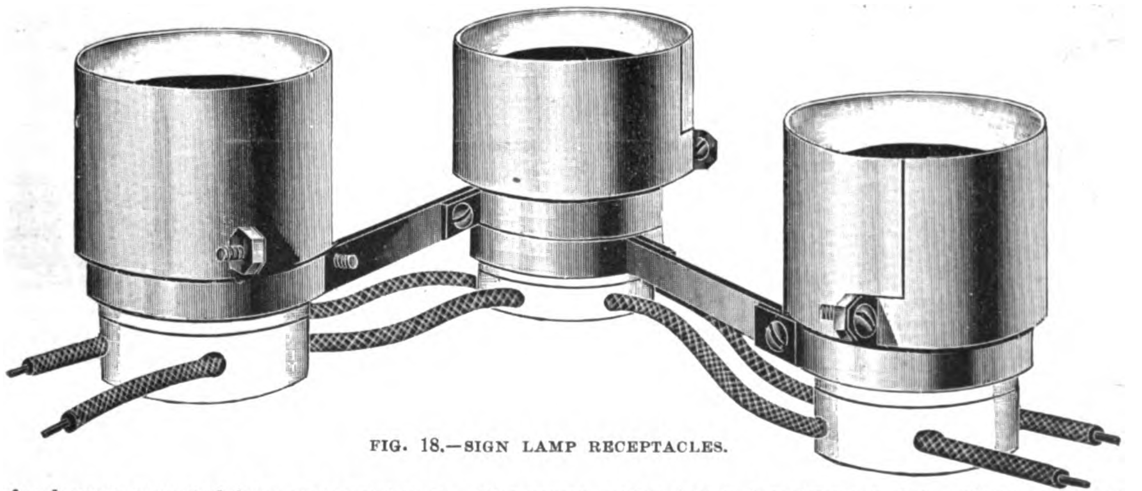

FIG. 18.—SIGN LAMP RECEPTACLES.

Figs. 18 and 19 herewith show the "Brewster universal" sign receptacle made by the Electric Motor & Equipment Company, of Newark, N. J., by means of which it is claimed any form of electrically illuminated sign or decoration for the interior or front of a building may be quickly made up and changed at will at comparatively small expense. The receptacles are linked together by S-shaped clamp hooks which bind firmly about the receptacles, clamping the whole structure into a rigid outline of any design or proportion desired. For in-door use the receptacles may be readily wired, using the contacts projecting at the back of the main receptacle. For out-door use in an exposed position where weatherproof construction is desirable, the wires are run through openings in the contact cap provided for that purpose. The space between the wires and the holes may then be filled in with some waterproof compound, and a thoroughly water-tight and safe construction obtained. As an additional protection to the lamp and socket when used in exposed positions out of doors, a metal guard is provided, which is adjustable upon the projecting shoulder of the receptable and which is said to make a practically water-tight junction between the metal cap and the bulb of the lamp. Fig. 19 shows one of the braces and Fig. 18 illustrates the application of the device.

A NEW TUBE CLEANER.

A novel tube cleaner, which is practically a little engine operated by steam or compressed air, is shown by Figs. 20 and 21 and is manufactured by the Power Specialty Company, of Buffalo, N. Y. At the end of what would be the piston rod of a steam engine is a small iron vibrator which oscillates very rapidly. The apparatus is connected by a steam hose to an adjacent boiler and is then introduced at the front end of the boiler flues to be cleaned. Under a steam pressure of 40 to 50 lbs. the machine makes 800 to 1,000 vibrations a minute, which, while sufficient to loosen and detach the scale, is not violent enough to in any way injure the tube. Fig. 20 shows the operation of the cleaner in a horizontal tubular boiler. With slight variations and the addition of a simple feeding device the cleaner is said to cope successfully with the task of cleaning light or heavy scale from water tube boilers. The vibrator in this case carries a sharp head, the function of which is to cut and shatter the scale as shown in Fig. 21; the cutter is so guarded that the sharp edge cannot make the slightest indentation in the tube. The method of operation also differs in the water-tube boilers in that a feeding device works the cleaner through the tube. This is accomplished by attaching the machine to the end of a pipe as long as the tube to be cleaned, and connecting this pipe with the steam hose. A collar with a removable lip is fitted to the boiler front, and a long screw with a hand wheel slides over the pipe and is fastened to it. The revolving wheel feeds the machine into the tube, the spiral working over the lip in the collar, and four jets of steam eject the broken scale at the open end of the tube as fast as it is detached.

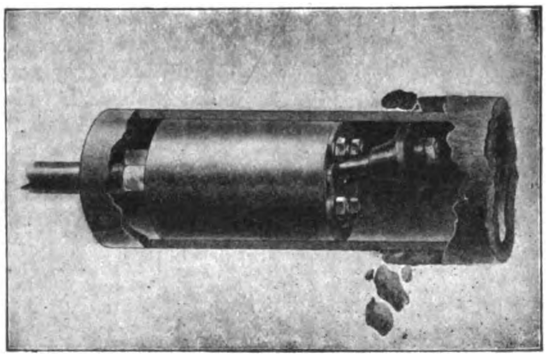

FIG. 20.—CLEANER IN HORIZONTAL TUBULAR BOILER.

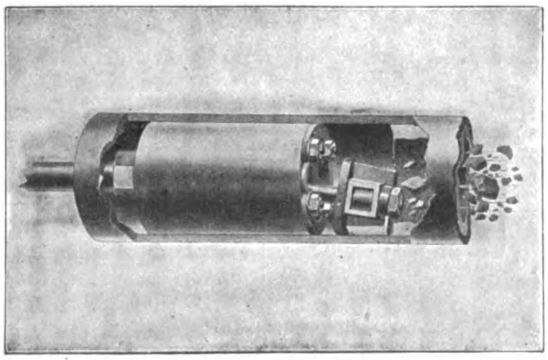

FIG. 21.—CLEANER IN WATER TUBE BOILER.

DIRECT-CONNECTED GENERATOR AND TURBINE.

A notable combination of direct-connected turbine and electric generator is shown by Fig. 24. The plant was installed for the Massachusetts Chemical Company at Walpole, Mass., by the Thresher Electric Company, of Dayton, Ohio, the turbines were furnished by the Stilwell-Bierce & Smith-Valle Company of the same city. Fig. 22 is an outline sketch of the generator and turbine, showing the manner of connecting the shafts of the two. The arrangement of the oil pockets and bearings are shown in Fig. 24, and a full view of the generator is given by Fig. 23. It will be noted that the generator is mounted on top of the turbine, the object being to economize space, and at the same time to obtain the simplest possible mechanical connection between the dynamo and the turbine. The wheel shown operates under 14-ft. head and develops about 115 horse-power, maintaining a speed of 150 r.p.m. It is set in a steel flume having cast-iron heads, and the water is conveyed to the flume by a steel feeder pipe. The flume itself stands on I-beams across the pit, with the usual draft-tube leading from the wheel to the tail water.

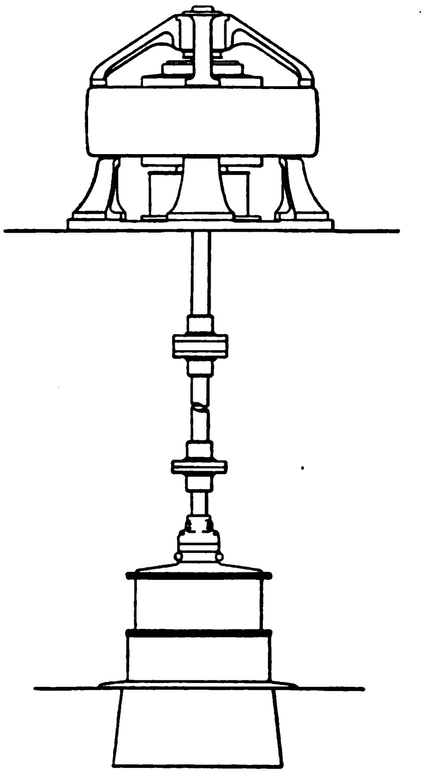

FIG. 22.—ARRANGEMENT OF TURBINE AND GENERATOR.

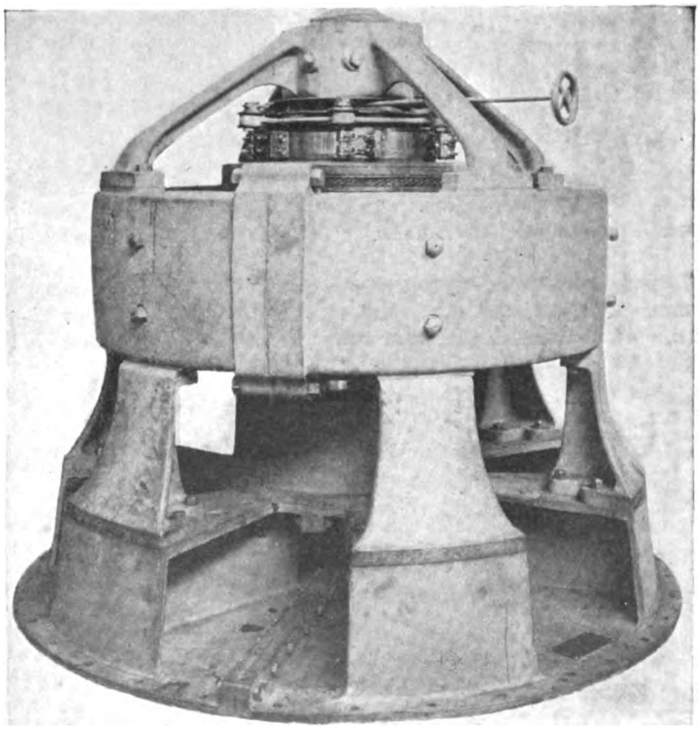
Certain original features are embodied in the construction, among them a flexible coupling on the shaft between turbine and generator, permitting free longitudinal action and making the machine self-contained and supported separately on its own thrust bearings. These are composed of several annular rings about the shaft,



FIG] 23.—VIEW SHOWING MOUNTING OF GENERATOR.

which bear on a number of babbitted projecting surfaces. The shaft of the turbine may be varied in length, depending upon the head of water, and having the generator either over the penstock or over the head of the tail race, the flexible coupling taking care of any expansion or contraction of the shaft without throwing any compression strains on the turbine shaft. The lower and upper bearing of the generator are overhung, having a heavy umbrella-shaped form projecting into the oil pocket containing the lubricant. An oil bath surrounded by a water jacket encloses the annular rings, and projecting surfaces mentioned above.

The circulating ducts with which the pocket is provided keep the oil in constant circulation, and any excessive heat is dissipated by the surrounding water jacket. The plant is provided with 80-kw. and 125-kw. machines running at 150 and 200 r.p.m., respectively, each giving an e.m.f of 600 volts. The advantages claimed for this method of connection are: First. the moving parts are simpler, and presenting to the whole revolving mechanism less inertia (upon which the regulation largely depends), they respond more quickly and with greater harmony to the controlling device, which is connected to the gates that regulate the turbine. Second, the generators dispense with the racket and vibration produced by gearing from turbines to horizontal generators. Third, there is greater efficiency of transmission. Fourth, the unit is more certainly regulated for speeds of variable loads, and since it takes less space and foundation, no provision is needed for any movement of the commutator along the length of the brushes, since these generators do not need lateral movement of the commutator to produce uniform wear.

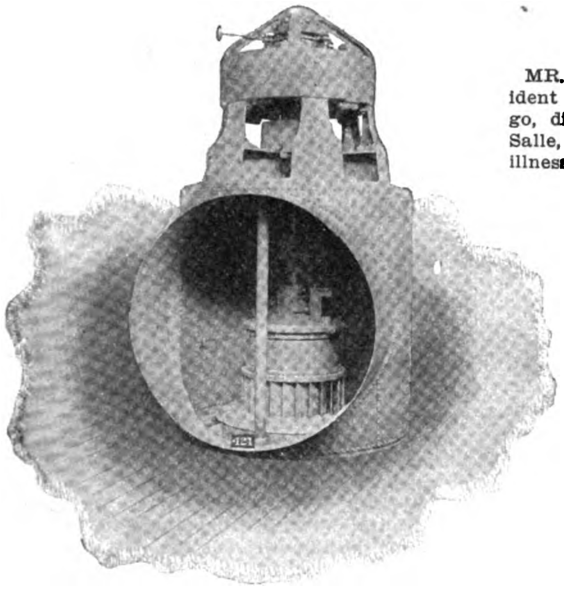


FIG. 24.—DIRECT-CONNECTED GENERATOR AND TURBINE

LEGAL NOTES.

MAGNESIA BOILER AND PIPE COVERING.—The Keasbey & Mattison Company, owners of patents for magnesia boiler and pipe covering, have instituted suit against the Philip Carey Manufacturing Company to restrain this company from making and selling coverings for boilers and steam pipes containing more than 50 per cent of magnesia, and especially such coverings containing 85 per cent of magnesia.

RICE BRUSH-HOLDER.—A preliminary injunction has been granted to the Thomson-Houston Electric Company (General Electric Company) in the suit against the Lorain Steel Company for infringement of the Rice brush-holder patent No. 394,999. The patent covers the combination of a brush follower pressed toward the brush by means of a spring and having an auxiliary spring interposed between the follower and the brush itself.

TROLLEY CONTACT SPRINGS.—Judge Wanty, sitting in the United States Circuit Court of the Western District of Michigan, Southern Division, has given a decision in favor of the General Electric Company in a suit brought by that company against the Starr Brass Works for infringement of the Anderson patent No. 412,155. The patent covers the use of metallic conducting brushes located between the hub of the trolley wheel and the trolley fork, on the inside of the fork.

OBITUARY.

MR. CHARLES SCHLESINGER, vice-president of the Alden Electric Company, Chicago, died at the home of his parents at La Salle, Ills., on March 30, after a prolonged illness.

MR. ULRICH EBERHARDT, president of the company which trades under the style of Gould & Eberhardt, died at his home in Newark, N. J., on March 31. Mr. Eberhardt was born in Switzerland 50 years ago.

HENRY HERBERT LUSCOMB, secretary and superintendent of the Johns-Pratt Company, of Hartford, Conn., and one of the pioneers in the development of trolley-wire insulators and molded insulation, died on April 17, after an illness of only a week. Mr. Luscomb was only 35 years old at the time of his death. He became connected with the Johns-Pratt Company in 1892 when the manufacture of molded insulators for trolley-wire service was in a more or less embryonic condition. At this time the Johns-Pratt Company absorbed the Gould & Watson Company, with which Mr. Luscomb was connected at the time. Mr. Luscomb took charge of one of the departments of the Johns-Pratt Company as foreman, and soon rose to the position of superintendent; he was elected secretary of the company in 1896, which position he held up to the time of his death.

PERSONALS.

MR. ROBERT L. McOUAT, Indianapolis, Ind., was in Chicago last month on a business trip.

MR. V. C. GRAU, formerly connected with Robert L. McOuat, has been appointed western agent for J. Jones & Son, New York, and Queen & Co., of Philadelphia, with headquarters at 934 Monadnock Building Chicago.

MR. H. C. SPALDING has been appointed New England manager for the American Stoker Company, and will be pleased to meet the many friends of himself and his company at the Boston office, 176 Federal Street.

MR. WILLIAM R. HEWITT has been appointed permanent Chief of the Fire Alarm Telegraph system for the city of San Francisco. Mr. Hewitt has been practically the head of the fire alarm and police telegraph system for the past 13 years.

MR. L. E. FRORUP, who has been identified with Schiff, Jordan & Co., has resigned his position with that firm to accept the position of general sales agent for the Falcon Electric Manufacturing Company, New York. Mr. Frorup assumes his new duties on May 1st.

MR. T. B. BOYLES, of the General Electric Company's engineering staff, read a paper on switchboards at the April meeting of the Cleveland Electric Club, which was held April 3. Mr. Boyles was for a long time chief assistant to Mr. E. M. Hewlett, who is the chief engineer of the General Electric Company's switchboard department; the paper, therefore, was authoritative and of high value.

MR. W. S. BARSTOW, general manager of the Edison Electric Illuminating Company, of Brooklyn, and president of the electrical section of the Brooklyn Institute, delivered a lecture last week on the later developments of the twentieth century. Mr. Barstow reviewed in a most interesting manner the recent improvements and inventions, and expressed optimistic views concerning future developments.

MR. STEPHEN L. COLES, for a number of years managing editor of the "Electrical Review," has resigned his connection with that paper to engage in commercial work in the electrical field. Mr. Coles has made a host of friends by reason of his amiable personality and the excellent work which he has done in the newspaper field during the past 10 or 12 years, and will doubtless continue in commercial directions the success which he has achieved in journalistic work.

MR. CHARLES H. DUELL, recent United States Commissioner of Patents, has resigned his position to resume his law practice, and has established headquarters in the St. Paul Building, New York City. Associated with Mr. Duell are Messrs. Wm. A. Megrath, who has been connected with the Patent Office for 15 years, and Frederic P. Warfield, who has been assistant examiner in the Patent Office for several years; these three gentlemen will practice under the firm name of Duell, Megrath and Warfield.

TRADE PUBLICATIONS.

GARTON LIGHTNING ARRESTERS. Garton-Daniels Company, Keokuk, Iowa.—Catalogue No. 24 of the well-known Garton lightning arresters for electric lighting, power and street railway circuits.

CHLORIDE ACCUMULATORS IN MILLS AND FACTORIES. The Electric Storage Battery Company, Philadelphia, Pa.—Bulletin No. 64 describing accumulator installations in textile mills and a coffee and spice establishment.

STANDARD DIRECT-CURRENT CEILING FANS. The Robbins & Myers Company, Springfield, Ohio.—Circulars Nos. 15 and 16, illustrating and describing the well-known Robbins & Myers ceiling fan motors, styles A and B.

INDUCTION MOTORS. General Electric Company.—This is bulletin No. 4248, superseding bulletin No. 4209, and containing illusarations and descriptions of General Electric induction motors with and without starting resistances.

THE AUTOMOTONEER. Garton-Daniels Company, Keokuk, Iowa.—A folder illustrating and describing an arrangement devised for attachment to any of the Type K controllers, the function of which is to prevent "fast feeding" by the motorman.

PELTON WATER WHEELS. Pelton Water Wheel Company, San Francisco, Cal.—This is a preliminary folder containing complete data relating to Pelton water wheels of all sizes from six inches up to six feet in diameter, and for heads ranging from 10 to 1000 ft.

BIPOLAR DYNAMOS AND MOTORS. Thos. P. Benton & Son, La Crosse, Wis.—A pamphlet catalogue illustrating and describing a line of bipolar machines of the well-known Manchester type. These machines are built in sizes ranging from 1¼ to 75 kilowatts.

ELECTRICAL HEATING APPARATUS. American Electrical Heater Company, Detroit, Mich.—Catalogue No. 17, containing illustrations and prices of a complete line of electrical heating apparatus, which includes soldering irons, disc heaters, foot warmers and glue pots.

EXHAUST FAN AND MOTOR OUTFITS. The Emerson Electric Manufacturing Company, St. Louis, Mo.—This is bulletin No. 3029, displacing bulletin No. 3017, and describing the Emerson line of alternating-current and direct-current fan motor equipments for ventilating purposes.

HIGH-VOLTAGE TESTING SETS. Stanley Electric Manufacturing Company, Pittsfield, Mass.—This is bulletin No. 115, describing and illustrating an elaborate arrangement for giving high voltage tests of insulators, insulating materials, etc. The apparatus described gives facilities for making insulation tests up to 120,000 volts.

MICA MINING. Eugene Munsell & Co., New York and Chicago.—This is a handsomely-illustrated pamphlet containing pictures which portray various features of mica mining, including some very interesting photographs of "open cuts," and a picture of the great "Sergeant D" mine in India. Other pictures show Indian laborers cleaning and trimming the mica, and sorting it into packages.

DIRECT-CURRENT VOLTMETERS AND AMMETERS. Thos. P. Benton & Son, La Crosse, Wis.—A folder containing illustrations and price lists of direct-reading voltmeters and ammeters, a feature of which is a wide scale in the neighborhood of the normal running point, the divisions narrowing down at each end of the scale of the voltmeter, and at the starting end of the ammeter scale.

ELECTRIC HEATING APPARATUS. The Simplex Electrical Company, Cambridgeport, Mass.—This is Catalogue No. 6 of electric heating utensils, the character of which ranges from foot-warming pads to street-car heaters, and from boilers to the heaviest laundry irons. The line of cooking utensils includes coffee pots, five o'clock tea sets, griddle-cake discs, chafing dishes and sheet-metal ovens.

THE AUTOSPARKER. Motsinger Device Manufacturing Company, Pendleton, Ind.—This is a compact little catalogue of vest-pocket size, in which is illustrated and described the small dynamo for gas engine ignition which is known as the "autosparker." The feature of this machine is an automatic device which maintains the speed of the dynamo armature practically constant, regardless of variations in the speed of the gas engine fly-wheel from which it is driven.

TELEPHONES AND SWITCHBOARDS. Sun Electric Manufacturing Company, Philadelphia, Pa.—An unusually handsome catalogue of the telephone apparatus manufactured by this well-known company. The catalogue is profusely illustrated, and contains descriptions of the company's entire line. Among other attractive features of its line is the standard toll box telephone for common battery systems, which is arranged so that when the door of the box is opened the relay is connected across the line and automatically shows whether or not the line is busy.

TELEPHONE PAY STATIONS. Baird Manufacturing Company, Chicago, Ill.—A pamphlet devoted to the Baird telephone pay stations, the salient feature of which is a case having a number of slots in the cover, one slot for five-cent pieces, another for tens and so on, and in line with each coin slot, a lever which is pulled forward when the coin is placed in the slot and registers the amount deposited. A rejector is provided which throws out coins deposited in the wrong slot or slugs differing in size from the coin which may be inserted in an attempt to cheat the machine.

PUMPING MACHINERY. The Stilwell-Bierce & Smith-Vaile Company, Dayton, Ohio.—This is catalogue No. 22, containing illustrations and data relating to Smith-Vaile duplex boiler-feed pumps, of both the outside-packed and ordinary types; pressure pumps, pumping engines, marine feed pumps, triplex pumps, pumps for handling viscous and semi-fluids, such as sugar-house product, tar, wet cement, etc., combined air pumps and jet condensers, pumps and surface condensers, etc. The catalogue is handsomely illustrated and contains a considerable amount of general information which is of value to pump users.

INTERIOR TELEPHONES. The Simplex Interior Telephone Company, Cincinnati, Ohio.—A vest-pocket catalogue of interior telephones and auxiliary apparatus. Prominent in this line is an extremely convenient telephone outfit for apartment houses comprising a telephone switchboard to be mounted in the hallway and telephone equipments in each of the apartments. The switchboard consists of a simple arrangement of push buttons, one under each name plate, together with a telephone transmitter and receiver mounted in the center of the board. The arrangement is designed to displace the crude speaking tube outfit which is now extensively used for this class of service.

BUSINESS NEWS.

E. B. LATHAM & CO., New York, have removed their headquarters from 136 Liberty Street to 39 Vesey Street.

KNICKERBOCKER TELEPHONE & TELEGRAPH COMPANY, New York, has removed its general offices from 418 Broome Street to 100 Broadway.

C. O. MAILLOUX, the well-known consulting electrical engineer, has removed his offices from the American Tract Society Building to 76 William Street, New York.

THE BURT MANUFACTURING COMPANY, Akron, Ohio, reports that another Cross oil filter has been added to the equipment of the Hoover, Owens & Rentschler Company, of Hamilton, Ohio, manufacturers of the well-known Hamilton-Corliss engines.

THE CLING-SURFACE MANUFACTURING COMPANY, Syracuse, N. Y., will have a working exhibit in the belting section of the Machinery Building at the Pan-American Exposition showing belts treated with Cling-Surface running slack beside untreated belts running tight.

THE CENTRAL ELECTRIC COMPANY, Chicago, Ill., has been appointed sales agent for the Hylo baby filament lamp, which was described in the December number of the American Electrician. The company carries a large stock of line construction material, and is able to make prompt shipments.

THE FARR TELEPHONE & CONSTRUCTION SUPPLY COMPANY, Chicago, has found its quarters at 357 Dearborn Street too small and cramped to fill the demands of its business, and has consequently moved into larger quarters at 118-120 Jackson Boulevard, on the ground floor of the Electrical Building.

AN IMPORTANT COMBINATION.—The Bullock Electric Manufacturing Company, of Cincinnati, and the Wagner Electric Manufacturing Company, of St. Louis, have effected a combination of their selling organizations under the management of Mr. E. H. Abadie, formerly sales manager of the Wagner Company.

THE STANDARD AUTOMATIC GAS ENGINE COMPANY, of Oil City, Pa., has received an order from the Tintern-Manor Water Company, of Red Bank, N. J., for four double-acting tandem gas engines of 300 horse-power each, which will be furnished under an economy guarantee of 1 lb. of coal per brake horse-power-hour.

THE CUTLER-HAMMER MANUFACTURING COMPANY, Milwaukee, Wis., has opened a branch office at 403 Fisher Building, Chicago, in charge of Mr. C. H. Norwood. For the convenience of eastern customers the company is carrying a stock of standard apparatus at its Westfield (N. J.) factory, and at its eastern office, 136 Liberty Street, New York.

J. H. BUNNELL & CO., of New York City, are rapidly completing the equipment of their new factory, which will have a much larger floor space and greater facilities in the way

A COMMUTATOR NECESSITY.

The Only Article that will Prevent Sparking.
Will keep the commutator in good condition and Prevent Cutting.
Absolutely will not gum the brushes.

Sole Manufacturers,
909-100 Washington Street, CHICAGO.

of modern machinery than were contained in the Canal Street factory which was recently burned. The new factory will doubtless be completed and in full operation by the time this number of the American Electrician is issued.

JAMES McCREA & CO., manufacturers of steam specialties, have removed their headquarters from 11 and 13 South Canal Street, Chicago, to 67 West Washington Street, where they have a manufacturing floor space of about 5000 sq. ft., and a commodious office space. The firm's business for each month of the present year so far has been double the amount of business for the same months of last year.

THE HAINES & NOYES COMPANY, Chicago, manufacturer of high-grade telephone apparatus, has consolidated its sales department and factory at 118-132 West Jackson Boulevard and is prepared to fill all orders, large and small, promptly. The increased space will permit the company to manufacture telephone apparatus in larger quantities, and a large stock will be carried on hand at all times.

ELMER G. WILLYOUNG, New York City, has been compelled by growth of business to remove his headquarters from 112 Fulton Street to 11 Frankfort Street. At the new place Mr. Willyoung will have something over 1500 sq. ft. of space available for offices and draughting room, and ample space for a private testing laboratory which is being equipped with the latest types of instruments for making electrical measurements.

THE AMERICAN DISTRICT STEAM COMPANY, of Lockport, N. Y., is erecting five large buildings at its new manufacturing plant at North Tonawanda, N. Y. The company during the past three years has been unable to supply the demands made upon it for the construction of underground district steam heating systems, and is increasing its facilities in view of the amount of work now coming in and the large increase which is expected.

SPIES ELECTRIC COMPANY.—The firm of Spies & Co., Chicago, manufacturer of electrical specialties, has changed its name to the Spies Electric Company in order to avoid confusion with other firms doing business under a somewhat similar name. The company will continue at the old address, and has added to its line of work the manufacture of the entire line of bells and buzzers known to the trade as "bug-proof," under license from the Western Bell Works.

THE H. C. ROBERTS ELECTRICAL SUPPLY COMPANY, Philadelphia, Pa., has been compelled to increase its facilities in order to take care of its flourishing business in electrical specialties, and has accordingly leased a four-story store house. The company has just issued its usual monthly calendar blotter, which is fully up to the standard of the previous artistic efforts in this direction. The company has recently added to its already extensive list of good agencies the Gutmann watt-meter.

THE VILTER MANUFACTURING COMPANY, Milwaukee, Wis., reports among other recent important sales the following: J. P. Suberveille, New Iberia, La., three 15 x 36 Corliss engines; Plymouth Refrigerating, Water, Light & Power Company, Plymouth, Wis., one 30 x 20 Corliss engine; Standard Manufacturing Company, Appleton, Wis., one 13 x 20 Corliss engine; Dorschel, Schultz & Co., Chilton, Wis., one 12 x 30 Corliss engine; and Wm. Jacobs, South Bethlehem, Pa., one 10 x 30 Corliss engine.

FRINK REFLECTORS.—The merits of the Frink special patent window reflectors are well known throughout electric lighting circles, and we note with interest that these reflectors are not only used in some of the finest department stores in this country but are rapidly gaining in favor abroad. I. P. Frink, of New York, the manufacturer, reports that these reflectors are in use in the large department store of Tomas Mendirichaga, Monterey, Mexico, and that a large order has been received for the equipment of the show windows of one of the best-known stores in Dublin, Ireland.

LUNDELL MOTORS AT THE EXPOSITION.—Visitors to the Pan-American Exposition at Buffalo will be able to see the practical operation of Lundell motors in connection with printing presses and other machines used in the allied trades. Among other exhibits will be one of the John Thomson Press Company, whose job presses will be operated by a Lundell 10-hp. round-type motor; R. Hoe & Co. will drive all of their electrotyping machines by Lundell motors, and the Dexter Folder Company will have several machines and a Scott printing press operated by a Lundell motor.

THE LAMBERT SCHMIDT TELEPHONE MANUFACTURING COMPANY, New York, has just secured a contract for equipping the Majestic Hotel with a 400-drop switchboard equipment, this installation being the largest of its kind in New York. The common battery system will be used. The company has recently installed this same system in a number of factories, among these equipments being a 30-drop outfit in the Keuffel & Esser Company's factory, Hoboken, N. J.; a 30-drop equipment for Lehn & Fink, New York; and similar outfits for the Fulton Foundry & Machinery Works, Brooklyn, N. Y., and many others.

THE STURTEVANT FIRE.—The fire at the works of the B. F. Sturtevant Company, Jamaica Plain, Mass., on April 14, proved to be far less disastrous than was first reported. Only the engine and electrical departments were injured. The power plant was started up with but a single day's delay incident to renewing belts damaged by fire, and the en-

tire blower, heater, forge, galvanized iron and shipping departments with the foundry and pattern shop were in full operation on that day and shipments were going forward as usual. New offices were established on Monday morning in a nearby building and on Monday noon the business was running as usual.

THE COMMERCIAL ELECTRIC COMPANY, of Indianapolis, Ind., demonstrates its faith in the efficacy of electrically-driven machine tools by using in its own works a number of heavy engine lathes equipped with Commercial motors. These motors are built to give three speeds, and these combined with a simple system of gearing give the lathe head-stocks 12 speeds, varying from 2½ r.p.m. to 450 r.p.m. A feature of the motor control is that the three speeds are obtained without the use of any external resistance. The company is building a new pattern shop, and contemplates other extensions and improvements in this plant during the coming year.

THE BULLOCK ELECTRIC MANUFACTURING COMPANY, Cincinnati, Ohio, has acquired control of 15 acres of land directly opposite the present plant at East Norwood, Ohio, upon which tract the Norwood Foundry Company will erect a foundry building 200 feet long by 150 feet in width; a pattern storage house of fire-proof construction, 50 x 150 feet, three stories high; and a modern office structure. All these buildings will be built of buff pressed brick with steel frames and trusses to conform to the present buildings of the Bullock Electric Manufacturing Company. The foundry will be equipped with three electric cranes, the largest of which will have a capacity of 50 tons. The side bays, which will be 25 feet in width, will be served by hand traveling and jib cranes. This foundry, though separately operated, will primarily serve the needs of the Bullock Company.

LUNDELL DYNAMOS AND MOTORS.—The new large machine shops being erected at Elizabethport, N. J., for the Central Railroad of New Jersey, will be equipped exclusively with the well-known Lundell dynamos and motors by the Sprague Electric Company. The equipment will consist of three 100 kw. generators of 240 volts, to be direct-driven at 250 r.p.m. by Ball & Wood engines, and 75 motors of various sizes for driving the machine tools. In Government work Lundell motors and generators are used to a very large extent. Recent orders include seventeen motors of various sizes for the Norfolk Navy Yard; three 35-hp. motors for the Mare Island Navy Yard; four motors for the Boston Navy Yard, to be used on metal working machines, and five motors, one generator and a 2-kw. ventilating set for the Brooklyn Navy Yard. In addition to the Government orders, the Sprague Company reports the following sales: Steelton Light & Power Company, one 125-kw. belted generator; Columbia University, three 75-kw. engine-type generators; C. S. Ashley, one 125-kw. generator; Pittsburg Reduction Company, one 25-hp. and one 166 hp. motors; National Meter Company, one 37½-kw. engine-type generator; Chase Rolling Mill Company, one 125-kw. belted generator, and the Evansville Gas & Electric Company, one 150-kw. generator.

THE THRESHER ELECTRIC COMPANY, of Dayton, Ohio, has been incorporated under the laws of the State of West Virginia, with an authorized capital of six hundred thousand dollars ($600,000), for the manufacture and sale of all kinds of electrical machinery and appliances. This corporation succeeds the company of the same name of which Mr. Alfred A. Thresher has been the sole proprietor, and which he has incorporated for the purpose of providing more ample facilities for conducting the large and growing business which has been built up during the past eight years under his individual management. The company offers a complete line of direct-current apparatus for electric railways, lighting and power transmission, comprising generators, both direct-connected and belted, of the most approved design, exact in regulation at all points of load and economical in operation; a complete system of motors adapted to the varied requirements of industrial uses, including an entirely enclosed type said to have a very high efficiency, and marine generating sets of highest efficiency, designed to meet the severe requirements of the Government naval service. Plans are being prepared for extensive shops with a complete equipment, affording thoroughly modern facilities for manufacturing and testing.

Mr. Alfred A. Thresher, who is the dominant spirit of the enterprise, is a member of the American Institute of Electrical Engineers, of the Franklin Institute of Philadelphia, an associate member of the Society of Naval Architects and Marine Engineers, and a graduate of Denison University, where he obtained the thorough grounding in the principles of higher mathematics essential to the education of an electrical engineer. After graduation he spent more than a year abroad in travel and observation, and soon after his return established the business which he has brought to such successful fruition.

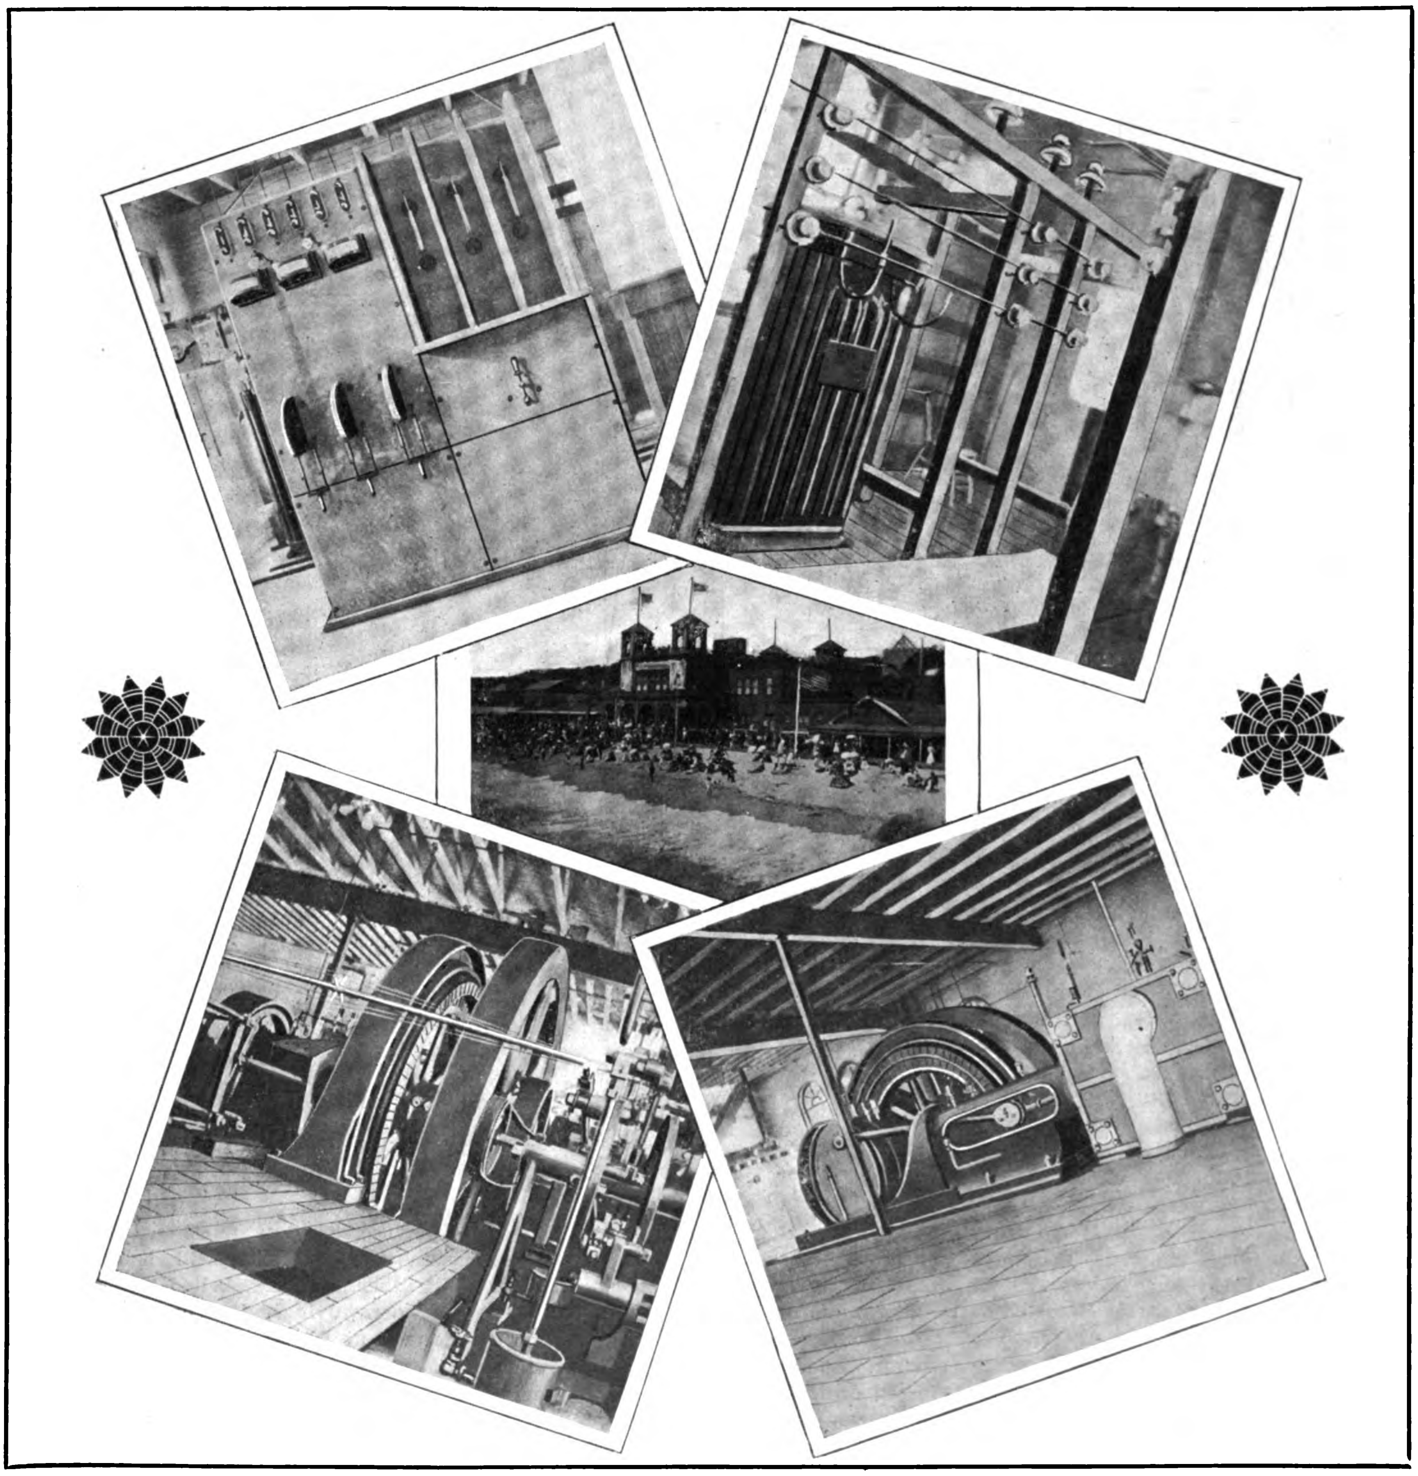
A STEAM-DRIVEN ELECTRICAL TRANSMISSION PLANT.

THE 22,000-VOLT SYSTEM OF THE UNITED ELECTRIC, GAS & POWER COMPANY AT SANTA MONICA, CALIFORNIA.

BY J. R. CRAVATH.

The plant of the United Electric, Gas & Power Company at Santa Monica, Cal., should be of considerable interest to owners and operators of small electric light stations because it offers a suggestion of what may be done in many other localities where several small electric lighting stations are within transmitting distance of one another. The generating station at Santa Monica is an economical steam plant which supplies electric lighting service at Santa Monica and also transmits current at 22,000 volts to electric light sub-stations at Long Beach, Terminal Island, San Pedro and Redondo. These sub-stations displaced small steam plants previously operated. The saving in fuel and labor is roughly 50 per cent as compared with the small plants previously operated.

The power house is located on the famous Santa Monica beach and adjoins the North Beach Bath House, to which it sells the warm salt water discharged from its condensers for the purpose of supply-



FIGS. 1 TO 4.—VIEWS IN THE SANTA MONICA STATION AND SUB-STATION.

ing the swimming tanks. It also supplies both heat and light to the Arcadia Hotel close at hand. The power station is on the beach just under the edge of the bluff. Condensing water is taken from the ocean through a pipe running out on the pier. The general plan of the power house and arrangement of machinery are shown in Figs. 5, 6 and 7. It was designed and built by Chas. C. Moore & Co., of San Francisco.

FIG. 5.—PLAN OF SANTA MONICA ENGINE-ROOM, AND END OF BOILER ROOM.

There are two Hamilton-Corliss engines, built by Hooven, Owens & Rentschler Company, Hamilton, Ohio. The large one, which is direct-connected to a 400-kw. alternator, is a cross-compound condensing engine, 34 and 18 x 42 ins., and runs at 100 r.p.m. It is provided with an individual Wheeler marine-type condenser. A Davis regulating valve permits the steam to be shut off from the high-pressure cylinder and the engine to be operated by the low-pressure cylinder alone on short notice, the change being accomplished by the movement of a single valve handle. As mentioned before, the condenser discharges into the swimming tank of the bath house adjoining. If the water in the tank becomes too warm a by-pass is used. The baths have a capacity of 150,000 gallons. The Arcadia Hotel baths are also supplied with salt water. The steam heating of the Arcadia Hotel is supplied with live steam through a Davis reducing valve. A Blake automatic relief valve is provided to open the exhaust to the atmosphere in case of accident.

The condensed water delivered by the air pump is discharged into a combined hot well and separator shown at the extreme left in Fig. 9, and the cylinder oil is extracted from it by passing the water through straw. The two boiler feed pumps shown in Fig. 9 are 5-in. stroke with 5½-in. steam and 2¾-in. water cylinders, made by the Laidlaw, Dunn, Gordon Company. They pump the feed water from the hot well through a Goubert heater, supplied from the exhaust of the pumps, and then through Green economizers which are placed near the base of the stack at one end of the boiler room. The economizer scrapers are driven by a two-horse-power three-phase induction motor. The stack is only 35 ft. high and forced draft is afforded by either one of two steam-driven 90-in. fans running at 300 r.p.m. maximum; these were built by the Buffalo Forge Company.

The boilers are Babcock & Wilcox, one of 400 horse-power and three of 200 horse-power rating. As in all steam plants in Southern California, crude oil is burned for fuel. This oil is obtained nearby and has an asphalt base. It is very thick and viscous and has to be warmed before it can be successfully used in an oil burner. Fig. 11 shows the boiler fronts and piping to the oil burners. Chapman high-grade valves are used on the entire plant.

There are two three-phase General Electric generators, one a 400-kw. direct-connected, revolving-field machine and the other a 200-kw. belted machine, also of the revolving-field type. Both deliver current at 60 cycles and 2,200 volts, at which e.m.f. current is distributed throughout Santa Monica to transformers for lighting service. The main switchboard, Fig. 8, has a generator panel on each end and three feeder panels between.

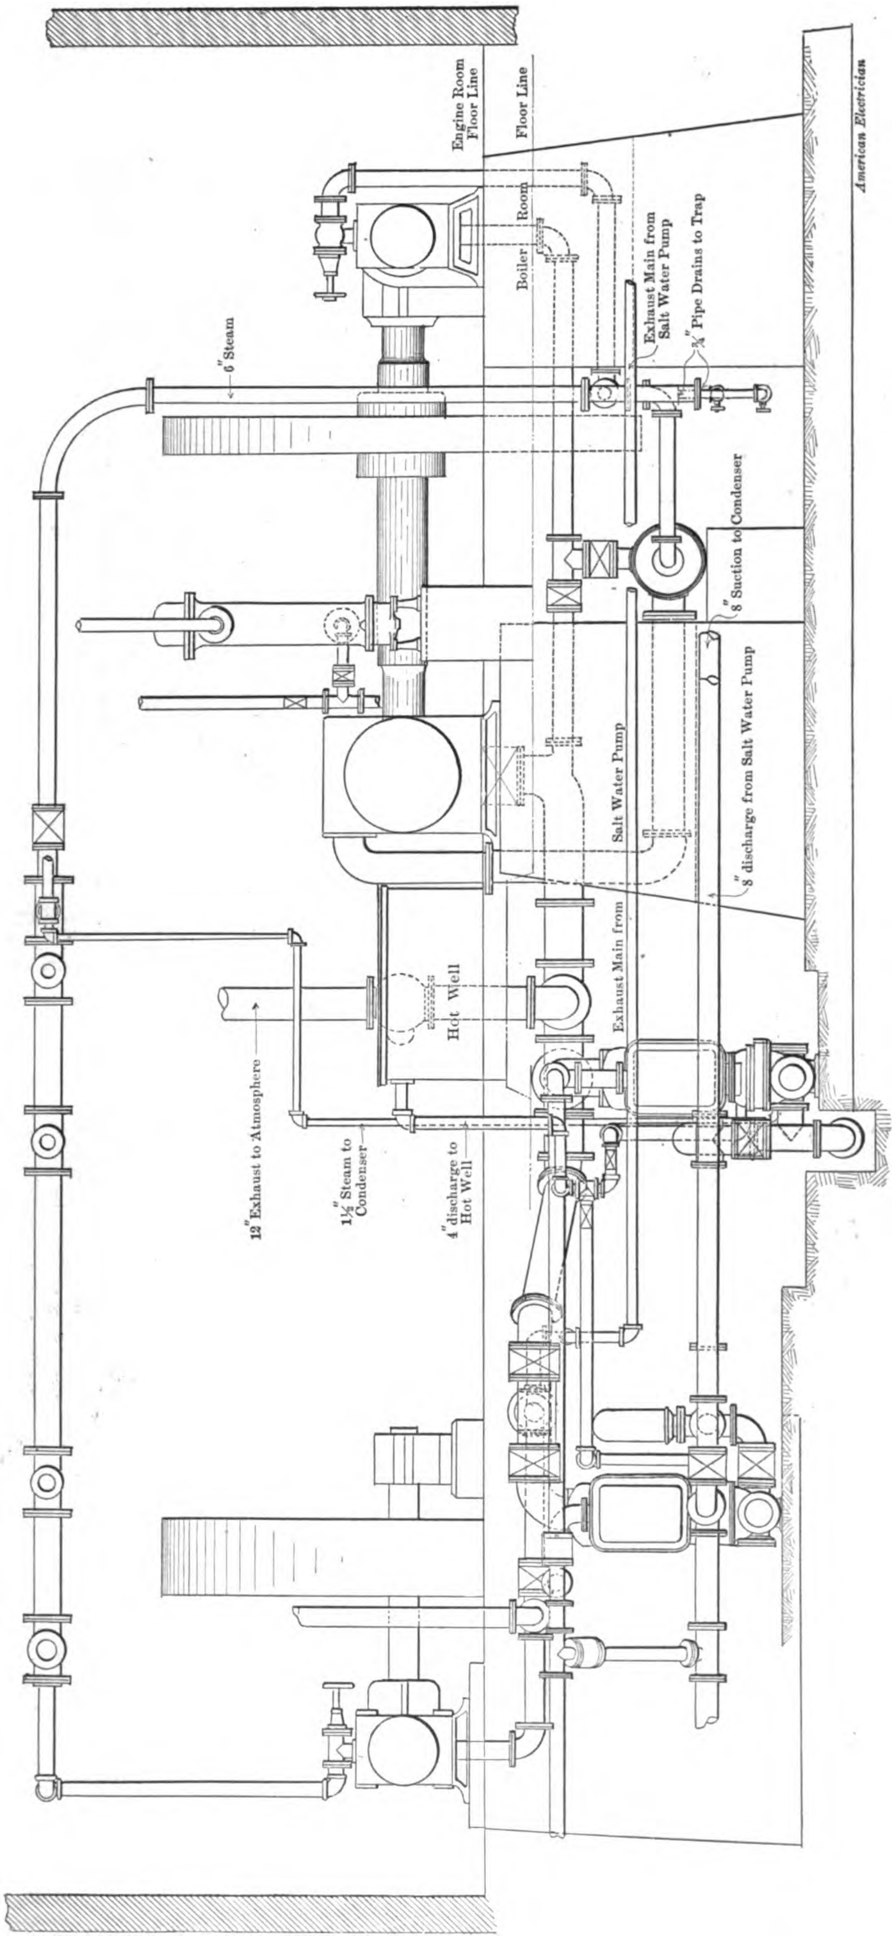

FIG. 6.—ELEVATION OF ENGINES AND CONDENSING APPARATUS.

The large generator panel has a double-throw triple-pole oil-break switch, one main exciter double-pole switch, a field rheostat for the exciter, a field rheostat for the generator, two ammeters, one voltmeter, and a synchronizing plug. There is one feeder panel for the high-tension line, one for a special feeder to the Soldiers' Home and one for the local Santa Monica distribution. Each of the first two has a triple-pole double-throw oil-break switch for throwing the feeder onto either the upper or lower bus; a recording wattmeter, three ammeters and a voltmeter. The Santa Monica feeder panel has three single-phase circuits going out from it and is equipped like any single-phase feeder panel. The three single-phase feeders are provided at the switchboard with General Electric "C. R." type compensating regulators which will raise or lower the voltage 10 per cent. The arc lighting of Santa Monica is done by means of G. E. alternating-current series arcs supplied from two 25-light "tubs" or constant-current transformers.

From the high-tension feeder panel on the main board three 100-kw. G. E. oil-cooled high-tension transformers take current and "step up" the e.m.f. to 22,000 volts. The outgoing high-tension board is equipped like the high-tension boards in the sub-stations, described below.

The sub-stations are of brick and concrete, with an office in one end and the transformer room in the other. All of the sub-stations have the same apparatus, so there is uniformity throughout. Each sub-station has three 50-kw. oil-cooled and insulated General Electric transformers stepping down from 22,000 to 2200 volts. The three incoming leads are provided with G. E. fuses, each consisting of a flat aluminum strip eight inches long held between spring tension terminals and clamped between two lignum-vitae blocks with an opening in the block opposite the center of the fuse. There are also knife switches in the incoming 22,000-volt leads. The switches have no handles, but are operated by a long wooden pole with a hook on the end. These knife switches are shown in the upper right-hand corner of the board at the Long Beach sub-station. The fuses are behind the board. On each of the 2200-volt secondary leads there is a quick-break triple-pole oil switch located just below the high-tension switches.

There are three single-phase lines taken out of each sub-station. Each is fused with a G. E. enclosed fuse, as seen at the top of the left-hand panel in Fig. 1, and each phase has an ammeter, a two-pole knife switch and a G. E. potential regulator. At the left is a voltmeter which can be used on any of the three circuits by plugging in. The fuses and high-tension switches are well provided with arc guards, as can be seen from Fig. 2. During the early part of the evening a man stays at each sub-station to watch the voltage; the rest of the time the sub-station is unattended. Although no power work has been taken on as yet there are irrigation pumps aggregating 800 horse-power scattered along the line that are now operated by gasoline and steam engines and these will probably be secured as customers.

There are 40 miles of high-tension line;

but the longest distance over which current is transmitted is 35 miles. The transmission line consists of three No. 6 medium hard drawn copper wires on "Provo No. 1" glass insulators furnished by the Hemingway Glass Company, of Covington, Ky. These insulators get their name from the 40,000-volt transmission plant at Provo, Utah, where they were first employed; they are 7½ ins. in diameter.

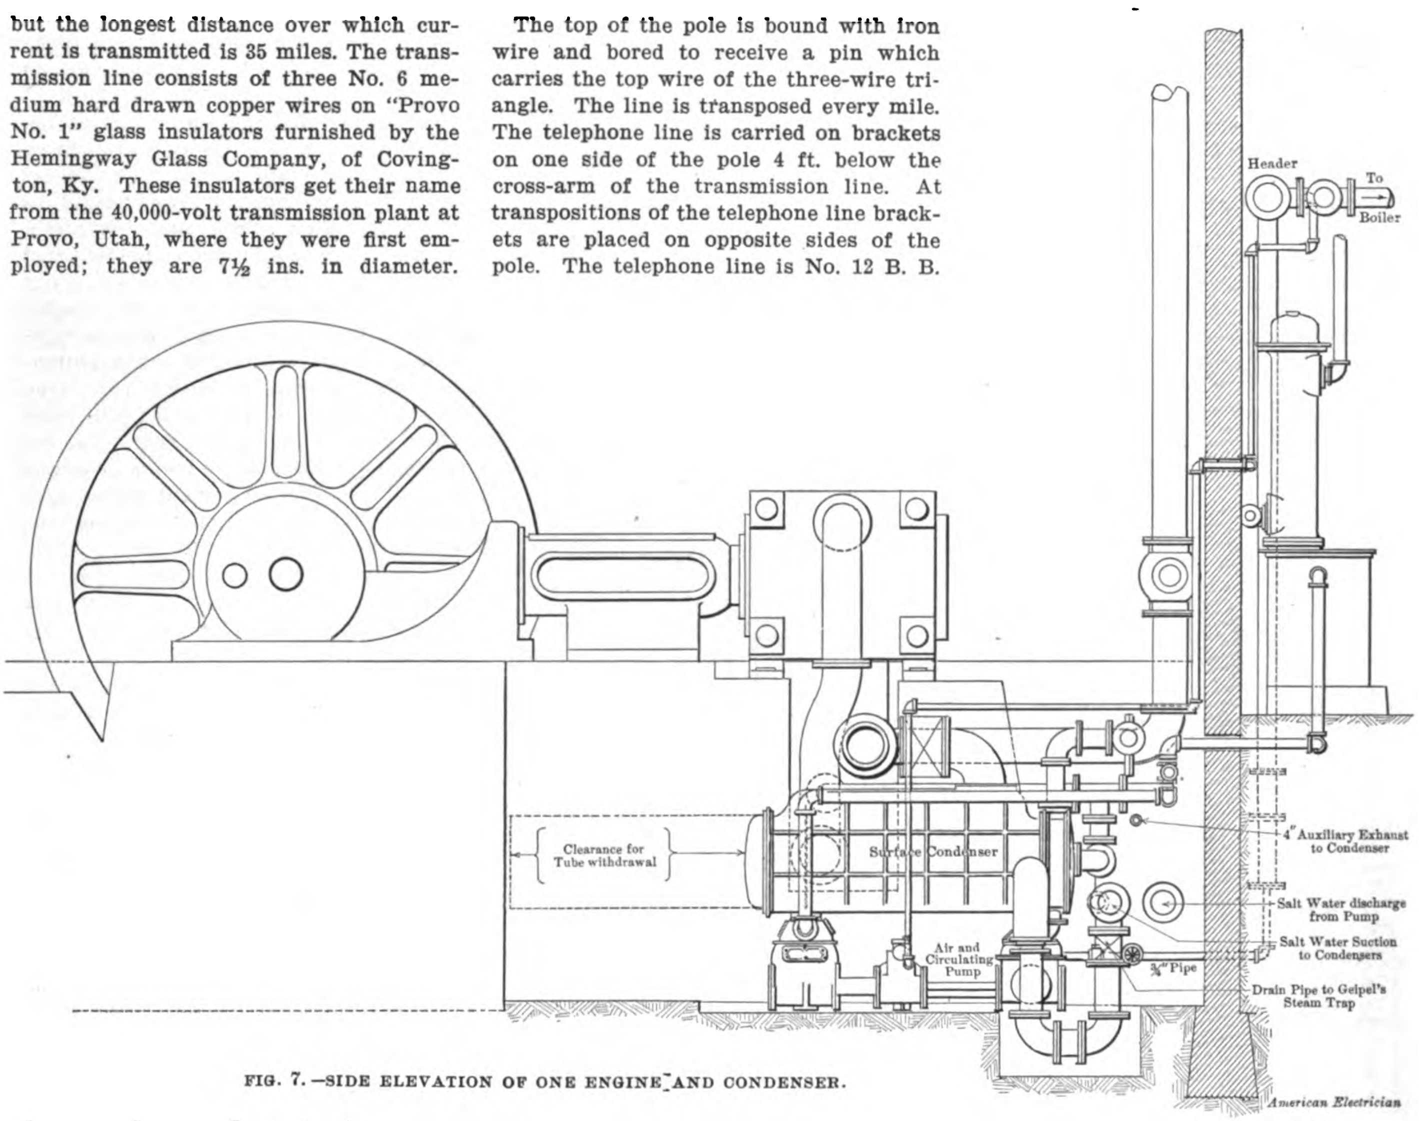

FIG. 7.—SIDE ELEVATION OF ONE ENGINE AND CONDENSER.

There are also some Locke insulators. The insulator pins are 12½ ins. long over all, 8½ ins. from the top to the shoulder, and raise the insulator 4 ins. from the cross arm. They are made high to prevent leakage from the edge of the insulator to the cross-arm. The cross-arms and pins are boiled in linseed oil. The cross arms are 44 ins. long and carry a pin on each end; the distance between wires is 34 ins.

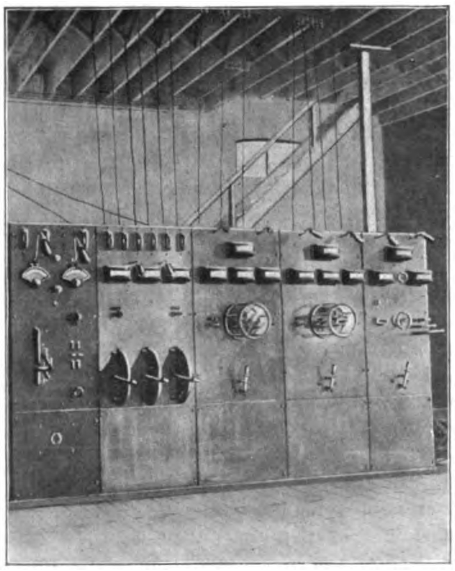

FIG. 8.—SWITCHBOARD.

The top of the pole is bound with iron wire and bored to receive a pin which carries the top wire of the three-wire triangle. The line is transposed every mile. The telephone line is carried on brackets on one side of the pole 4 ft. below the cross-arm of the transmission line. At transpositions of the telephone line brackets are placed on opposite sides of the pole. The telephone line is No. 12 B. B. iron wire, and is carried on pony double-petticoat glass insulators. The poles are spaced 130 ft. apart; they are 35 ft. long in the country and 40 ft. long in the towns. The line is designed to transmit 300 kilowatts and is now carrying 150.

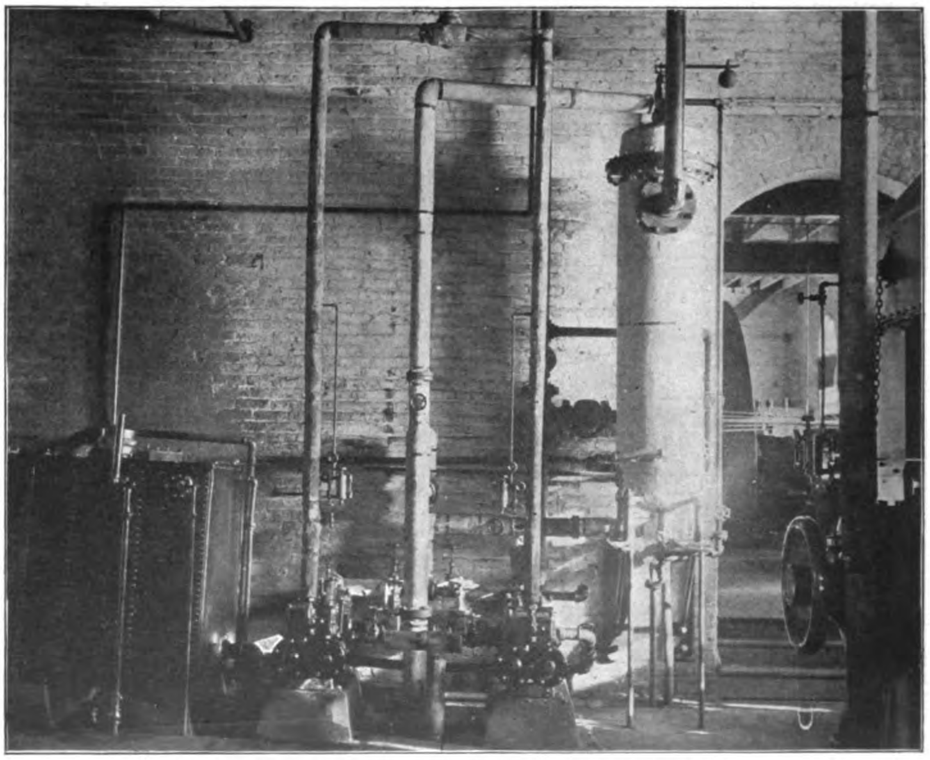

FIG. 9.—HOT WELL, BOILER FEED PUMPS AND HEATER.

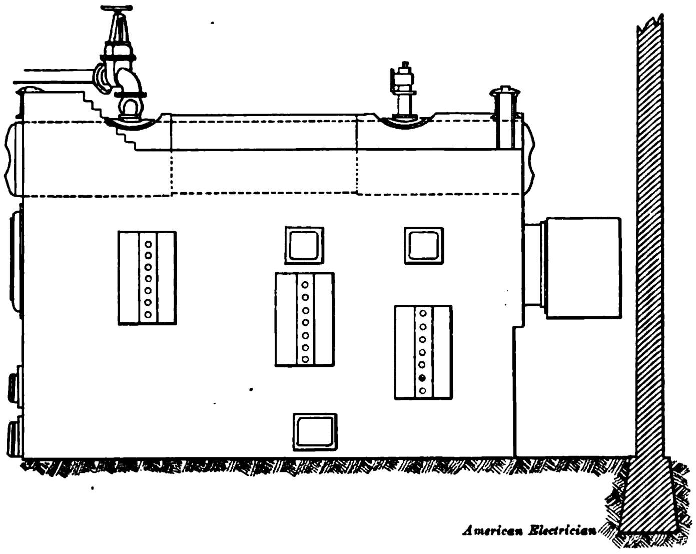
The apparent energy required to charge the line is 34 kilowatts. The voltage is 16 per cent higher at the far end than at the Santa Monica power house, due to the capacity of the line.

It should be mentioned here in connection with the change from small power houses to sub-stations in some of the villages that there were some old 125-cycle 1,000-volt plants. The plant just described is 60-cycle. The discrepancy was provided for by connecting the primaries of two 1000-volt transformers in series and their secondaries in parallel, and going ahead with the old transformers at 60 cycles.



American Electrician

FIG. 10.—BOILER SETTING.

The United Electric, Gas & Power Company has main offices at 254 South Broadway, Los Angeles, Cal. Mr. J. J. Davis is the superintendent, and acknowledgment is due him for many courtesies extended in connection with the preparation of this article.

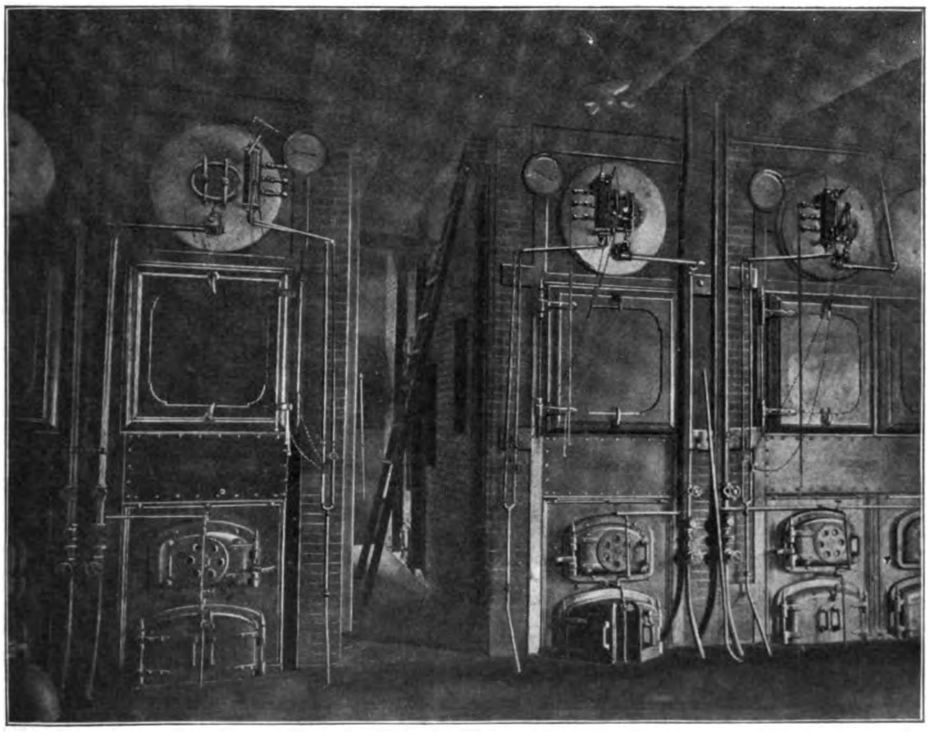


FIG. 11.—PARTIAL VIEW OF BOILERS.

ELECTRICITY IN COAL MINING IN THE PITTSBURG DISTRICT.

BY WM. G. IRWIN.

While the application of electricity to coal mining dates back some years, yet it is within comparatively recent years that the intelligent and economic use of this agent in coal mine operation has received any considerable attention in this district. To-day electric lighting, even to the workings, electric haulage and electrical and compressed air machine mining have in a large degree superseded the older methods and at the same time these modern methods have removed many of the sources of danger in coal mining. Although electric lighting was introduced in the Connellsville coke region more than ten years ago and has in a large degree obviated the necessity of miners' lamps, the more extended use of electricity first came into use in the mines of the Pittsburg gas coal seam, having been here introduced after the success of elecricity had been established through its use in the mines of the anthracite fields.

About eight years ago the W. L. Scott Coal Company installed a complete electrical power plant at Scott Haven, on the Youghiogheny, for the purpose of furnishing electric lighting for its mines as well as for furnishing haulage power and electrical power for operating mining machinery. Ever since that time electricity has been in successful use at these mines (which are to-day the property of the Pittsburg Coal Company). Save for the purpose of gathering the cars in the headings the pit mule is now entirely supplanted by electricity in these mines. At first some little trouble was experienced with the trolley wires, but experience has eliminated these troubles.

Since that time there have been numerous installations of electric power plants at the mines in the same district, and while there are no available statistics as to the proportion of electrically equipped plants and the annual output of such mines, it is known that they form an important figure in coal mine operation hereabouts. All the new mines being opened up are being equipped with electrical apparatus, and many of the older mines are now changing to the system. Probably one of the most modern mines in Western Pennsylvania is that of the Berwind-White Coal Mining Company at Windber, a description of whose equipment was published in this paper last July. In the coke regions electricity has displaced the old larry system for charging the ovens, and experiments are being made with it in the operation of automatic coke drawing and loading machines.

The economy resulting from the use of these modern methods in coal mining is enormous. Formerly eight mules and as many drivers were required to haul out 200 tons per day, and the cost under the old system was nearly 10 cents per ton. An electric locomotive like those in use at Windber will haul 1000 tons daily at a cost of less than one cent per ton.

Electrical machine coal mining is also in quite general use in the Pittsburg district. These machines are easily manipulated, and in construction they are extremely simple. Of the several electrical mining machines the chain cutting machine is most widely used in this district. This machine can be used in different veins for coal, for it has a height of less than 20 ins., is less than 4 ft. wide and about 8 ft. long. It is equipped with an iron-clad multipolar motor. The cutter-frame consists of a forged steel rail, a cutter head and two steel guides in which the cutter chain runs. This machine will undercut 5 ft. deep and about 3½ ft. wide. In using these machines the only necessary preparation is stringing the wires and the machine is then mounted on its truck and taken into the room where the mining is to be done. It requires about four minutes to make a cut and one minute to withdraw the machine when the jacks are loosened and the cutter moved up for another cut. When shearing is found necessary a vertical cutting machine is used. With these machines it is possible to cut from 50 to 100 ft. of entry per day of ten hours, according to the character of the coal. For the adjustment of mining scales and computing wages it is estimated that one machine will do the work of twelve men.

MODERN PRACTICE IN STEAM ENGINE CONSTRUCTION.

While an industry is young and its field wide and comparatively unobstructed inventions are likely to be numerous, and changes in methods and design are promptly made if thereby a better adaptation of product to conditions is secured. As the industry grows older conditions become better understood, the product of different shops becomes to a greater or lesser degree specialized, the field becomes limited through increasing competition, profits diminish and an increasing tendency appears to resist changes in methods and design, and to compel the adaptation of conditions to what is termed "standard practice."

So far as this tendency acts as a balance wheel by resisting erratic and ill-considered innovations on the one hand and by demanding the elimination or modification of unreasonable conditions on the other, it is a very valuable conserving force; but when it becomes a dead weight by refusing to recognize the right of conditions to be considered, its influence becomes distinctly reactionary to the direct detriment of the industry itself and to the indirect detriment of related industries.

A candid observer, reviewing the improvements in engine design and construction during the last six or eight years, can hardly fail to come to the conclusion that the engine industry as a whole is verging on the dead weight condition and that substantial progress has been confined to hardly more than a half dozen manufacturers out of the scores of engine builders in this country. This is a regrettable condition, since the reactionary influence of the unprogressive builders is a distinct drag on the efforts of the comparatively few moderately conservative, yet progressive, builders to raise the general standard of engine construction; while indirectly the electrical industry has been unfavorably affected.

It will not be out of place to add that a manufacturer can continue to make only what he can sell, and as the first cost of high grade engines is much greater than the first cost of low grade engines, the success of the builders of high-priced engines is in no small degree due to the encouragement and support received from central station managers, superintendents and engineers who have had the judgment and business acumen to select the best the market afforded, looking to decreased operating and maintenance charges and a larger average output for a return on the increased investment; and it is only through their continued encouragement and support that further improvements can be looked for.

Engines may be divided with respect to speed into three groups: high-speed engines, with speeds from 180 r.p.m. up; moderate-speed engines, with speeds from 100 to 170 r.p.m.; slow-speed engines, with speeds below 100 r.p.m. This method of grouping is not strictly accurate, as the several groups overlap to a certain extent, and what may be a moderate-speed engine in one size or type may be a high-speed in some other size or type; nevertheless it is not likely that any misunderstanding will arise on that account since the division indicated is generally accepted by both builders and users. Furthermore, there are certain differences in design which closely follow the grouping by speeds; for example, the dominating types among so-called high-speed engines have the following characteristics: a stroke not exceeding 24 ins.; self-contained construction; center crank; a single eccentric; a single valve; automatic shaft governors. The dominating types among moderate-speed engines are characterized by strokes from 24 to 48 ins.; side-crank construction, unless the conditions require the side and center crank or the center crank arrangement; single or double eccentrics; four positively driven valves, two for steam admission and two for exhaust; automatic shaft governors. The dominating types among slow-speed engines are characterized by strokes from 42 to 72 inches; side-crank construction, occasionally modified to side and center crank to meet special conditions; single or double eccentrics, releasing valve gear; four valves; fly-ball governors.

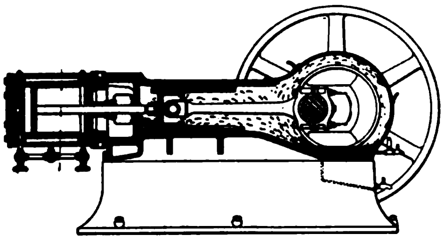

FIG. 1.—SECTION THROUGH SELF-OILING ENGINE.

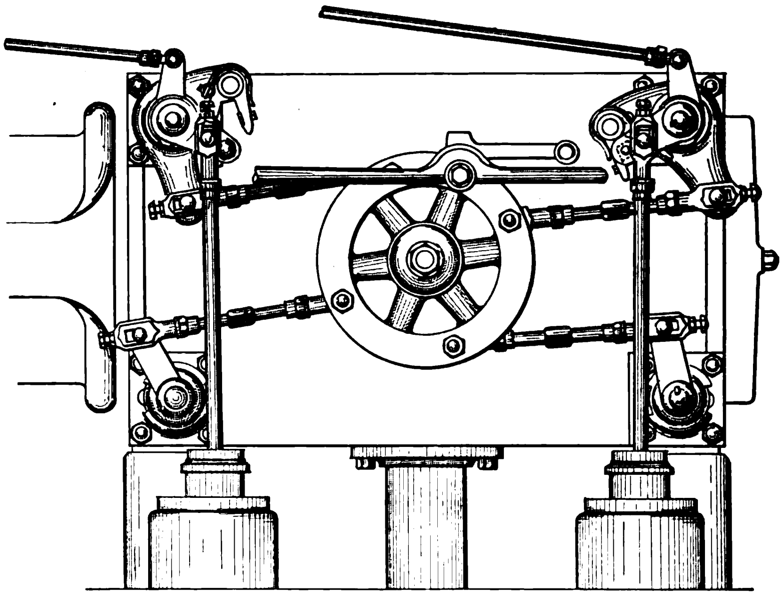

Am. Elec.

FIG. 2—ORDINARY FORM OF CORLISS GEAR.

High-speed engines show few improvements. Shafts and pins have in some instances been increased in size. Two or three builders have designed a very satisfactory form of shell bearing. An example of a bearing with removable shell and adjustable quarter boxes, designed for a large engine, is shown farther over by Fig. 19; the advantages of such a design seem obvious, since it allows the removal of the bottom shell with a minimum amount of dismantling and loss of time; nevertheless, many builders still adhere either to solid bearings or bearings provided with flimsy, unmechanical liners.

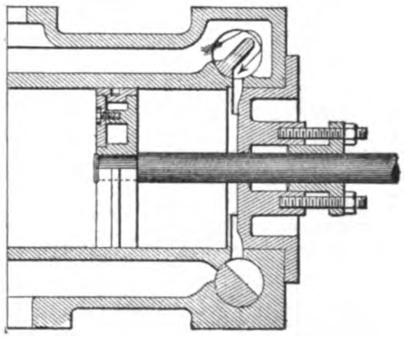

FIG. 3.—ORDINARY FORMS OF CORLISS VALVE.

The most conspicuous change is in the methods adopted to prevent waste and throwing of oil. Something has been gained by the substitution of grease for oil to lubricate the governor mechanism and more or less of the valve gear, but the main reliance has been placed upon the thorough enclosing of all working parts. The desire to promote cleanliness is most commendable and the method adopted has been fairly successful, but unfortunately many builders have enclosed the working parts in such a way as to seriously interfere with their accessibility both for inspection and for repairs. Fig. 1 shows a section through a self-oiling engine in which this system of lubrication has been very thoroughly worked out; the rotation of the crank discs fills the case with a spray of oil which reaches all parts of the guides and the crosshead pin; a portion of the oil is caught in a trough on the inside of the hood in front of the discs and is delivered by pipes in a continuous stream to the main bearings and the crank-pin.

As a class, engines of this group have too high a rotative speed, clearances are abnormally large, methods for following up wear are crude or altogether lacking, details are designed primarily to reduce the first cost and secondarily, or not at all, with a view to reducing the cost of repairs and renewals, and attention is concentrated on such relatively unessential features as the precise method by which lubrication is secured and the ability of the governor to maintain the average speed within abnormally narrow limits—to the partial or complete exclusion of questions relating to cost of operation and maintenance, reliability, and economy.

The most interesting of the three groups is the intermediate group, comprising engines running at speeds within the limits, somewhat arbitrarily imposed, of 100 and 170 r.p.m. The growth and development of this group have been exceedingly rapid during the past five or six years and it is probable that its importance will increase even more rapidly in the future than in the past, and that it will encroach more and more upon the fields now occupied by the high-speed and slow-speed groups, since the growing tendency is to decrease the speed of high-speed engines above about 300 horse-power and to increase the speed of slow-speed engines of all powers.

In the high and slow-speed groups, especially the former, there are comparatively few differences in the general de-

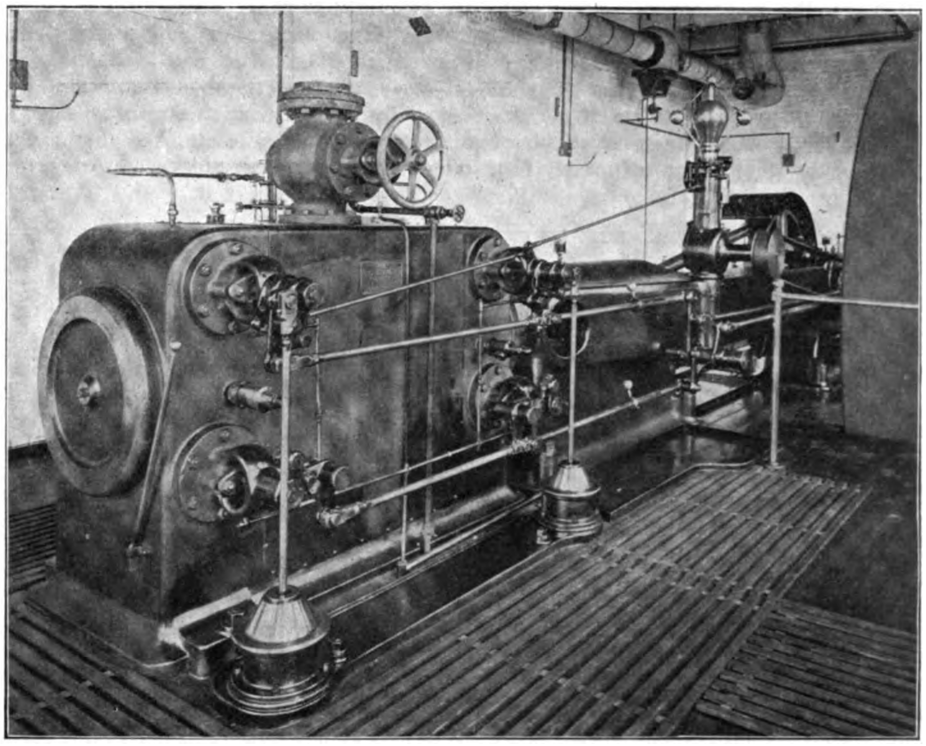

FIG. 4.—DIRECT-ACTING CORLISS VALVE GEAR, OBVIATING WRIST PLATES.

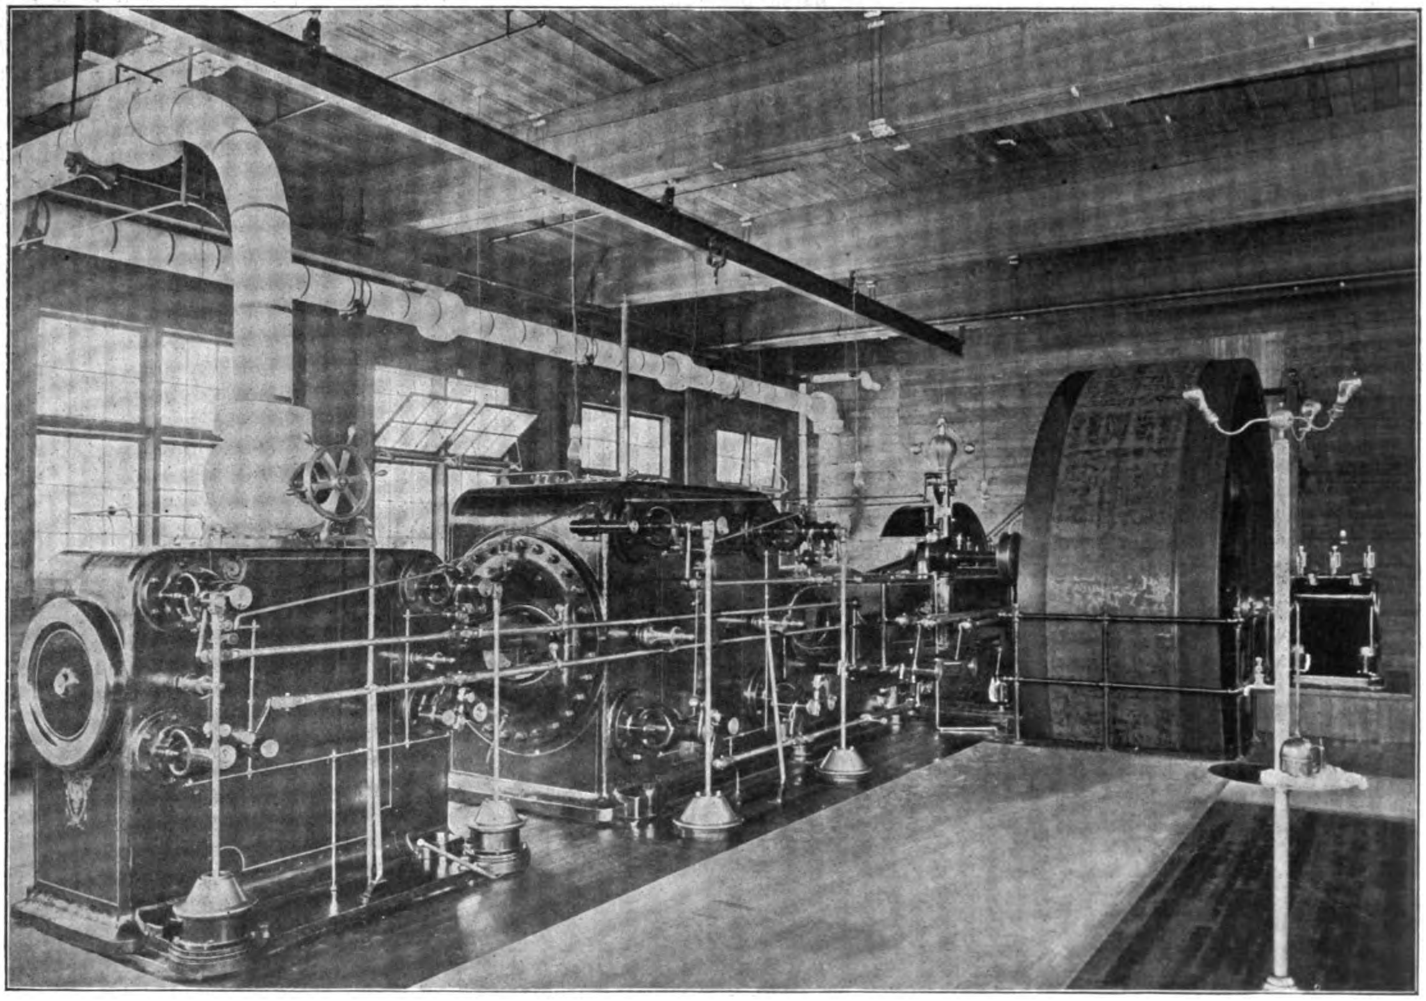

FIG. 5—DIRECT-ACTING CORLISS VALVE GEAR APPLIED TO A TANDEM COMPOUND ENGINE.

sign, but among moderate-speed engines practice is still divergent in several particulars, the most conspicuous of which are the valves, valve gear and governing mechanism. A few builders still persist in attempting to adapt valves and cylinder construction of the distinctively high-speed type to moderate-speed engines, but as these attempts must ultimately fail, it is not necessary to discuss them here; such engines are uneconomical in steam consumption, whereas the foundation of the success of moderate-speed engines is, and must be, a degree of steam economy closely approaching that of slow-speed engines combined with a higher degree of economy of material. The method generally followed has been the adoption of the design of valves and (to a less extent) valve mechanisms of slow-speed engines which have proved their economical qualities, and the modification of these valves and gears to suit higher speeds and the style of governor used.

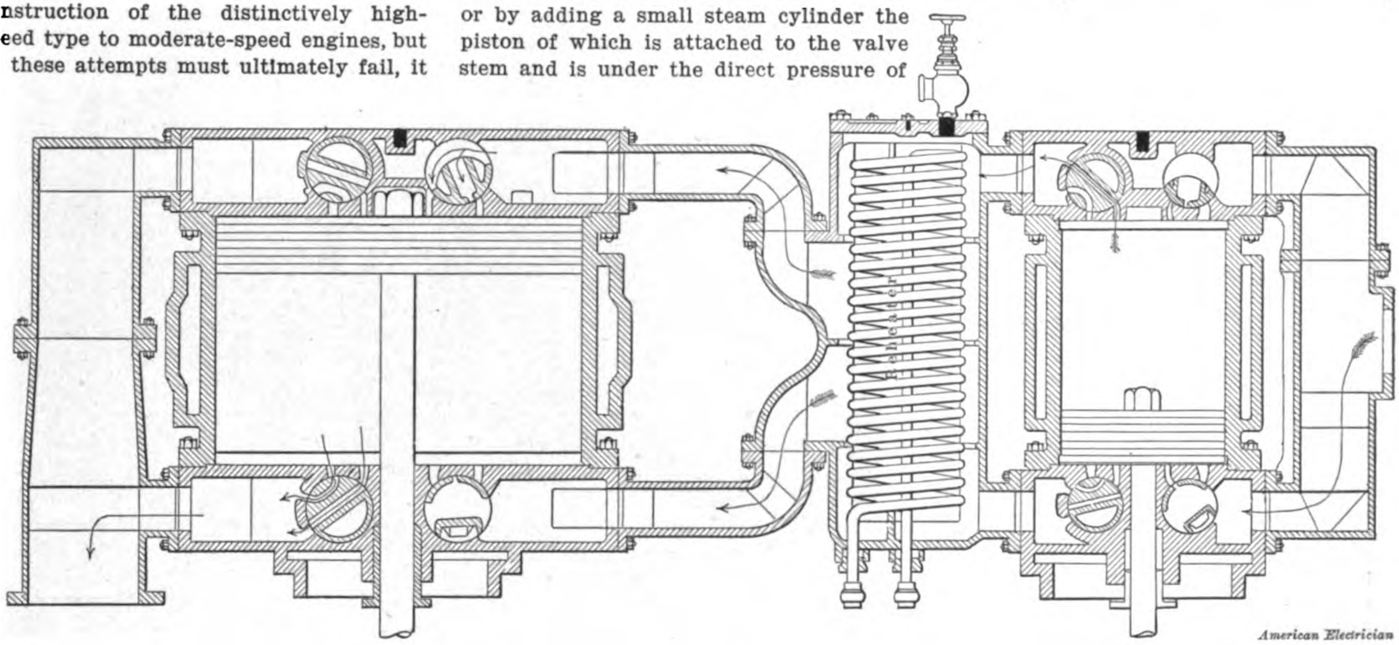

FIG. 8.—A CROSS-SECTION THROUGH THE CYLINDERS OF A VERTICAL COMPOUND CORLISS ENGINE HAVING A POSITIVELY-DRIVEN VALVE GEAR.

With but few exceptions manufacturers of releasing-valve-gear engines have ignored or refused to attack the fundamental limitation to their success in this field —the fact that the speed of such engines is strictly limited by the releasing feature of their valve gear, since only within narrow limits can the speed of valve movement in closing be independent of the engine speed. To meet tne demand for higher speeds the principal builders have lightened their valves and gear; have substituted double for single-ported valves, thus shortening the valve stroke or travel; and have improved the action of the dash-pot. A few builders have gone still further, increasing the rapidity of valve closure by supplementing the action of the dash-pot by means of a spring acting directly on the valve stem or by adding a small steam cylinder the piston of which is attached to the valve stem and is under the direct pressure of live steam. Fig. 2 illustrates the older form of valve gear; Fig. 3 is a section showing single-ported valves. The speed of an engine containing such valves and gear is limited by conservative practice to a maximum of about 85 to 90 r.p.m. for moderate sizes and 75 r.p.m. for large sizes—considerably below the lower limit for moderate-speed engines.

Figs. 4 and 5 illustrate an improved valve-gear of comparatively recent design; the light, neat construction, the absence of wrist-plates, and the easy lines represent a distinct advance over the rather heavy construction and harsher lines usually met with. The method of driving the valves is especially clear in Fig. 4, which shows the cylinder and a portion of the frame of a simple engine. It will also be noted that the cylinder rests on a plate bolted to the foundation, and that the foundation bolt boss has an overhanging lip under which is a projection from the cylinder machined to a close fit; this allows a free movement of the cylinder forward or backward, but prevents any tendency to lift and relieves the structure of the objectionable strains induced by bolting the cylinder itself fast to the foundation. Fig. 5 shows the tandem construction. Double eccentrics are used and the governor controls simultaneously the cut-off on both cylinders.

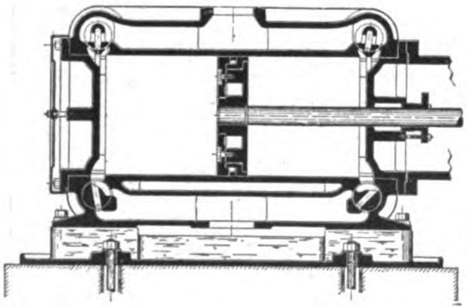

FIG. 6.—IMPROVED FORMS OF CORLISS VALVE.

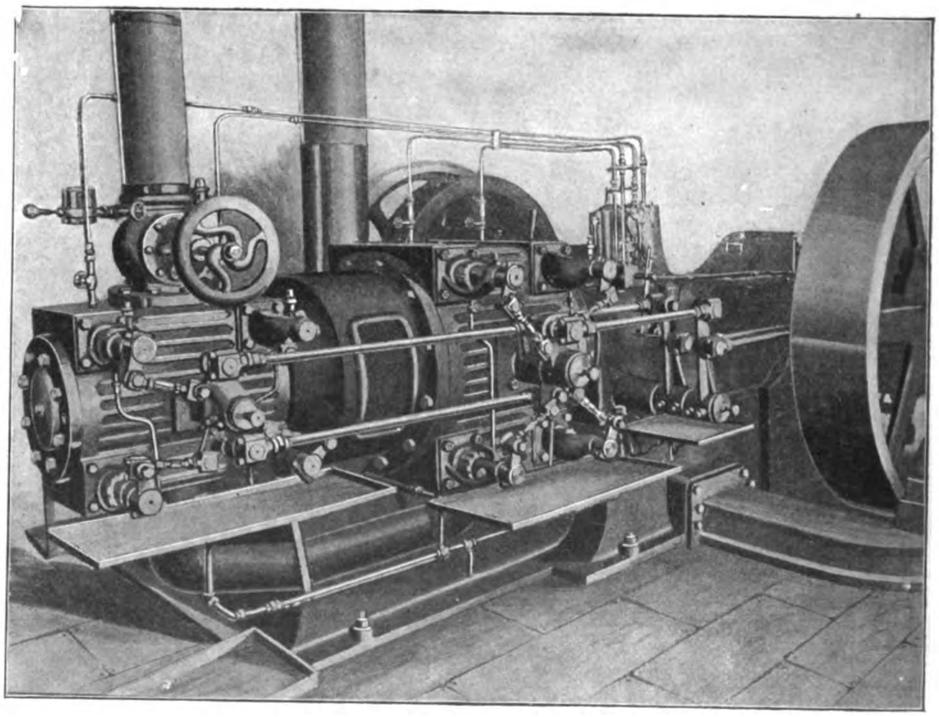

FIG. 7.—A POSITIVELY-DRIVEN VALVE GEAR HAVING NO RELEASE.

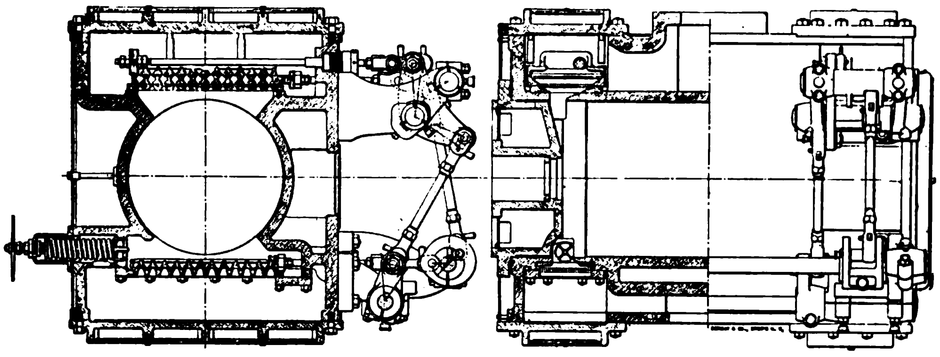
Fig. 6 shows in section a comparatively light, short stroke, double-ported valve which is used in another Corliss-type engine.

The superiority of these later constructions is clearly apparent merely from a mechanical standpoint, but their chief advantage lies in their permitting an increase in the speed of small engines to 110 and of moderate sized engines to 100 r.p.m., bringing them within the moderate-speed group. One or two manufacturers are building engines with speeds up to 120 r.p.m. without and 150 r.p.m. with steam or spring-accelerated valves; but such engines have hardly been tried long enough to demonstrate whether or not these speeds are commercially desirable; in any event the logical solution is the elimination of the question by abandoning entirely the releasing feature and substituting positively-driven, non-releasing forms of valve-gear, as has already been done by several manufacturers, most of whom previously built high-speed engines exclusively. Some of these manufacturers have adopted the Corliss valve, the exhaust valves being driven from a fixed eccentric and the admission valves from a movable eccentric controlled by a shaft governor, the cut-off being determined by the position of the eccentric, and the speed of opening and closing varying directly with the speed of the engine. Fig. 7 shows a tandem-compound engine equipped with this type of valve-gear operating Corliss valves. Fig. 8 shows in section the Corliss valves and cylinders of a vertical cross-compound engine of a different make, in which the same class of positive valve-gear is used.



FIGS. 10 AND 11.—SECTIONS OF THE ENGINE IN FIG. 9, SHOWING ALSO GRIDIRON VALVES.

Other builders have adopted modified forms of slide valves or gridiron valves. A form of the latter is illustrated in Figs 9 to 11, one showing the external appearance of tandem cylinders, the others showing sections through valves and cylinder. As with the Corliss valve arrangement cited above, the exhaust valves are driven from a fixed eccentric, but there is a radical difference in the steam valves, which are double, comprising a main valve driven from the same eccentric that operates the exhaust valves, and a riding cut-off valve driven from a movable eccentric controlled by a shaft governor; as these valves move in opposite directions while opening and closing, the valve travel is short and admission and cut-off are very rapid, the rapidity of these operations varying directly with the speed of the engine.

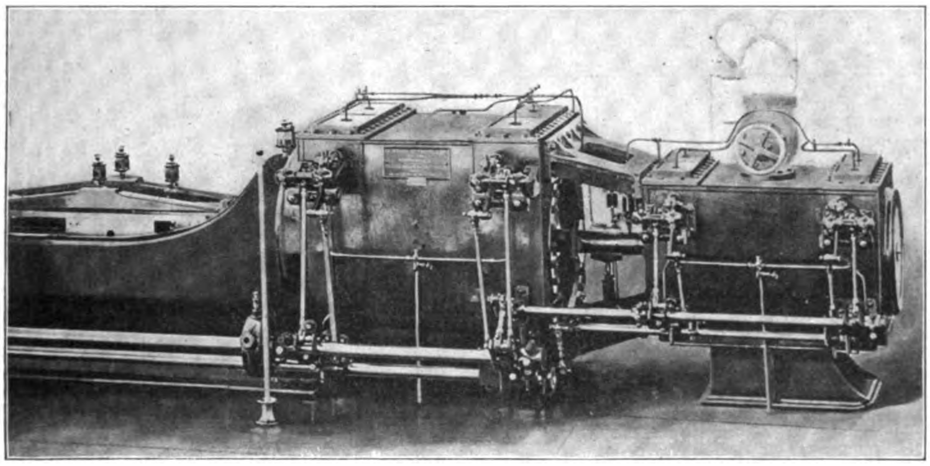


FIG. 9.—CORLISS VALVE GEAR DRIVEN FROM SECONDARY SHAFTS INSTEAD OF WRIST PLATES.

The adoption of the four-valve construction, with the consequent reduction of clearances, has doubtless been a considerable factor in the higher economy of such engines as compared with high-speed engines; but the principal factor has been the increase in the length of stroke and the piston speed, the further decrease in clearances which this permits, and a greatly improved valve design, so that to-day the best moderate speed engines rank with the best slow-speed engines in the matter of steam consumption. For example, a 48-in. stroke engine at 75 r.p.m. shows a certain steam consumption; other things being equal, it will show practically the same steam consumption at 100, 110 or 120 revolutions, while there is a very marked difference in the economy of material, since every increase in speed reduces the weight per unit of capacity.

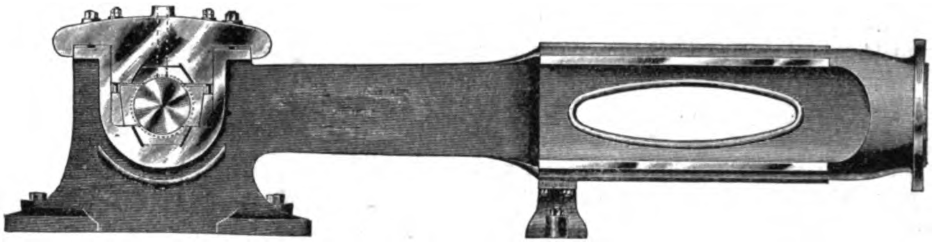

FIG. 12.—OLD-STYLE GIRDER TYPE OF ENGINE FRAME.

Nearly every manufacturer has adhered to the type of governor he originally used; consequently we find in the moderate-speed group all the governors of the high-speed and slow-speed groups—shaft governors on engines designed by high-speed engine builders and fly-ball governors on engines designed by slow-speed engine builders. Both types give very satisfactory results, but the so-called shaft or automatic governor doubtless governs more closely than the fly-ball type, especially under rapidly and widely varying loads, and several manufacturers of releasing-valve-gear engines have experimented with a view to substituting such a governor for the usual fly-ball type.

It is broadly claimed that moderate-speed engines are much more economical than high-speed engines under all conditions, are as economical as slow-speed engines under similar conditions, are adapted to a much wider range of conditions than either high or slow-speed engines, and, all things considered, give the highest return on the investment. The results obtained during the past five or six years seem to justify these claims and the increasing attention shown by high-speed and slow-speed engine manufacturers to this field is a tacit recognition of its importance.

There is little to be said which applies distinctively to slow-speed engines; nearly every improvement has been made under the pressure of competition from the moderate-speed group and in the attempt to lessen the severity of that competition by increasing rotative speeds; all of these improvements appear in engines which are included in the moderate-speed group. Some have been mentioned above and others will be cited in the following paragraphs but without referring them to either the slow or moderate-speed groups as they are common to both.

There still exists the widest diversity in practice with respect to horizontal engine frames. Some builders adhere to the girder type which met reasonably well the light mill duty of 20 years ago, but which is wholly inadequate to meet the exacting requirements of modern electrical work; and in the better class of mill work there is a growing demand for something better. Fig. 12 illustrates the girder type of frame; it is weak in every direction, has insufficient bearing surface on the foundation, and continues to exist only because it is cheap.

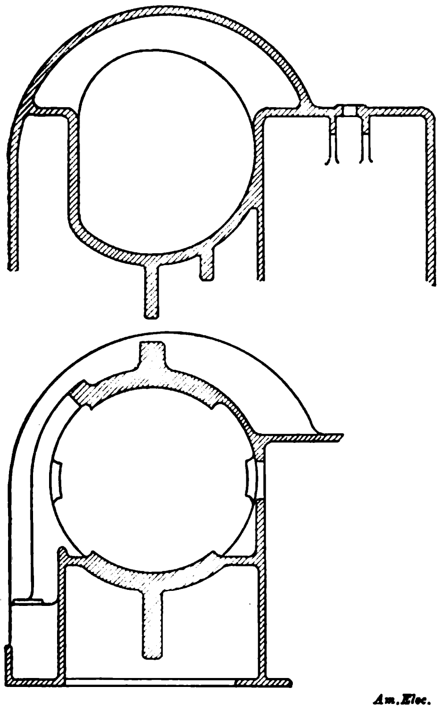

FIG. 14.—SECTIONS OF FRAME SHOWN IN FIG. 13.

The opposite practice is represented by the few builders who have had the courage and good judgment to go to the root of the trouble by discarding old drawings, patterns and methods, and adopting a design of maximum rigidity, strength, bearing surface and grip on the foundation. A good example of such a frame is shown in Fig. 13, sections of which are shown in Fig. 14; it is in one piece, caps the foundation over its entire length and breadth, and relieves the cylinder of certain objectionable strains inseparable from the girder construction. A frame on similar lines, but for another type of engine, is illustrated by Fig. 15, and sections of it are shown in Fig. 16.

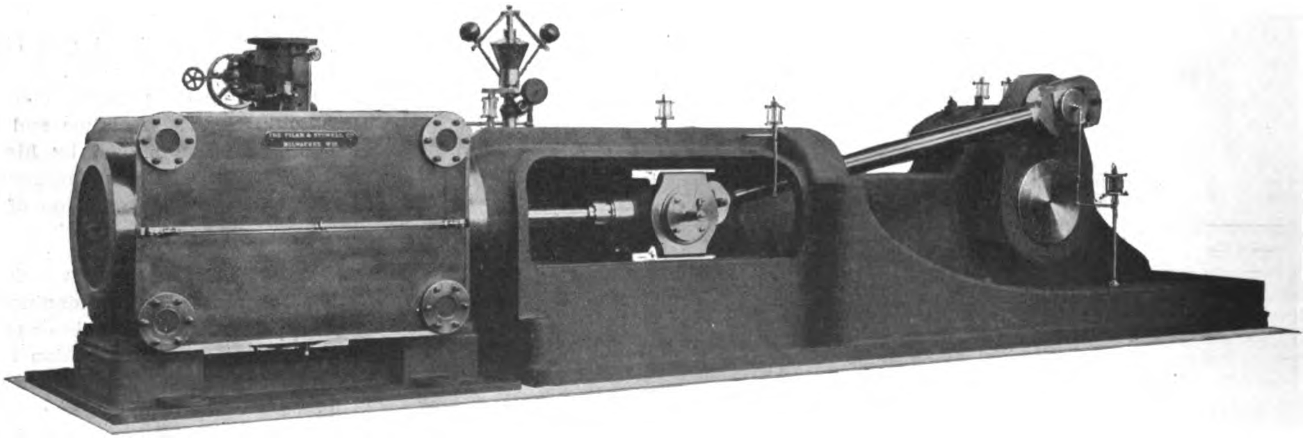

FIG. 13.—MODERN FORM OF CORLISS ENGINE FRAME SUPPORTED THROUGHOUT ITS LENGTH.

There is quite a number of builders who have compromised by putting a substantial frame under the main bearing but retaining the girder construction for the guides and casting the frame in two pieces. An example of this construction is given in Fig. 17; it is a decided improvement over the earlier design, but inferior to the admirable designs illustrated in Figs. 13 and 15. Other modifications consist in casting heavy ribs under the guides, or putting a support under them resting on the foundation and thus transmitting direct to the foundation strains which would otherwise reach it through the cylinder.

It is, perhaps, but natural that one should find in bearings the same diversity that has been noted in frames; still there is less excuse for antiquated and inconvenient construction, since a good bearing is not difficult to design, involves comparatively slight changes in patterns, and the additional cost is inconsiderable. Occasionally one finds solid bearings, that is, bearings with the babbitt cast directly in the frame or outboard pedestal; such bearings can be properly scraped or rebabbitted only by lifting the shaft entirely out, and it is surprising that they are tolerated. The more usual construction consists of a flat-bottomed shell with quarter boxes. Fig. 18 shows a bearing of this type; here the adjustment for wear is made entirely from one side and by means of set screws, both of which features are objectionable. The frame in Fig. 12 also shows a bearing of this type, but both quarter boxes are adjustable and are followed up by solid wedges extending their entire length.

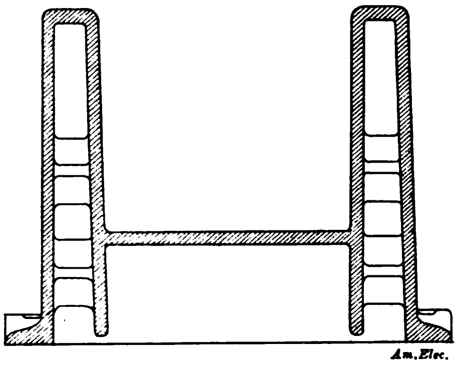

FIG. 16.—SECTION OF FRAME SHOWN IN FIG. 15.

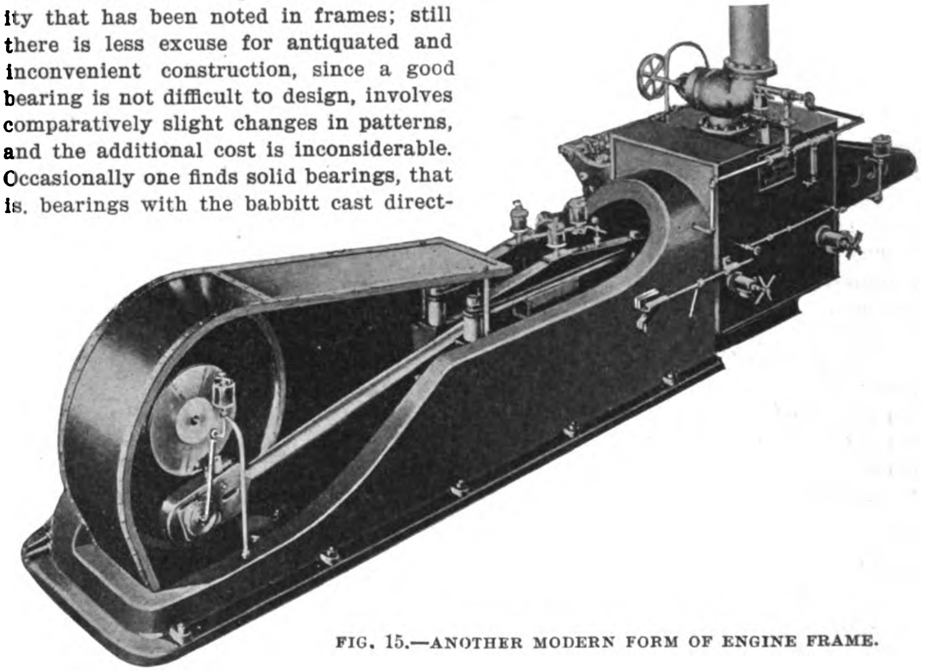

FIG. 15.—ANOTHER MODERN FORM OF ENGINE FRAME.

Flat-bottomed shells for bearings are objectionable for two reasons: they are not self-aligning and usually can be removed only by jacking up the shaft several inches; in the case of direct-connected units, lifting the upper field of the dynamo and jacking up the shaft, wheel and armature 5 to 10 ins. is a slow, hazardous and often expensive operation, the greater part of which may be avoided by making the lower shell cylindrical so that it can be revolved around the shaft by simply jacking up the shaft sufficiently to relieve the bearing of weight, and this can be done without dismantling either engine or dynamo. This construction is shown in Fig. 19, the lower shell being also water jacketed, an excellent feature, but found in few engines.

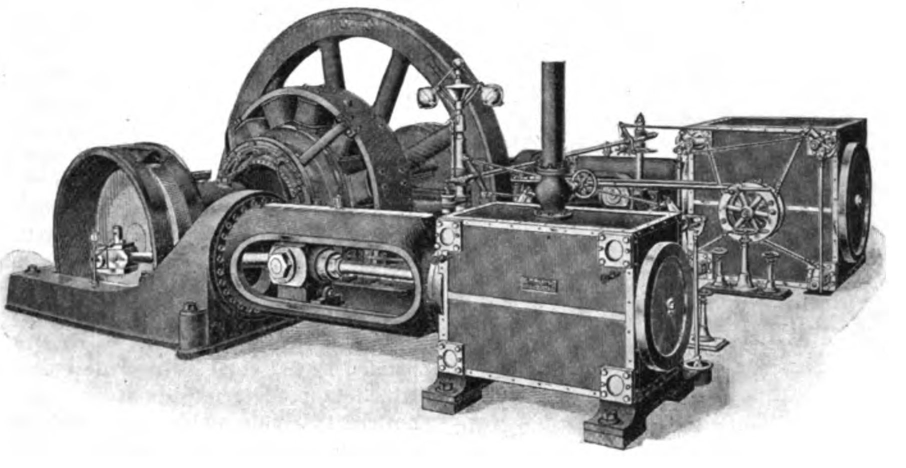

FIG. 17.—AN INTERMEDIATE TYPE OF ENGINE FRAME.

There is a widespread prejudice against tail-rods for horizontal engines; this prejudice is really unwarranted and has cost thousands upon thousands of dollars in reboring, bushing and renewing cylinders, in new pistons, and in the delays incident to making those changes. Do not misunderstand the use of the term "unwarranted." It will be granted that with few exceptions tail-rod constructions have been mechanical monstrosities and that of the two evils the bull-ring piston is the lesser; but purchasers are not obliged to accept such constructions, since there are proper constructions which can be had by requiring them, and therefore a prejudice based on the deliberate selection of an inferior design may fairly be stigmatized as unwarranted.

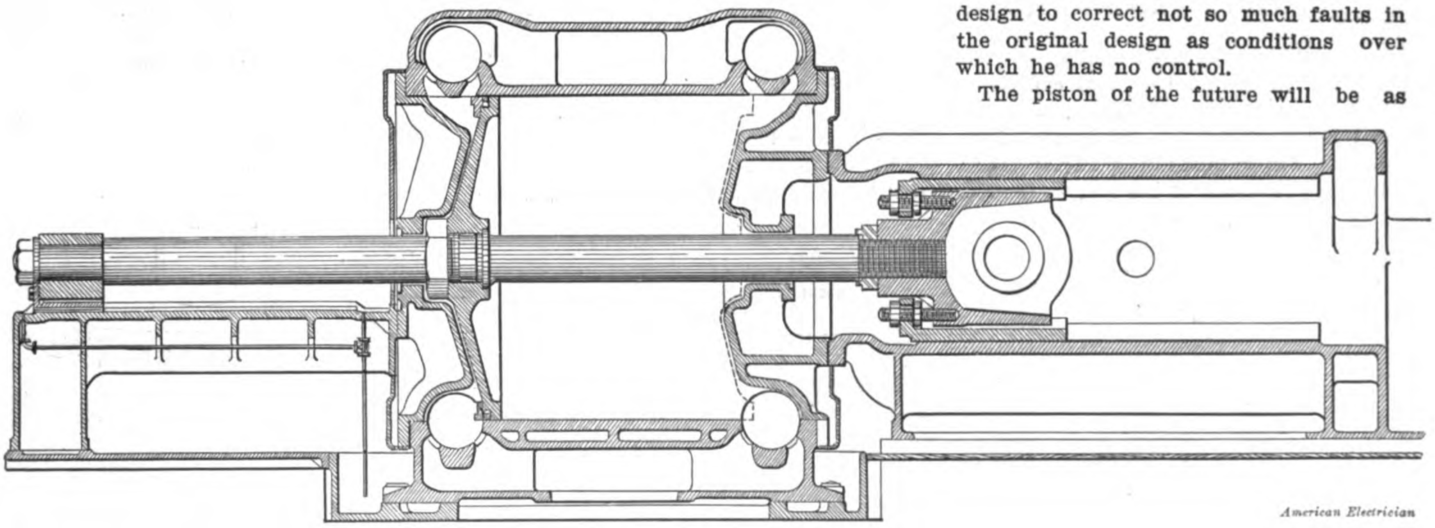

FIG. 20.—SECTION THROUGH CYLINDERS AND GUIDES OF A MODERN CORLISS ENGINE, ALSO SHOWING THE MOUNTING OF THE TAIL-ROD.

A substantial construction is shown in Fig. 20; the cylinder is 76 ins. in diameter and has 60 ins. stroke; the back end of the rod is carried by a cross-head so that the piston is supported between two fixed points; the piston is light and may be partially supported and steadied by the cylinder wall with but a slight increase in the rate of cylinder wear.

Fig. 21 shows an overhung tail-rod support on a 36-in. stroke cylinder; this construction dispenses with foundation work under the support and is suitable for all but very long stroke engines when a foot is placed under the free end. As in the former case, the back end of the rod is carried by a cross-head. This manufacturer also turns the piston rod under a transverse strain equivalent to its own weight and that of the piston, so that the rod is straight when the parts are assembled and supported between the two cross-heads; this method is far superior to bending or cambering the rod, or to stiffening it by using a hollow rod of large diameter.

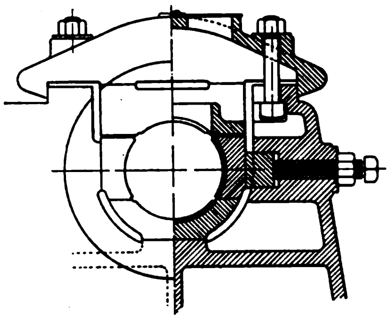

FIG. 18.—MAIN BEARING.

There is probably no single detail in the construction of an engine which has been the subject of as much complaint from purchasers or of as much thought on the part of designers as the piston and rings. A list of all the complaints and a description of all the pistons and rings which have been tried would fill a volume of considerable size, and therefore cannot be attempted here; there are manufacturers who have designed and tried ten or more distinct constructions, yet it is improbable that to-day there is a single design against which complaints have not been lodged. Many, perhaps most, of the complaints have been unwarranted, the trouble being caused by unfavorable conditions rather than by the construction of the piston or rings; but as the conditions generally disappear with the stopping of the engine, while the results, piston and rings are clearly in evidence, the deduction is immediately drawn that the piston and rings constitute the sole condition that causes the results. This form of reasoning and the exposure of its fallacy are certainly as old as recorded history and probably much older; but it is still resorted to, and if the designer cannot definitely point out fundamental causes apart from the piston and rings, his failure is accepted as an admission of the correctness of the deduction, and he is urged to make a new design to correct not so much faults in the original design as conditions over which he has no control.

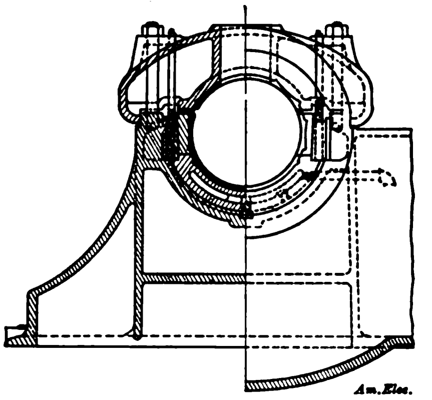

FIG. 19.—MAIN BEARING.

The piston of the future will be as strong as steel and as light as aluminum; will automatically adjust itself so that it will not strike the heads, irrespective of adjustments in bearings; will automatically and instantaneously enlarge the clearance spaces to accommodate doses of water, irrespective of quantity or frequency; will always keep central in the cylinder; will not spring under pressures 50 per cent higher than it was designed for; and will not slam sideways even after the cylinder has been bored out so that there is a ¼-in. clearance all the way around.

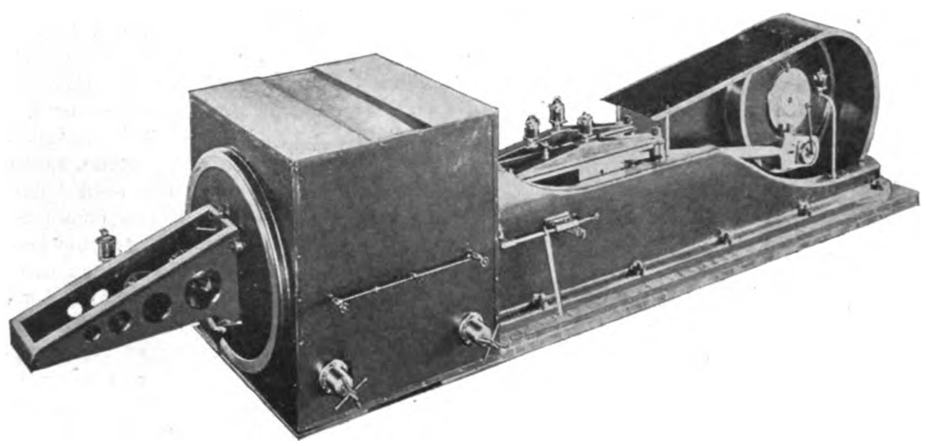

FIG. 21.—ENGINE HAVING A SELF-CONTAINED GUIDE FOR THE TAIL-ROD.

Piston rings of the future will take all of the wear but will last indefinitely; will be steam tight without appreciable pressure against the cylinder walls; will fit perfectly either round or oval cylinders; will work without lubrication; will not lose their tension under any degree of superheat; will automatically adjust themselves to the width of the slot so that no steam can get behind them; will clean the cylinder walls of grit and push it out through the exhaust ports, even in vertical engines, without allowing a single particle to get between the rings and the wall; and will notify the engineer, without the necessity of an inspection, a sufficient length of time before they require renewing, so that he may order new rings and have them on hand against the hour when they ask to be placed on the retired list, which will be at a time when the engine is shut down for rest and recuperation and the engineer is wondering what he can do to kill time.

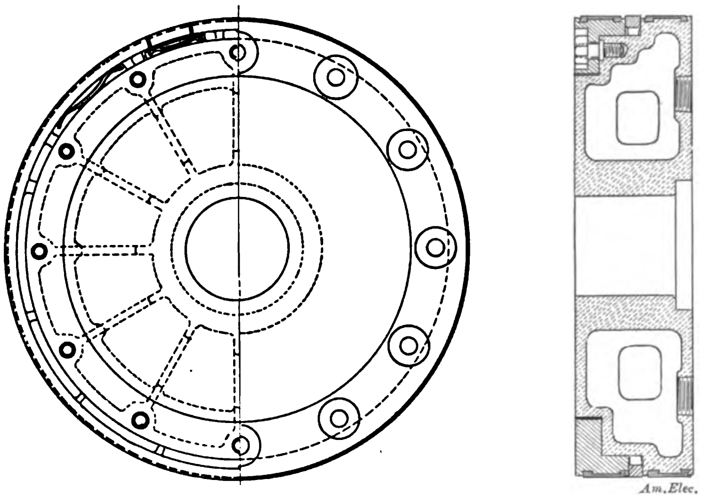

FIG. 22.—A BABBITTED BULL RING PISTON.

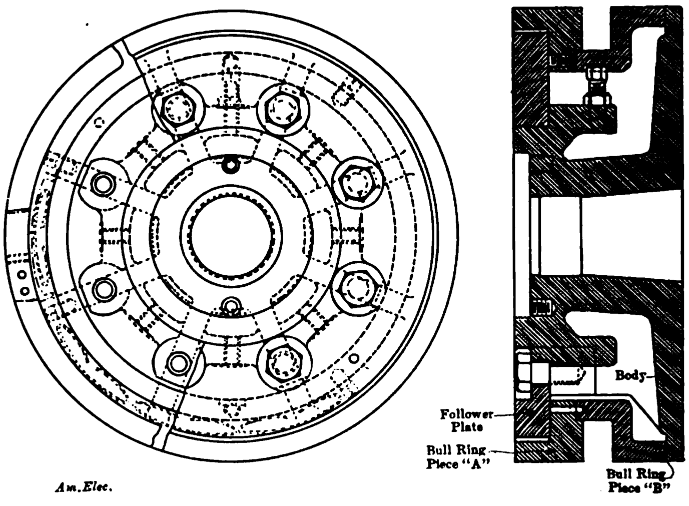

FIG. 23.—AN UNBABBITTED BULL RING PISTON.

In short, the piston and rings will be endowed with qualities of mind and matter which will place them in an order of sentient beings considerably above the average human being.

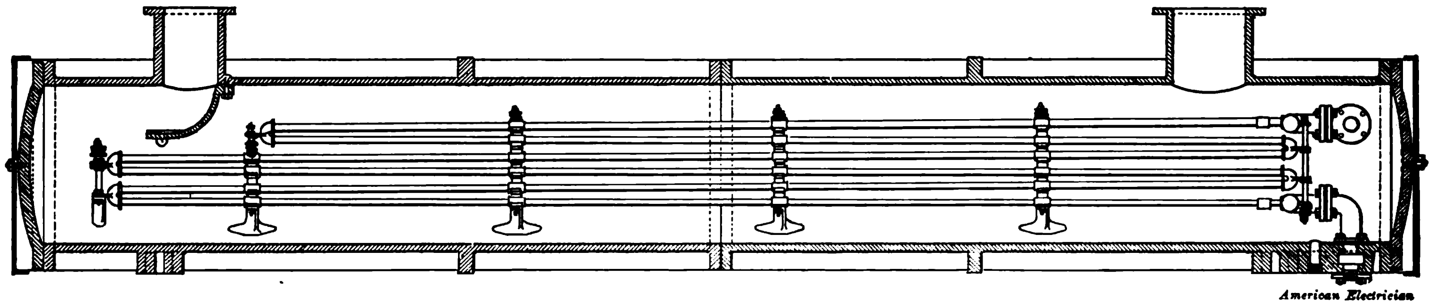

FIG. 24.—LONGITUDINAL SECTION OF A MODERN REHEATING RECEIVER.

Having described the construction that will be wrought out in the future, if the world lasts long enough, we will return to present-day practice. Figs. 22 and 23 show two constructions which, while yet inanimate and inorganic, and therefore extremely low in the scale of possible evolution, nevertheless have met with a favorable reception and seem to meet the requirements fairly well when controlled by external intelligence. The piston in Fig. 22 is well adapted for moderate pressures and saturated steam; the babbitt facing gives a smooth rubbing surface that does not abrade and takes nearly all the wear. In the presence of grit the value of the lining is doubtful; some claim that it is an advantage, as the grit beds itself in the babbitt, thus reducing the tendency to cut, while others claim that the grit, after bedding itself in the babbitt, will continue to cut until the lining is replaced, whereas with an all-iron face the grit will be gradually worked out of the cylinder into the exhaust. But, of course, it is not to be expected that ordinarily grit will be found in a cylinder. The ring is expanded by flat steel springs the tension of which is predetermined; it will also be noticed that side plates cover the opening between the ends of the ring to prevent steam from blowing through or working under the ring and forcing it out against the cylinder walls with an abnormal pressure—a frequent cause of excessive wear and cylinder cutting. The construction is not suitable for very high pressures or highly superheated steam, as the babbitt will not stand the temperature and the unequal expansion between the iron and the babbitt tends to loosen the lining, which when once loose rapidly goes to pieces.

Fig. 23 shows the construction of a bull-ring piston adapted for high as well as low pressures and for any degree of superheat short of a temperature which will destroy the tension of the steel expanding springs. The design embodies several unusual features and has been found to meet satisfactorily a very wide range of conditions; studs are inserted in the bottom of the slot and adjusted so that they almost touch the inner circumference of the ring when in position in the cylinder; this prevents the ring from collapsing on the springs while under steam pressure when over-running the counterbore, keeps the piston central, and prevents it from being blown to one side by the inrush of steam at the beginning of the stroke. Two grooves turned in the outer circumference of the ring assist the lubrication and serve an important purpose in facilitating the escape of any steam that may work under the ring, the steam escaping from the interior into these grooves through small holes drilled at intervals through the ring, and then working out between the face of the ring and the cylinder wall; the same ring is also used with other piston constructions. The bore for the piston rod is tapered, as this ensures a better fit and a firmer grip on the rod than can be secured with a straight bore and shoulder.

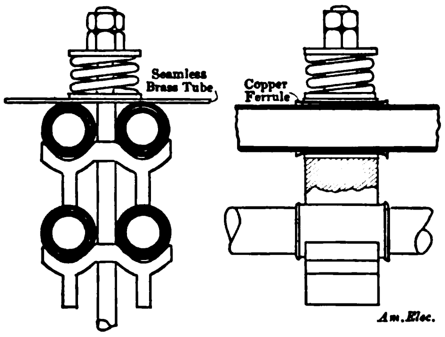

FIG. 25.—DETAILS OF REHEATER TUBE FASTENINGS.

The value of cylinder jackets and reheating coils between high-pressure and low-pressure cylinders has been much debated, but until recent years there has not been a sufficient body of reliable evidence on which to base positive conviction. The judgment of those manufacturers who have given the subject most attention may be briefly summarized as follows: High-pressure cylinder jackets have a small value, and aside from their steam economy are useful for warming up the cylinder before starting; intermediate reheaters have a decided value if properly proportioned and used; low-pressure cylinder jackets are likely to be wasteful, or at least not economical, and their function can be far better accomplished in the reheater; the combined action of a high-pressure cylinder jacket and intermediate reheater may reduce the steam consumption at full load from 7 to 10 per cent, the percentage of saving increasing for lighter loads and diminishing for heavier loads, and being greater at high than at low pressures.

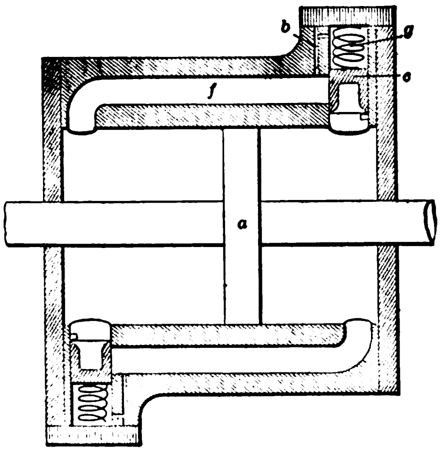

FIG. 27.—CROSS-SECTION OF DASH-POT.

The efficiency of jacketing, including in that term the reheater coils, is determined in part by the design and in part by the manner of using. High-pressure cylinders should have both heads as well as the barrel jacketed; the reheating coils should have sufficient surface area to evaporate all the water of condensation and slightly superheat the receiver steam at full load, when the moisture in the steam entering the high-pressure cylinder does not exceed 1½ to 2 per cent; the receiver must have ample capacity; steam for the jackets must be wholly independent of the steam used in the cylinders; the circulation of jacket steam must be rapid and constant; the condensation in jackets must be returned to the boilers. All of these canons are simple and almost self-evident, but they are nevertheless constantly violated with resulting loss of economy and condemnation of the system; jacket pipes are reduced in area, reheating coils have insufficient surface, receivers are too small, condensation is allowed to collect in the coils or is discharged to waste, and the active circulation of jacket steam is not maintained.

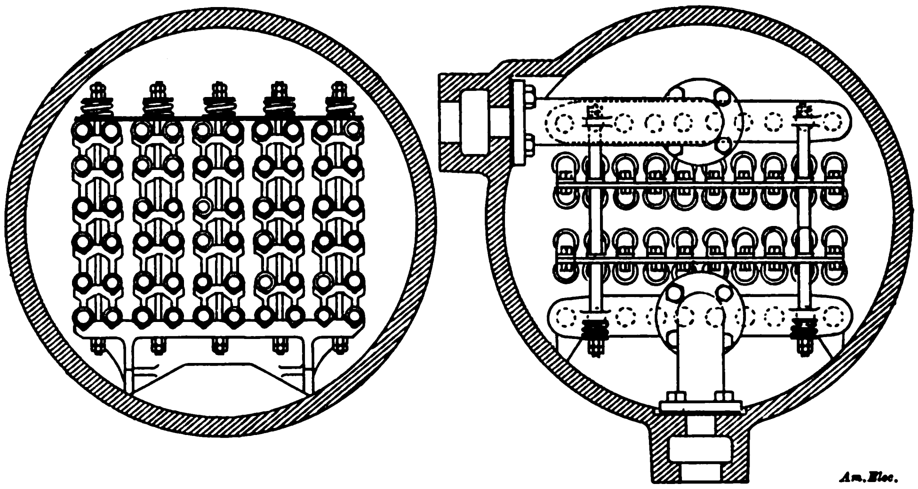

FIG. 26.—CROSS-SECTIONS OF THE REHEATING RECEIVER SHOWN BY FIG. 24.

An excellent example of reheater construction for a vertical engine is shown in Fig. 24. The receiver is sufficiently large to allow the exhaust from the high-pressure cylinder to traverse the tubes slowly, the brass tubes are inclined to insure drainage, one-third of a square foot of heating surface is allowed per rated engine horse-power, the tubes are held sufficiently tight to prevent jarring and wear from the pulsations of the steam, but with sufficient flexibility to prevent strains from expansion and contraction. The arrangement of ferrules, clamps and springs by which this is accomplished is plainly shown in the sectional views, Figs. 25 and 26.

The rapid growth of the alternating-current system has brought prominently to the front the problem of parallel operation. Generally speaking, parallel operation becomes important in proportion as the number and size of units increase; with a large system economy in the use of copper, the proper division of circuits, and the convenient and economical operation of the power plant make it a necessity. In their attitude toward this problem we have a good example of the lethargy and lack of initiative among engine builders in general, referred to at the beginning of this paper. For four or five years dynamo builders have continuously exerted a considerable pressure on engine builders in an effort to get them to devise a means for controlling the engine speed independent of the throttle, and for suppressing cross currents due to a synchronous action between the governor and the cross currents by which the currents are maintained and sometimes increased.

Under this stimulus one engine builder has promptly attacked the problem and has developed a highly efficient speed-changing device controlled at the board by the switchboard attendant, who has entire control of the engine speed within certain limits, and who can connect units in parallel, disconnect them, or divide the load in any desired proportions between two or more units operating in parallel without affecting in the slightest degree the sensitiveness of the governor or its capacity for regulation, or interfering with the duties or responsibilities of the operating engineer. The same manufacturer has developed, for preventing the synchronous inter-action of governor and cross currents, a special form of dash-pot with by-passes controlled by valves having a time element in their movement; this dash-pot is illustrated by Fig. 27. With a fixed load and the governor quiet, no pressure is exerted in either direction upon the oil with which the dash-pot is filled, but if the load changes, the governor weight tends to move, thus exerting a pressure on the by-pass valve through the medium of the oil. If the load is of very short duration, as is the case with cross currents, the effort of the weight to change its position does not persist for a sufficient length of time to open the by-pass valve, the piston in the dash-pot, and consequently the governor weight, is prevented from moving and the average engine speed remains unchanged; on the other hand, if there is a legitimate change of load the effort of the weight to change its position persists, the by-pass valve opens, giving a free passage to the oil, and leaving the governor perfectly free to move to the new position required by the change in load. The time required for the full opening of the by-pass valve is so short that the sensitiveness and accuracy of the governor are unimpaired.

One or two other builders are at work on devices to accomplish the same results, but they are as yet in the experimental stage, and owing to the possible effect on patent applications, details are not available for publication. The majority of builders, however, adhere to their established practice, so that dynamo builders are, in many instances, reduced to the crude, uneconomical and inefficient expedient of advising, in order to suppress cross currents, a degree of regulation that would not be tolerated with direct-current apparatus, while the division of load is largely left to take care of itself.

The question of cylinder ratios still continues to be discussed, but without definite progress; the final decision must rest on practical results, and thus far results prove nothing, as equally good results can be cited with widely different ratios. Until there is a decided preponderance of evidence in favor of a change it is probable that the present moderate ratios of 1:4 or 1:4½ for pressures of 130 to 150 lbs. will be adhered to by conservative builders, as there are certain mechanical disadvantages in the higher ratios.

The subject of highly-superheated steam is attracting increased attention which will undoubtedly be followed by an increase in its practical application. That there is an economy in the use of superheated steam is well established, but whether there is the degree of economy claimed by some of its extreme advocates may be doubted. The literature extant is confined mostly to tests on single engines under fixed conditions, while its real value must be determined by the results obtained for the entire plant, under the regular running conditions, and taking into account total operating expenses and not merely steam or coal. There is very little authentic data, especially in large sizes, with respect to its use in engines with the high rotative and piston speeds now being adopted; rod packings have not been developed in this country to a point where they are guaranteed under more than very moderate degrees of superheat; few operating engineers have had any experience in its control, use and dangers; and there remains much to be learned with respect to its effect on auxiliary apparatus.

At the present time it is entirely feasible so to design a plant that a degree of superheat may be added sufficient to prevent initial condensation in the high-pressure cylinder, relying on the intermediate reheater for the additional superheat required by the low-pressure cylinder; the knowledge gained from a few stations operated under this condition will form a sure foundation for further experiments; in the present state of actual knowledge the wisdom of the suggestion which has been made to add at the beginning superheat sufficient to carry the steam dry through both cylinders is, at least, doubtful.

The economy in steam consumption obtainable from well designed compound engines is so close to the economy of triple-expansion engines that the difference is usually offset by counter charges for interest on the increase in first cost, the increase in maintenance, and the cost of the additional floor space required; there is also the practical objection of the diminished overload capacity of the triple.

The descriptions and illustrations throughout this article have referred almost exclusively to horizontal engines. The reason is solely that the horizontal type has offered a wider range of examples and practice than the vertical, and it is not to be inferred that the former possesses any inherent advantages over the latter; in fact, most of the subject matter may apply equally well to both. There is one type of engine that is most suitable for a given set of conditions, but the type must be subordinated to the conditions and not the conditions to the type; therefore, the engine should be horizontal or vertical, simple, compound or triple-expansion, high-speed, moderate-speed or slow-speed, as the conditions dictate.

A HINT FOR PRACTICAL ENGINEERS.

BY WILLIAM D. ENNIS, M. E.

The purely practical man in the central station works under one disadvantage; when a proposed line of improvement is suggested to him he has just two sources of information to fall back on. One is his good judgment, the other his experience. He may have plenty of both, and yet be compelled to say "I don't know" when he is asked whether doing this or not doing that will save coal. To illustrate: A thoroughly competent man is in charge of the steam plant, say, of a large department store. He carries steam at both high and low pressure for heating, restaurant and elevators. The owners decide to install a lighting plant. How is he to know and prove whether it will be best to purchase cheap simple engines and supply the low-pressure mains with exhaust steam, or to put in expensive and highly economical compound-condensing units? One manufacturer of steam engines advises the first course, another advocates a precisely opposite procedure. It is a question of calculation. The engineer needs all the theory that is in him or that he can invoke, and even then he must be extremely careful, unprejudiced and conservative in his estimates.

He may be contemplating the purchase of a feed-water heater. One manufacturer guarantees to produce a temperature of 212°, another of 160°. Both are apparently reliable people. What is the buyer to do, unless from the quantities and pressures of steam and water and the design of the heater he can calculate which of the two bidders is naming a reasonable efficiency? If he is sufficiently good at figures to work out the problem, he has still to convince his employer that he is right and the sanguine manufacturer wrong. What is wanted in the great modern central station engine room, such as those of the Metropolitan and the Manhattan systems in New York City, is the man who is able to think in B. T. U. or to stop a Corliss engine without getting it on center; to analyze flue gases or to show a new fireman how to wash a boiler; to calculate clearance volumes or to oil an eccentric. He must, and can, be a master of the machinery he handles, knowing not only what it does but why.

The fundamental idea that must be mastered by every engineer who wants to handle steam engineering problems is that of the difference between heat and temperature. Temperature is nothing more than a measure of quality or intensity of heat, and has very little to do with quantity. A pound of water and a pound of steam may both be at a temperature of 300°; but the latter contains four times as much heat as the former. Put the pound of water into a tank and mix it with a pound of comparatively cold water, say at 100°; the final temperature will be about 200°; but mix the pound of steam with a pound of water at 100° and the resulting temperature will be above the boiling point.

The amount of heat contained in a substance depends upon its temperature, weight and specific heat. The specific heat is the amount of heat that would be set free by one pound of the given substance while cooling one degree Fahrenheit. It is measured by comparing it with the amount of heat that would be set free by water under the same conditions. The specific heat of water is considered to be 1. That of liquid ammonia is 1.02 times that of water, the heat unit being a measure of quantity of heat. In heating 10 pounds of water from 20° to 120°, the temperature is raised 100 degrees, and there will be required, therefore, $10 \times 100 \times 1$ heat units, or 1000. The same quantity of liquid ammonia heated through the same range of temperature would require 1,020 heat units, approximately.

The ordinary steam table, as given in all handbooks and manuals on steam engineering, consists of a number of columns. The fourth column of the table usually gives in heat units the quantity of heat in boiling water at the pressure stated in the second column. This is measured above 32° Fahr., and is, for each pound of water, equal to the temperature in degrees less 32 (practically). The fifth column gives the quantity of heat in steam at the stated pressure. This is equal to that given in column 4, plus what is known as the "latent heat of evaporation," and which is tabulated in column 6. These values represent the amount of heat which must be provided to evaporate water after it has been raised in temperature to the boiling point; the same amount being set free in the condensation of steam without loss of temperature. Upon this point—the large quantity of heat imparted or lost without any change whatever in temperature—hinges all computations of efficiency of feed-water heaters.

An illustration will plainly show the wide application of the steam table to practical uses. In a certain power plant there were in use two feed-water heaters. The main heater was connected in the exhaust pipe of a condensing engine; the small heater received several pump and condenser exhausts. The feed-water passed first to the large and then to the small heater, on its way to the boilers. After the plant had been operated for some time a new engine and condenser were purchased. Some original genius conceived the idea of piping from the small heater to the new condenser in order to get the benefit of a vacuum on the small exhausts. The feed-water after passing the second heater, instead of being at a temperature of 192° as before, dropped to 137°. The explanation was not far to seek. The vacuum of the main engine and original condenser was 24 inches. The temperature, according to the steam table, was therefore about 141½°. This was the highest possible temperature that could be imparted to the feed water at this point by means of a closed heater. The new condenser maintained a vacuum of 26 inches, and a temperature, consequently, of 126°. Instead of being a feed-water-heater, the second heater was therefore a feed-water cooler, and was actually chilling the water as it came from the first heater. This could have been avoided by the use of a little "theory."

As an illustration of an opposite tendency, an eminent consulting engineer—one whose name is often quoted as authority—was once inspecting a large mill plant in company with the president of the manufacturing corporation. The man in charge of the engines was called from the room. The piston-rod gland of the main engine began to let steam through. The president noticed it and knew enough to realize that the engine needed a little cylinder oil. The scientist saw, too, almost at the same minute, that the lubricator was nearly empty. Neither of them knew how to fill or adjust it, although the oil can stood on the cylinder lagging close by. The consequence was that when the practical man came back and pumped a little oil into the cylinder through the hand cup, neither of the two had enough dignity at call to reprove him for his negligence.

A FEW COMMON BOILER TROUBLES.

BY R. A. DOUGLASS.

Blisters.—Blisters often appear on the plates of a boiler after the boiler has been in service a short time. Formerly, when iron plate was used in boiler construction, it might be said to be exceptional to find a boiler that had been in use for some time without showing, somewhere, evidences of a blister. This was because the mode of manufacture of the iron tended to produce a laminated product, of such a character that a part of the plate could easily separate from the rest of it. If at some point the various layers of plate were not firmly united to one another, the heat-conducting power of the plate would be materially lessened where the layers were not firmly united, and the result would be that the outer layers could become so much overheated as to soften and bulge outward. Now that steel is used so commonly in the manufacture of boilers, it is rare to find a blistered or laminated plate, although occasionally they do occur. Blisters, in most cases, are harmless, as they cover only a small area. A blister on the heating surface can be best treated by chipping off the projecting part so as to leave a clean surface of the sound plate exposed to the fire. Unless the blister is very large in extent, it is not wise to cut out the part of the plate in which it occurs. Many a boiler has had its strength materially reduced by having part of the plate cut out in this way and replaced by a single riveted patch, when the other seams of the boiler were double riveted.

Fire-cracks.—These are cracks extending from the edge of the plate to the rivet holes. On the horizontal tubular type of boiler they are found chiefly on the girth seams over the furnace, and in internally fired boilers any of the joints in the fire box may show them. (The inner side of the door is liable to be attacked also.) In most cases fire-cracks do not leak unless they extend past the rivet hole. In this case a half-inch hole should be drilled at the end of the crack, and a stud-bolt screwed into it. This will stop the leakage and prevent a further extension of the crack. Fire-cracks are due to several causes. Thus they are especially likely to appear when the material composing the plate is hard, and does not possess a proper degree of ductility. Again, the plate may have been injured in the construction of the boiler, by the careless use of the drift-pin. Poor management of the fire doors is also responsible to a considerable extent; for when the fire doors are thrown open while a hot fire is burning, so as to allow the cold air from the outside to strike directly against the heated plates, a sudden contraction of the material results, and this is likely to be followed not only by fire-cracks, but also by leakage at the seams in general, or at the tube ends in the rear head. Care should always be taken to avoid all unnecessary admission of cold air against the plates when the boiler is under steam.

Oil.—When heavy lubricating oils, or oils of any sort that leave a considerable residue upon evaporation, find admission to a boiler, it is almost certain that defects will sooner or later make their appearance, and be followed by an extensive bill for repairs. The commonest way for oil to get into a boiler is by being pumped into it together with the drips from a system where exhaust steam is used for heating, and the water of condensation is returned to a receiver. In all systems of this kind an oil separator should be used, and the drip from this should be carried to a sewer. (The writer remembers a case in which the drip from the separator was led into the receiver instead of the sewer, so that the oil passed into the receiver even more directly than it would have done had there been no separator present. The boilers at this plant were nearly ruined in a very short time.) In some cases the exhaust pipe from the engine may be provided with a separator, and yet the receiver may receive the returns from one or more pumps, each of which contributes a certain amount of oil. Oil also gets into the feed-water in connection with condensing engines, when the condenser water taken from the hot well is used as part of the feed. It is impossible to prevent oil from getting into the boiler when feed-water is taken from this source. The importance of excluding oil absolutely from boilers can hardly be understood by those who have not seen the damaging effects that may result from the admission of even a small quantity of it.

Pitting.—Pitting in boilers or piping is usually observed where the water is kept for a considerable time at a temperature somewhat below 212 degrees. The boilers that are mostly affected by this sort of trouble are those that are used for heating; and in these it is observed chiefly in the fall and spring, when the boilers are used only a part of the time. At such times pitting is likely to be very marked, and it is nothing unusual to see a set of tubes used up in two or three years. In an instance that came under my observation, a new boiler was put into service, for power, in the month of December, being used in connection with five others. Business becoming slack at this factory about the time the new boiler was installed, only three of the available six boilers were needed at any one time. The practice was to use three of the boilers for two weeks, and then to allow these three to stand idle for two weeks, without emptying them. In the following August three of the tubes in the new boiler gave out. Upon examination it was found that the tubes in this boiler were all badly pitted. The three that had given out were replaced with new tubes, and the boiler was thoroughly boiled with soda ash. Two more tubes gave way during this process, and were replaced.

The battery was then put in use again under the same conditions as before, except that every boiler was now emptied when not in service. This occurred eight years ago, and the tubes are still in good condition. The tubes in the older boilers were not affected, as they were covered with a film of scale which protected them. To protect boilers in which pitting takes place the writer would advise that about 10 lbs. of lime be slacked and put in each boiler. This will cause the formation of a thin lime scale which will prevent pitting for a time. When this thin protective coating is dissolved away, the operation should be repeated. Of course this treatment is not recommended for a boiler is which there is already a plentiful supply of scale. This would naturally be understood, because it is not in these boilers that pitting occurs. Still, it may be as well to speak of this point explicitly, in order to avoid misunderstanding.

THE CHOICE OF A PHOTOMETER FOR CENTRAL STATIONS.

BY WILBUR M. STINE.

It is well for those who have but a slight knowledge of the matter and the practice of photometry to realize that the measurement of the luminous properties of light is far from being in the state of an exact science in which invariably accurate rules and laws may be stated. The chief reason for this condition of the subject, is that photometry is devoted to the action of light which affects the eye in giving rise to the acts of vision. The apparatus for photometrical measurements is thus of a different character from the exact instruments for the measurement of the properties of electricity.

At the outset then, it must be realized that the selection of an appropriate photometer, is a matter to be decided by the suggestion of some one who is sufficiently experienced in such measurements to weigh the relative merits of the different forms of photometers now on the market. The requirements of each particular case would thus be considered and a recommendation made of the type of instrument which would best meet them. In a general way, however, some suggestions may be given in an article like the present one, which will prove helpful, even if they are not adequate for a final selection of the particular instrument.

The first step toward an intelligent choice of an apparatus is to consider the commercial photometers made and sold in this country, under two classes. In one class will fall the photometers made by several firms of established instrument makers, who are sufficiently familiar with the state of the art to know the requirements of its practice, and who have carefully designed apparatus to meet such requirements.

Under the second class must be placed the photometers which are made by firms who do not manufacture high-grade apparatus, either from the standpoint of design or construction. Such instruments are usually given considerable exterior finish, but in their essential parts they are in a large measure worthless. A finely-polished brass case and a neat plate glass cover do not necessarily imply that a voltmeter, for instance, which they cover, is reliable. The essential parts of such apparatus, the soul of the thing, if one may be permitted the expression, is so neglected in design and construction, that the instrument is a delusion and a cheat. No amount of polished mahogany, nor array of bellows, and display of poor scales, can make a good photometer.

There is at least one type of photometer on the market which, from the standpoint of manufacture, is undoubtedly entitled to confidence on the part of at least one of its makers. However, from the considerations of its design this apparatus is to be avoided. This type employs a kerosene lamp for a secondary or comparison standard. A standardized incandescent lamp is usually provided in order to calibrate the oil flame; and when this is so done, the photometer is supposed to be ready for action. If the reasons for the condemnation of the petroleum flame as a standard of light were to be set forth at large, it would require more space than the present article can be given. But briefly, the color of the flame, and more especially its inconstancy, unfit it for such use. Even in the hands of a skilled photometrician, the petroleum flame is unsuited for use as a working standard; and it is especially unsuitable for those who simply make occasional photometrical measurements.

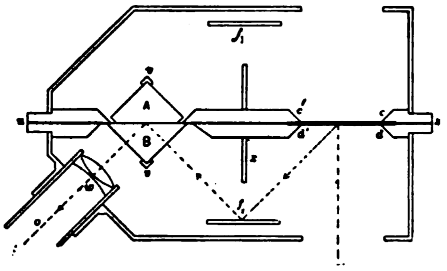

FIG. 1.—BUNSEN SIGHT BOX.

Returning to the consideration of the first class of photometers, which are well made and correct in design, they may be divided into two groups for the present discussion. To the first group belong a few photometers of an especially compact and self-contained design. This type has mounted on a base-board with suitable ways, the supports for the tested and standard lamps, the rheostats for the control of the voltage, and the connections for wattmeter and voltmeters. The essential feature of the apparatus is a Bunsen sight-box; and the whole train of optical fixtures is fitted into a bellows for the exclusion of extraneous light. These instruments may be distinguished by the term "portable," and they have their own sphere of usefulness. They should always be used with a rated incandescent lamp for the working standard of light; and as a rule they are suitable only for the photometry of incandescent lamps. But they may profitably be used to a limited extent in arc lamp photometry. An enclosed-arc lamp giving a rather yellow color of light may be successfully photometered for horizontal candle-power with the use of such apparatus. These portable photometers are to be recommended for general central-station use, and they have the added merit that they do not require an especially fitted dark room; and being comparatively inexpensive, they are admirably adapted for extending photometrical measurements into general station practice.

The second group of accredited photometers comprises those which are designed for the careful and exact measurement of light. Whether they are made by one maker or another, they are closely similar in their general design. They consist in the first place of a *bank*, which is merely a mechanical device for mounting the essential parts of the photometer. The entire group has been modeled over the photometer devised in the German Imperial Physical Institute, or the Reichsanstalt. This type, by reason of the simplicity of its design and its satisfactory character, has been adopted by all the leading American makers.

The bank consists of two parallel ways, usually cylindrical, which serve as a track for the essential parts of the photometer. This track is variously framed and stiffened, and is mounted either on a table or a pair of pedestals. Both a proportional and a candle-power scale should be engraved on the track. When the photometer is to be used for incandescent-lamp testing, the bank is equipped with the lamp holders and the sight box. In addition there should be auxiliary devices for spinning the lamp under test, and rheostats for the control of the voltage; and preferably an universal holder for measuring the candle-power at any angle of inclination. Canopies may be fitted to the track for excluding extraneous light, or the measurements may be carried out in a suitable dark room.

The sight box contains the photometer proper, or the light measuring screen; all the other details and fittings are auxiliary in their relation to this member. There are now but two types of sight box used with this Reichsanstalt photometer, one is the so-called "optical" or the Lummer-Brodhun screen; and the second is the well-known Bunsen screen. We will raise the question, which shall be selected?

It will be assumed that extensive and exact measurements are to be made, and measurements of a more varied character than can be carried out with an instrument of the portable type. A well equipped Reichsanstalt bank is then the only photometer to be considered. Regarding the details of its equipment, the nature of the sight box must be considered.

The essential parts of the Lummer-Brodhun box are shown in plan in Fig. 1, where *A* and *B* are two glass prisms which are firmly clamped together on their hypothenusal faces. One of the prisms is slightly cut out on this face, over two small rectangular or other areas, according to the designed shape of the sight field. The axis, *uz*, of the sight box is set at right angles to the axis of the lamps, or what should be the same thing, to the axis of the bank. A white screen, *cc'*, *dd'*, reflects the light from each lamp respectively to the mirrors, f_1 and f_2, and these in turn reflect it to the prisms, *A* and *B*. The cut-out areas are shown in section in Fig. 2, and if in this figure the prism, *abd*, is taken to represent the prism, *A*, of the first figure, it will be seen that the light from the lamp on the left end of the bank, after being reflected from the screen, *cc'*, and the mirror, f_1, will pass through the portions of the face of the prism, *A*, marked 2 and 4 in Fig. 2; and thence it will pass to the observing telescope, *ow*, and appear to the eye as the parts 2 and 4 of the sight field shown on the right of the second figure. The light, however, falling on the areas, 1 and 3, of the hypothenusal face of the prism, *A*, will be totally reflected and not enter the telescope or appear in the sight field.

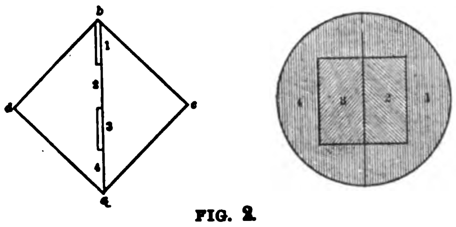

FIG. 2.

The light coming from the lamp on the right-hand end of the bank will be reflected from the side, *dd'*, of the white screen, and the mirror, f_2, to the prism, *B*, of Fig. 1, or *acb* of Fig. 2. The portion of the light falling on the areas marked 1 and 3 will be totally reflected and pass on to the telescope, *ow*, and appear in the sight field as the portions marked 1 and 3. Also the light falling on the areas marked 2 and 4 of the prism will pass on unchanged in direction and not enter the telescope.

The sight field will now be lighted, one-half by the lamp to the right and the other half by the lamp to the left. Precisely, the areas 1 and 3 will be lighted by the lamp to the right, and the areas 2 and 4 by that to the left. In the ordinary use of the sight box, the aim is to bring the two pairs of areas into an equality of illumination, when, if the compared lights are of exactly the same tint, the sight field will appear uniformly lighted. It is perhaps gratuitous to the reader to observe that such an apparatus is complicated in construction and adjustment, and may become perplexing in use.

Some of the advantages which may be advanced in favor of the complicated optical screen are that the plan of the sight field approaches very closely to the ideal requirements for the sensitiveness of adjustment between the illuminations compared, and that by the use of such an apparatus lights which differ considerably in color can be compared with some degree of certainty, and in consequence this screen is adapted to the photometry of arc lamps. The vital questions, however, to one who wishes to apply photometry to commercial and practical uses are: Does the optical screen satisfy these claims in practice, and is there no simpler apparatus which will yield sufficiently accurate results?

In answer to the first question just raised, it cannot be conceded by those experienced with the apparatus that such a screen does meet all the theoretical anticipations which follow from its design. The apparatus is faulty in a number of particulars, and does not in practice yield the high sensitiveness which its design would indicate. The Lummer-Brodhun screen, however, is an admirable instrument for the laboratory, and one that is valuable to the investigator; but it is scarcely advisable for the use of the mere practician.

Before proceeding further with the discussion of this question of practicability it is well to consider what sensitiveness is required in a photometer. Under the very best conditions the value of the standard light used is not accurate within 2 per cent, and the limit of uncertainty is rather apt to be double this value. For practical purposes this limits the sensitiveness required in the setting of the photometer. In the hands of one who is experienced with the Lummer-Brodhun photometer, the sensitiveness of the setting is perhaps many times as great as it need be, considering the unreliability of the standard of light.

Taking up now the second question, the Bunsen screen is about as simple a device for comparing the illuminating power of lights as could well be designed. For the comparison of the two types of screens, a sight box fitted with a Bunsen screen is shown in plan in Fig. 3. The screen is a sheet of paper, *sc*, with a transparent central spot. Two mirrors, *m* and *m'*, reflect the light from the screen to the observing tube, *o*.

The Netherlands Gas Commission, from a comparison of these two screens, found that the Bunsen screen was even more sensitive than the Lummer-Brodhun optical one; and this decision expresses the opinion of many who have had experience with both forms of apparatus. For exact practical photometry the Bunsen screen can be confidently recommended, and it will generally prove more exact and reliable than the more complicated optical screen. Besides, it is comparatively inexpensive and is easily kept in working order.

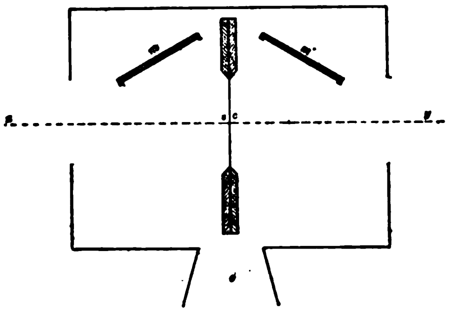

FIG. 3.

ELECTRICAL PROGRESS IN AUSTRALASIA.

BY LAWRENCE BIRKS.

The progress of electrical work in the new commonwealth is steady if not rapid, the tendency being to remodel existing plants on up-to-date lines. In Melbourne, Richmond, Bendigo, and other large cities, the old two-wire 110-volt plants are being scrapped in favor of large three-wire 440-volt systems. For this class of town lighting plant direct-coupled vertical enclosed high-speed engines are in favor, usually of the manufacture of Willans, Belliss or other well-known British builders.

Great developments in water-power schemes are promising in New Zealand and should be carefully watched by firms who are interested in selling the requisite apparatus. The city councils of Auckland, Dunedin, Gisbourne and Wellington have all obtained expert reports and are seeking Parliamentary powers to proceed with works costing from $250,000 to $750,000 each. In electric traction rapid progress is being made. Here, of course, American apparatus holds its own. In Sydney, N. S. W., the present government traction station, equipped with four Allis-General Electric 850-kw. sets is taxed to its utmost and three more 1500-kw. three-phase 6600-volt units by the same makers are on order, together with equipment for five 1000-kw. sub-stations. A large number of smaller towns have tramway systems in hand. Messrs. Noyes Bros., representing the Westinghouse Company, being particularly active.

In power distribution there are three high-tension polyphase stations in operation in Victoria for supplying gold dredging barges with power for pumping, the plant in two of them being American, in the third local. The Kalgoorlie (W. A.) Electric Power Company, which is slowly maturing its plans, promises to supply the mines of that district with an up-to-date system, but there is still a large and almost untouched field in Australian mining for electrical development.

With the introduction of electric power to the larger cities the possibilities of electric elevators are beginning to be recognized, and some three or four have been installed from the Sprague and Otis factories. But there is a big prejudice among the architects to be overcome. Good illustrated catalogues will go a long way in removing this prejudice.

Australian engineering firms have their possibilities fully taxed to supply the demands of the mining and hydraulic industries which are more or less peculiar to the districts. In electrical equipment standard imported lines will prove far more satisfactory than anything which can be manufactured here at present. The long time of mailing and delivery remains a great difficulty. This should be partially overcome as the demand becomes more steady and importing firms can carry larger stocks. For the present it can only be minimized by careful cataloguing.

TWO EXAMPLES OF MODERN AMERICAN CENTRAL STATIONS.

THE ATLANTIC AVENUE STATION OF THE BOSTON EDISON COMPANY.

BY ALTON D. ADAMS.

The history of the Edison Electric Illuminating Company of Boston is similar to that of all of the large Edison central stations. From a modest beginning, with two small bipolar dynamos and a high-speed simple engine under a single roof, of course, the plant has grown to a group of generating stations, the main one of which contains modern machinery in units any one of which has an ability that would have seemed absurdly superabundant when the plant was originated. The company now operates three generating stations and three storage-battery sub-stations. The particular subject of the present article is the Atlantic Avenue plant, which is known as the Third Division station, and has been recently very greatly enlarged.

The Atlantic Avenue station is located on the water front, at the foot of Pearl Street. The plan view given on page 278 indicates clearly the "lay-out." This station was established in 1891, when it was provided with seven Babcock & Wilcox water-tube boilers rated at 368 horse-power each; but space was allowed in the original boiler room for eight more boilers, each of equal capacity to the first. The length of the original boiler room parallel with the boiler fronts was 79 ft., but the extension just made to the station increases this length to about 203 ft. At first the brick setting of boilers was made continuous so that the boiler fronts presented an unbroken line, but the later additions of boilers have been set in pairs with an open passage from front to rear between the settings. One pair of boilers is equipped with Hawley down-draft furnaces.

The new equipment comprises eight double-deck Babcock & Wilcox water-tube boilers rated at 418 horse-power each. These boilers are equipped with Babcock & Wilcox chain grate stokers, 90 x 111 ins., providing a grate surface of 69.4 sq. ft. The stokers are driven by 7½-h.p. 220-volt motors, having a speed of 300 r.p.m., made by the Bullock Electric Manufacturing Company, of Cincinnati, Ohio. Each motor is geared to a jack shaft, having a speed of 70 r.p.m., which can be varied 12½ per cent above or below normal by means of a motor starting box.

There is an eccentric on the jack shaft with a rod connecting down to a rocker arm carrying a pawl, which engages a toothed wheel driving a worm, which in turn drives a gear fastened to the main sprocket shaft of the grate. The ashes are discharged from the furnaces through chutes to the ash room below the boiler-room floor, and then carted away. On the water side of the space beneath the boilers two rooms are partitioned off, one for the circulating pumps and the other for the feed-water pumps.

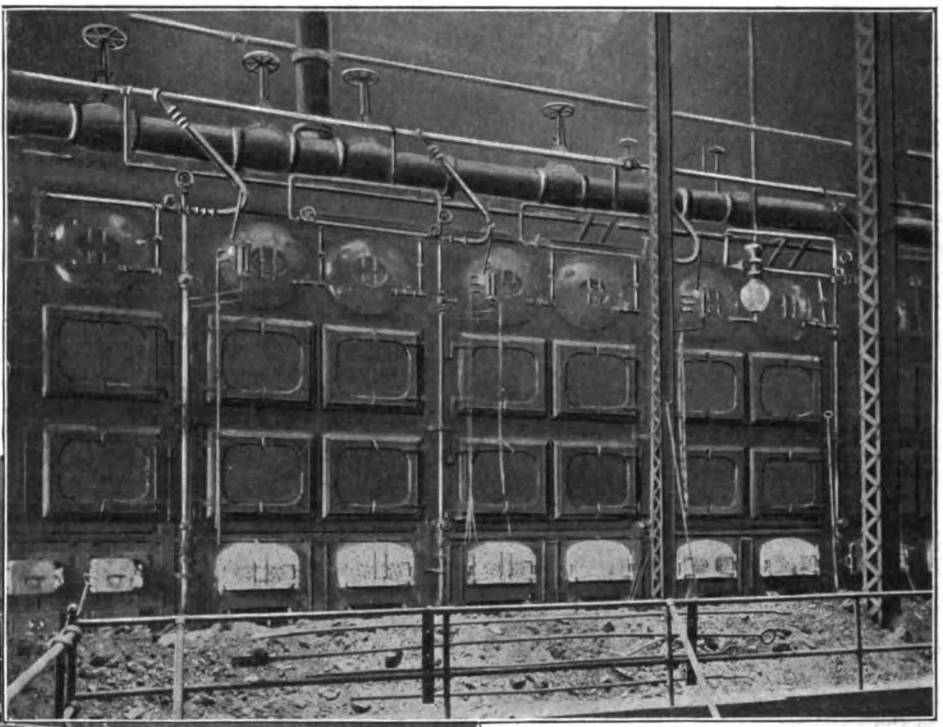

FIG. 2.—THE OLDER BOILERS.

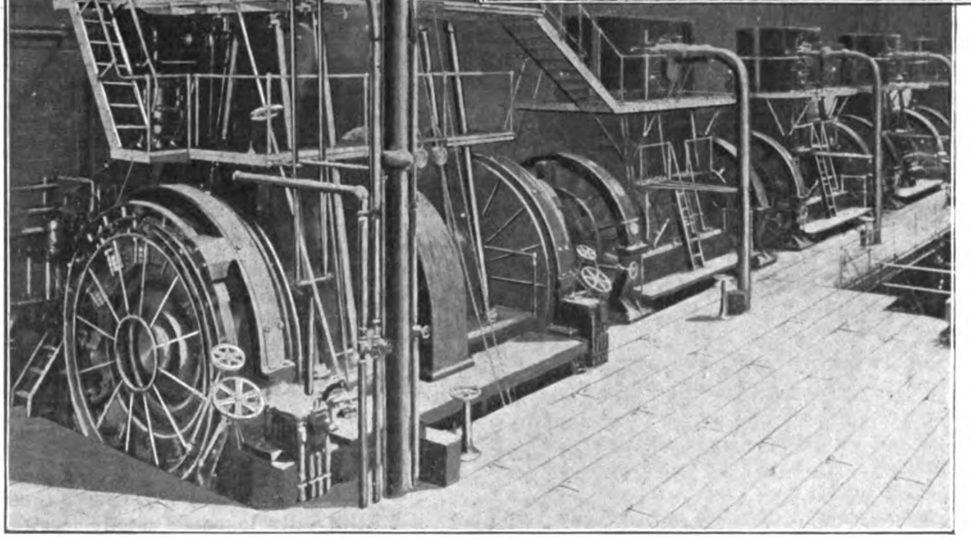

FIG. 1.—ONE SIDE OF THE OLD ENGINE ROOM.

The steam pressure of the boiler plant is 160 lbs., gauge. Natural draft was decided on, and a chimney erected of sufficient height to give the required draft and large enough to conduct the gases of 15 boilers like the first seven. This chimney is 200 ft. high, 11 ft. 5 ins. in internal diameter, while the top diameter outside is 18 ft. at the base and 14 ft. 6 ins. at the top. The outside wall of this chimney starts with a thickness of 20 ins., changes to 16 ins. at about 70 ft. from the base, and again to 12 ins. at about 140 ft., retaining this thickness to the top. The inside core of the chimney is 12 ins. thick at the bottom and to a height of 80 ft., where it changes to 8 ins., retaining this thickness to the top. The core is lined with fire brick to a height of 25 ft. from the base.

A second chimney has been added which is similar to the first one above the roof of the boiler house. The new chimney is octagonal from its base to a height of 55 ft., the outside diameter being 20 ft. between parallel faces. For the rest of the distance it is circular in shape, having a diameter of 14 ft. 7 ins. just below the cap. At the base the outside shell is 24 ins. thick, and the inside shell 16 ins., leaving an air space of 11 ins. between the two. The inside shell extends to a height of 135 ft., is 8 ins. thick at the top, and is lined with fire brick for 55 ft. of this distance. The outside shell is 12 ins. just under the cap. The inside diameter of the flue is 11 ft. 5 ins.

There are three M. T. Davidson compound tandem, non-condensing circulating pumps which supply the surface condensers with water from the harbor; the water ends being lined with composition metal to prevent any action of the salt water on the pipes. Two of the pumps have steam cylinders of 10-in. and 20-in. diameters, water cylinders 20 ins. in diameter and 24-in. stroke, with 14-in. suction and discharge pipes. The other pump has steam cylinders 7 ins. and 14 ins. in diameter, with 14-in. water cylinders and a stroke of 16 ins. For boiler feeding there are two Davidson simple pumps, each having a steam cylinder 14 ins. in diameter and a water cylinder 8¼ ins. in diameter, with a stroke of 14 ins.; also two Blake vertical compound duplex pumps with steam cylinders 10 x 16 ins. in diameter, and water cylinders 8 ins. in diameter, having a 10-in. stroke. There are also installed and ready for use, if necessary, 10 Korting universal injectors.

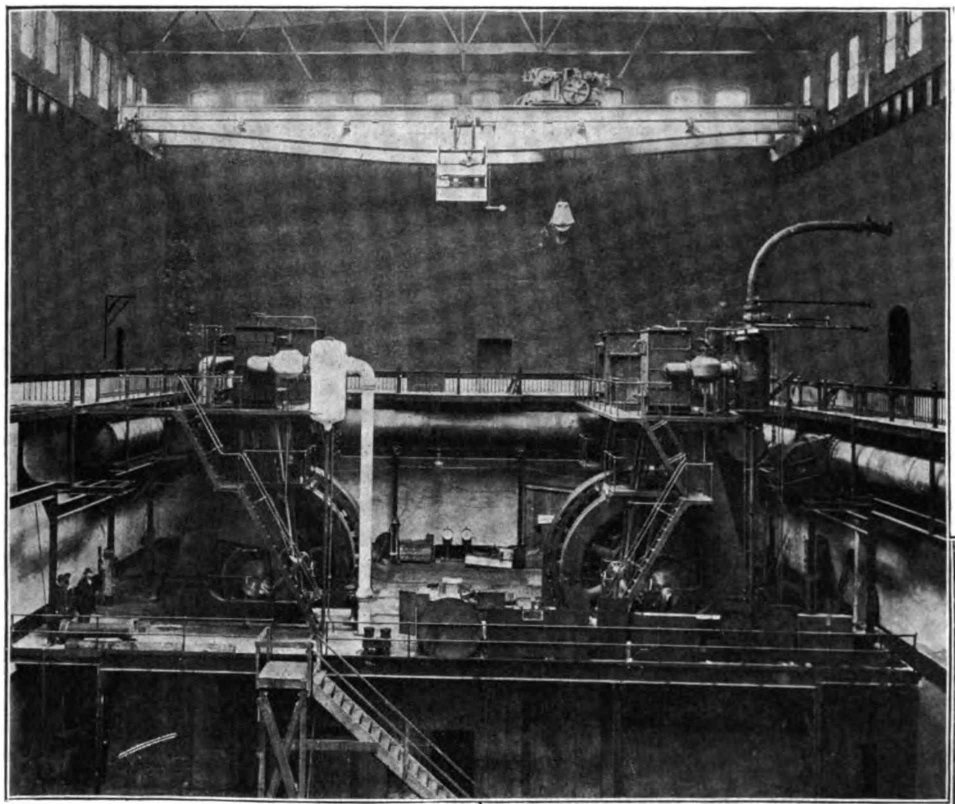

FIG. 3.—ONE END OF NEW ENGINE ROOM.

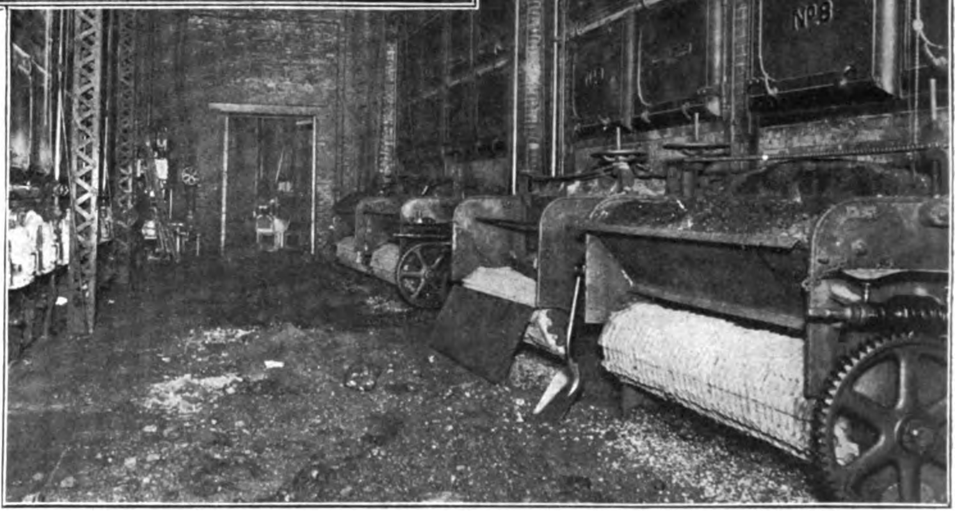

FIG. 4.—PARTIAL VIEW OF THE NEW BOILER PLANT.

Feed water for the boilers is taken directly from the city mains, the pipes in the street being so arranged that it would be almost impossible for the supply to fail. The main service pipe is 12 ins. in diameter, and delivers water under a pressure of 40 lbs. There is also a 12-in. high-pressure main which can be used in case of emergency. From the city mains the water flows through a Goubert exhaust steam feed-water heater, after which it passes into a Cochrane open heater, into which is turned the exhaust steam from all the auxiliaries; from this heater it is pumped into the boilers by the feed-water pumps. On the outside of the boiler room toward the wharf a space has been preserved for economizers, but at the time of writing they have not been installed. There is being drilled at the present time, just outside the boiler room, an artesian well which has already been sunk 500 ft., and if this well should supply the proper quality of water it will be used as a partial supply for the boilers.

The old engine room originally contained four triple-expansion engines rated at 650 horse-power each and built by the J. Morton Poole Company, Wilmington, Del., after designs supplied by the Edison General Electric Company. Each of these is provided with a Wheeler surface condenser and a combined air and circulating pump, these latter in each case being mounted on a cast-iron drip pan close to the engine base. The first addition to the plant was a McIntosh & Seymour cross-compound vertical engine, capable of developing 1200 horse-power under 160 lbs. steam pressure, and running at 100 r.p.m.

This engine has a combined reheater and receiver between the high and low-pressure cylinders, and also has a surface condenser and pump similar to those of the four smaller engines. The head and barrel of the high-pressure cylinder of this engine are jacketed, but not so the low-pressure cylinder. The guaranteed water consumption, including steam condensed in jackets and receiver coils, is 13¼ lbs. per hour per indicated horse-power. Both cylinders are four-ported, and are provided with valves of the flat gridiron type. The clearance is 2 per cent in the high-pressure cylinder and 3 per cent in the low-pressure. All four of the valves are driven by an eccentric controlling the admission of steam and the opening and closing of the exhaust. The cut-off of the steam is effected by separate cut-off valves which are driven by an individual eccentric and regulated by a shaft governor.

The valve gear is positive, composed of simple levers and links, and the cut-off can take place at any point between zero and the maximum cut-off. The piston rods of both cylinders are furnished with "Tripp" metallic packing, and are also provided with auxiliary glands for the use of soft packing. The throttle valve is a quick-opening valve of the double-poppet balanced type, operated from the floor-level by an operating wheel provided with a crank handle. The main steam pipe to the engine is fitted with an 8-in. "Direct" separator.

These five engines have two direct-current dynamos mounted one on each end of the shaft, but this practice was abandoned on the engines next installed, in favor of a single dynamo for each engine, mounted on the shaft between the parts

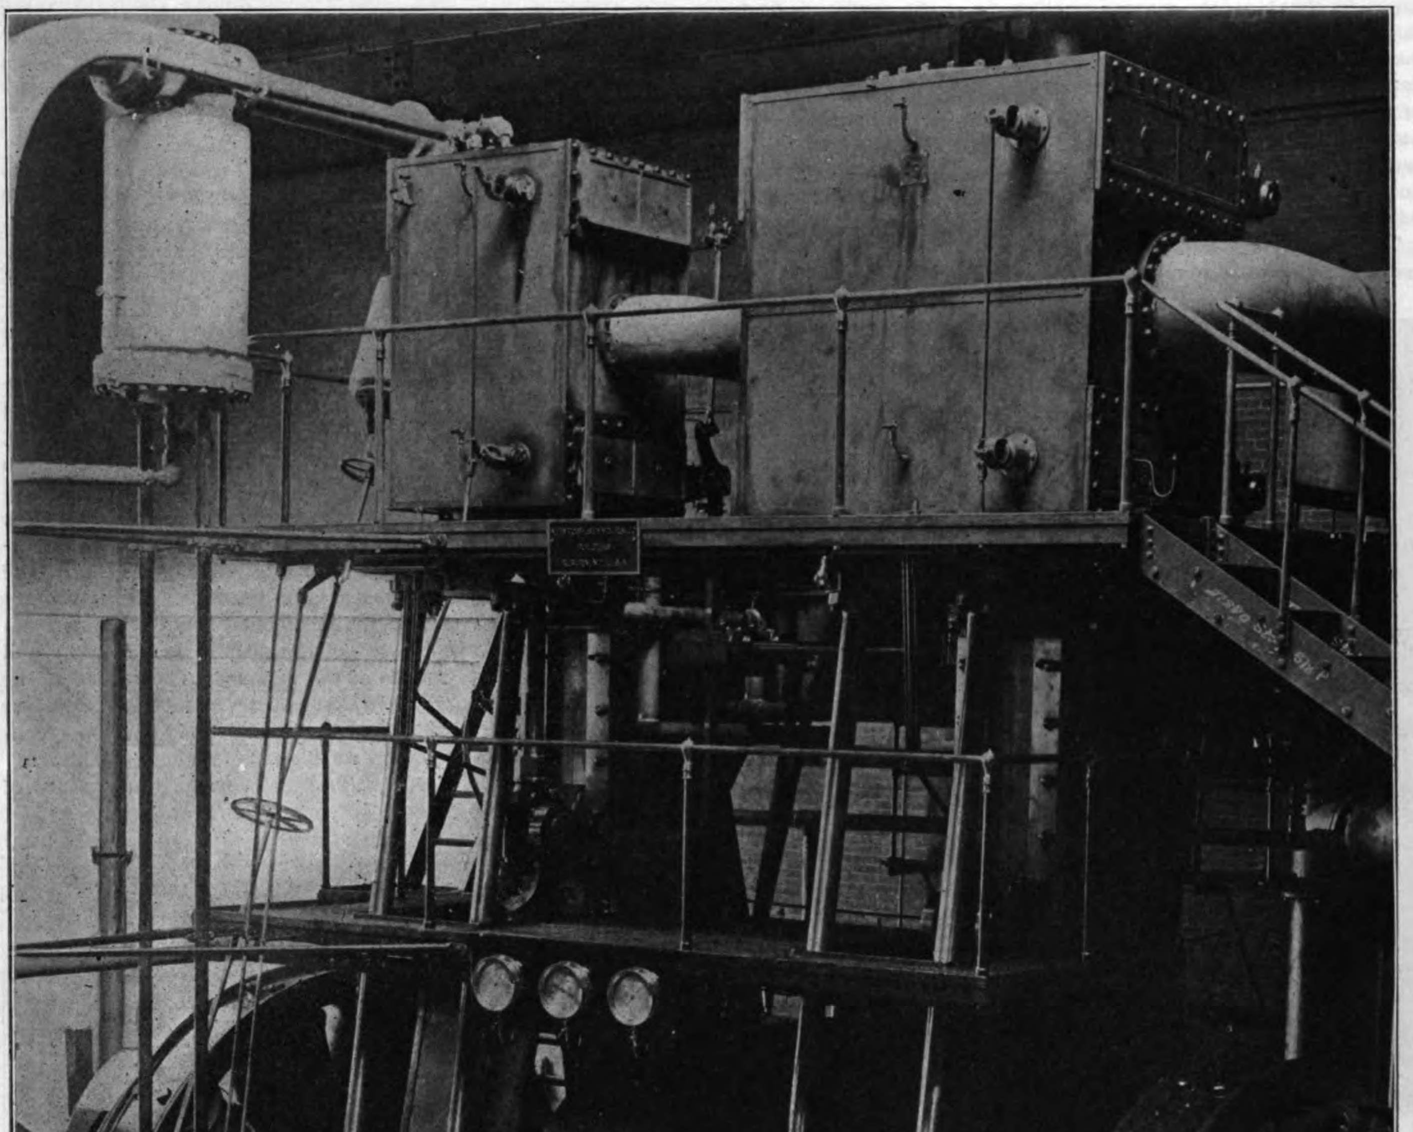

FIG. 5.—CROSS-COMPOUND ENGINE DRIVING TWO 400-KW. 110-VOLT DYNAMOS.

of the frame that support the high and low-pressure cylinders in each case.

The sixth and seventh engines to be installed were both of the McIntosh & Seymour make, and are capable of 1200 horse-power each at 160 lbs. steam pressure, running at 100 r.p.m. Each engine is guaranteed to regulate from no load to full-rated load within 2 per cent speed variation, and to develop an indicated horse-power, when running at full load, with a consumption of 13¼ lbs. of dry steam an hour. The cylinders and steam chests are lagged with magnesia fiber and sheet steel. Between the two cylinders is located a reheater containing about 440 sq. ft. of heating surface supplied with steam at boiler pressure. The cylinders are four-ported and provided with standard flat gridiron valves. The high-pressure cylinder has a clearance of 2 per cent, the low-pressure 3 per cent. The valve gears and governors are of the same type as the fifth one previously described. The bearings are hollow and provided for the circulation of water. They are also provided each with two sight-feed oil cups in addition to the oil which is supplied to the bearings by means of a brass oil pump driven from the valve gear. The crank pins, cross-head pins, guides and wipers are oiled continuously by means of a supply tank situated upon the upper plat-

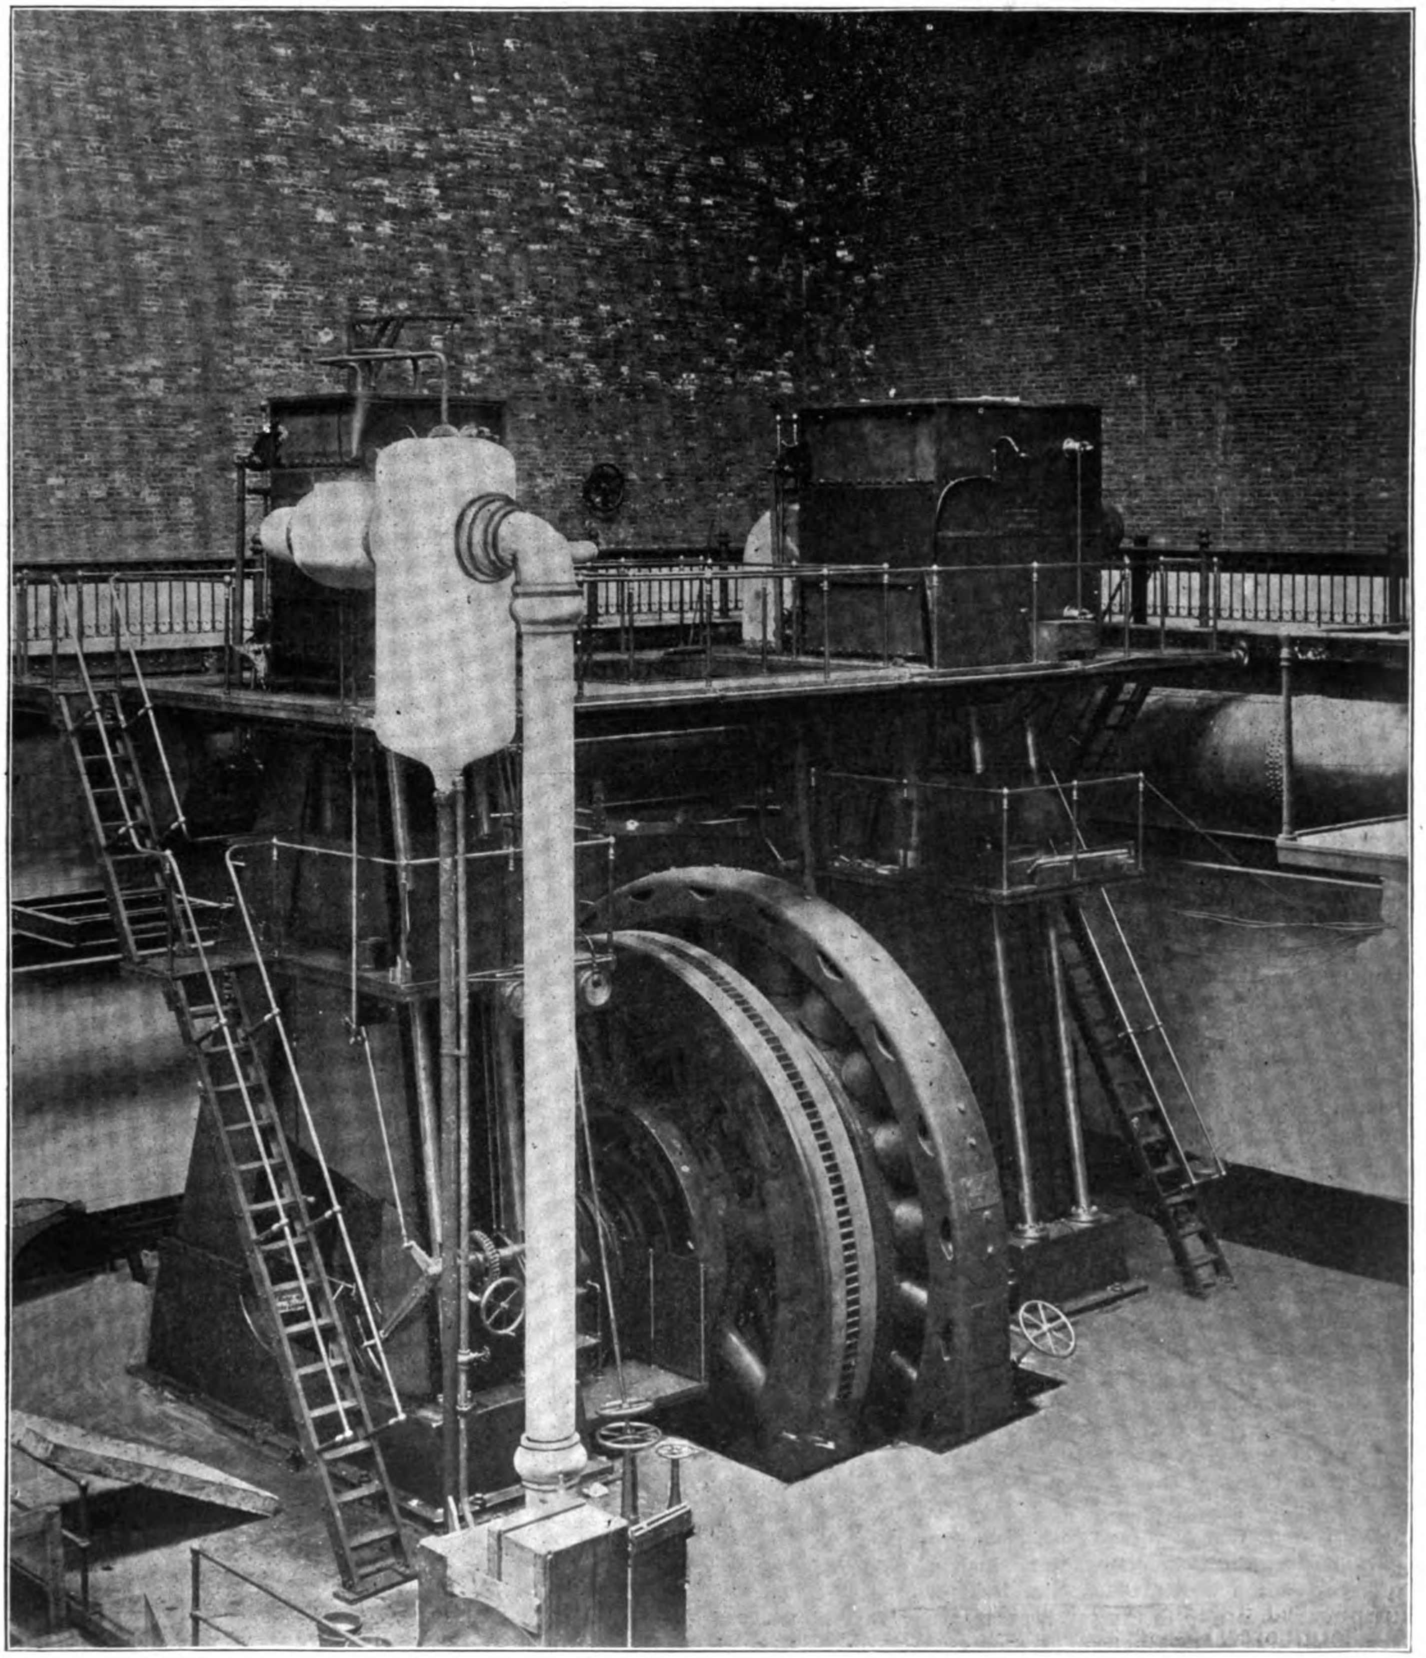

FIG. 6.—THE LATEST CROSS-COMPOUND ENGINE, DRIVING AN 800-KW., 300-VOLT DYNAMO.

form connected by a system of brass piping to an adjustable sight-feed outlet to each part to be lubricated. The engines are equipped with Cochrane receiver separators and have throttle valves of the quick opening piston type.

Both engines are provided with pumps and a condenser, as in the case of the other five. Cooling water for the condensers of all the seven engines thus far mentioned (which are all in the old engine room) is taken from the harbor underneath the wharf at the rear of the station. This water is conveyed to the condensers by a common suction main and is rejected through a common discharge pipe.

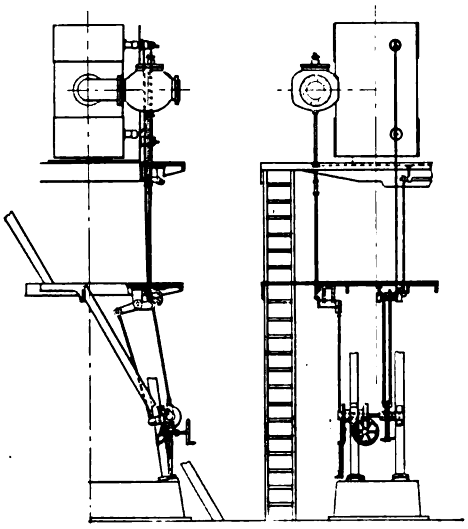

FIG. 7.—THROTTLE VALVE GEAR.

The first engines erected in the large extension of the engine room, that has recently been completed, are vertical cross-compounds of 2400 horse-power nominal capacity each at 100 r.p.m. and 160 lbs. gauge pressure. These are also McIntosh & Seymour machines. The speed is guaranteed to be maintained constant within 2 per cent from no load to full load, and the engines are guaranteed to operate on a maximum steam consumption of 12¾ lbs. per horse-power per hour, including steam condensed in jackets and receiver. Between the two cylinders is located a reheater having a total heating surface of 800 sq. ft. The clearance is 2¾ per cent in the high-pressure cylinder and 4 per cent in the low-pressure cylinder. The throttle valve is of the quick-opening piston type, operated by a set of levers. Each engine is provided with a turning gear operated by a 5-h.p. 220-volt General Electric motor, attached to the rear of the engine bed plate and supplied with a controller and rheostat giving five running speeds; the minimum being 200 and the maximum 960 r.p.m. The valves, governors and other details of these engines are similar to those of the 1200-h.p. engines previously described.

With the advent of these two latest engines an important change in the methods of condensation was introduced, and this change extends also to the seven engines previously installed. Instead of providing a separate pump and condenser for each of these new engines, both exhaust

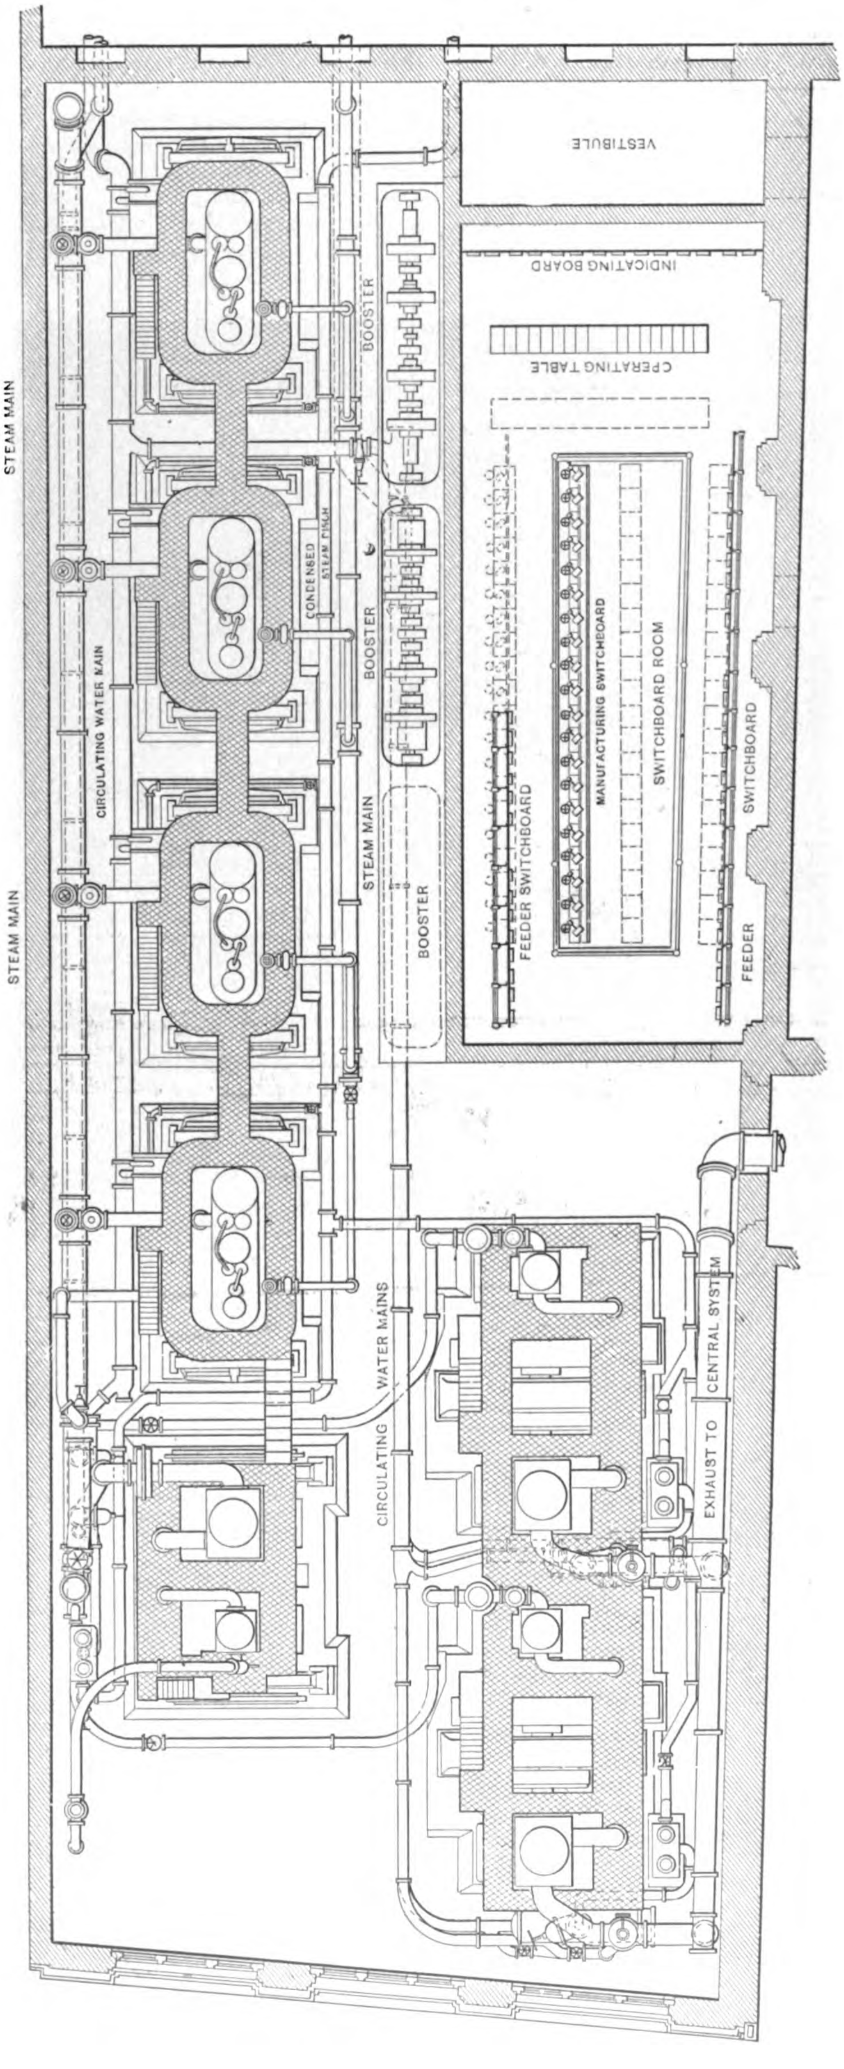

FIG. 8.—PLAN VIEW OF THE OLD ENGINE ROOM; ATLANTIC AVENUE STATION.

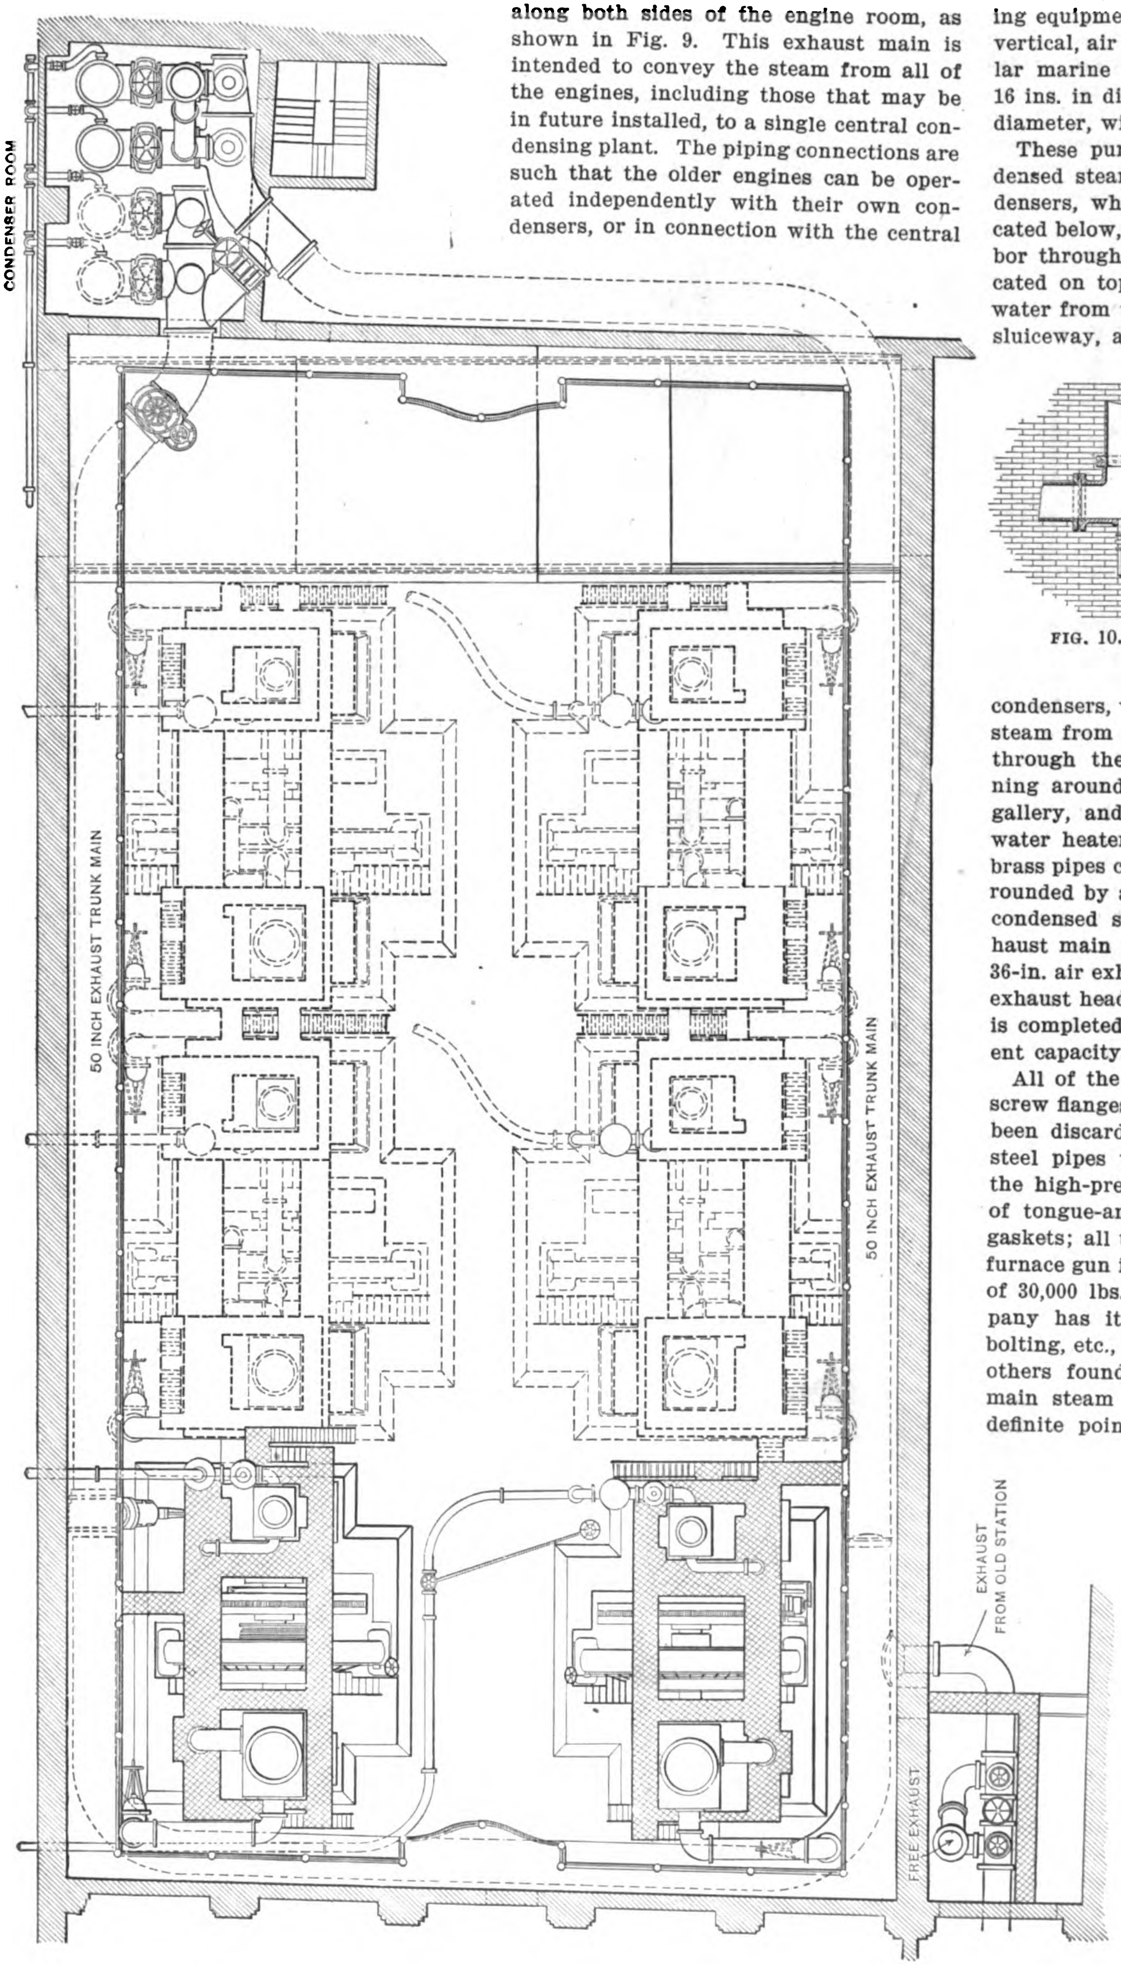

FIG. 9.—PLAN VIEW OF THE NEW ENGINE ROOM AND THE CONDENSER ROOM.

into a 50-in. exhaust main that extends along both sides of the engine room, as shown in Fig. 9. This exhaust main is intended to convey the steam from all of the engines, including those that may be in future installed, to a single central condensing plant. The piping connections are such that the older engines can be operated independently with their own condensers, or in connection with the central condensing system. The central condensing equipment comprises two Blake, twin, vertical, air pumps (inverted) of the regular marine type, having steam cylinders 16 ins. in diameter and buckets 44 ins. in diameter, with a common stroke of 24 ins.

These pumps take the water and condensed steam from the Knowles jet condensers, which are of the cone type, located below, and discharge it into the harbor through the 48-in. discharge pipe located on top of the sluiceway. The salt water from the channel flows through the sluiceway, already described, into the jet condensers, where it is met by the exhaust steam from the engines which has passed through the 50-in. condenser pipe, running around the engine room under the gallery, and also through Goubert feed-water heaters, consisting of a number of brass pipes conducting the feed water, surrounded by a chamber through which the condensed steam passes. The 50-in. exhaust main is furnished with two 30 and 36-in. air exhaust pipes, having Sturtevant exhaust heads. When the condenser room is completed it will have double its present capacity.

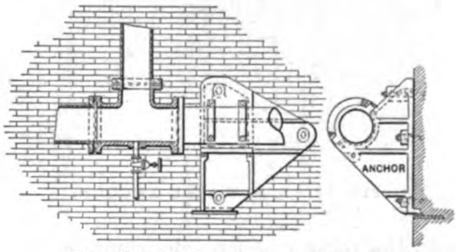

FIG. 10.—STEAM PIPE ANCHOR

All of the copper pipe and most of the screw flanges, as originally installed, have been discarded and are now replaced by steel pipes with flanges welded on. All the high-pressure steam pipe is made up of tongue-and-groove joints with copper gaskets; all the fittings being made of air-furnace gun iron, having a tensile strength of 30,000 lbs. per square inch. The company has its own standard for flanges, bolting, etc., those used being heavier than others found in common practice. The main steam pipe is anchored at certain definite points, so as to control the direction of expansion. Figs. 10 and 11 illustrate the methods of anchoring.

From the steam outlets on the boilers 6-in. vertical loops, carried high above the boilers in order to give the desired flexibility, connect to the steam mains which vary from 8 to 12 ins. in diameter. These mains run crosswise of the boiler room, discharging into short 12-in. headers parallel with and supported on the side wall between the boiler and engine rooms. From these headers, which are connected by means of 8-in. equalizing loops, the pipes lead directly to the engines.

The engines in the old room are divided into two groups, each group being supplied from a 12-in. main; the four triple-expansion engines are fed from one main and the three 1200-h.p. compound engines from the other. In the new engine room each engine has its own pipe connecting to one of the headers. Each has, besides its quick-acting throttle, an outside gate valve geared to a floor stand convenient to the engineer standing at the throttle. Each boiler is provided with an automatic stop check to prevent the back flow of steam in case of a drop in pressure or a rupture in the boiler. Each boiler has a stop valve which is geared to a handwheel located on the outside of the boiler-room wall, where it can be operated in case of an accident in the boiler room.

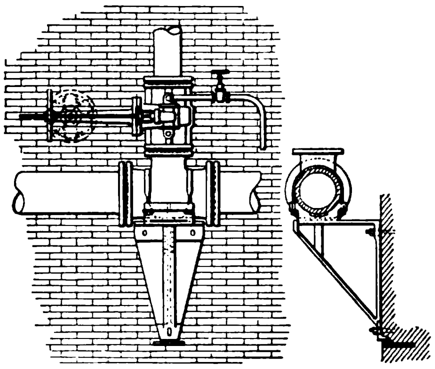

FIG. 11.—STEAM PIPE ANCHOR.

All the auxiliary apparatus, like feed pumps, circulating and air pumps, are fed independently from the boilers by means of a 6-in. pipe. All the high-pressure drains from the engines and main steam pipes are returned to the boilers by the Holly system.

The first eight dynamos installed at the Atlantic Avenue station were 200-kw. 14-pole machines, direct-connected in pairs on opposite ends of their engine shafts. The armatures of these dynamos are of the Gramme type, each having a winding of 980 convolutions formed by U-shaped copper bars and commutator bars that unite the ends of the U-shaped bars. The two dynamos mounted on each engine shaft operate on the two sides of a three-wire system, one between the positive and neutral and the other between the negative and neutral wires. These four dynamos are plain shunt-wound machines. The two dynamos next added are of 400 kilowatts capacity each, and are mounted on opposite ends of the shaft of the first 1200-h.p. engine described above. These two dynamos are similar to the first eight, and are also connected on opposite sides of the three-wire system. The two dynamos next added, which are driven individually by the sixth and seventh engines, are of 800 kilowatts capacity each.

The generator is located between the high-pressure and low-pressure cranks. The speed is 100 r.p.m. and each machine is guaranteed to deliver 2666 amperes at 300 volts, or 2963 amperes at 270 volts.

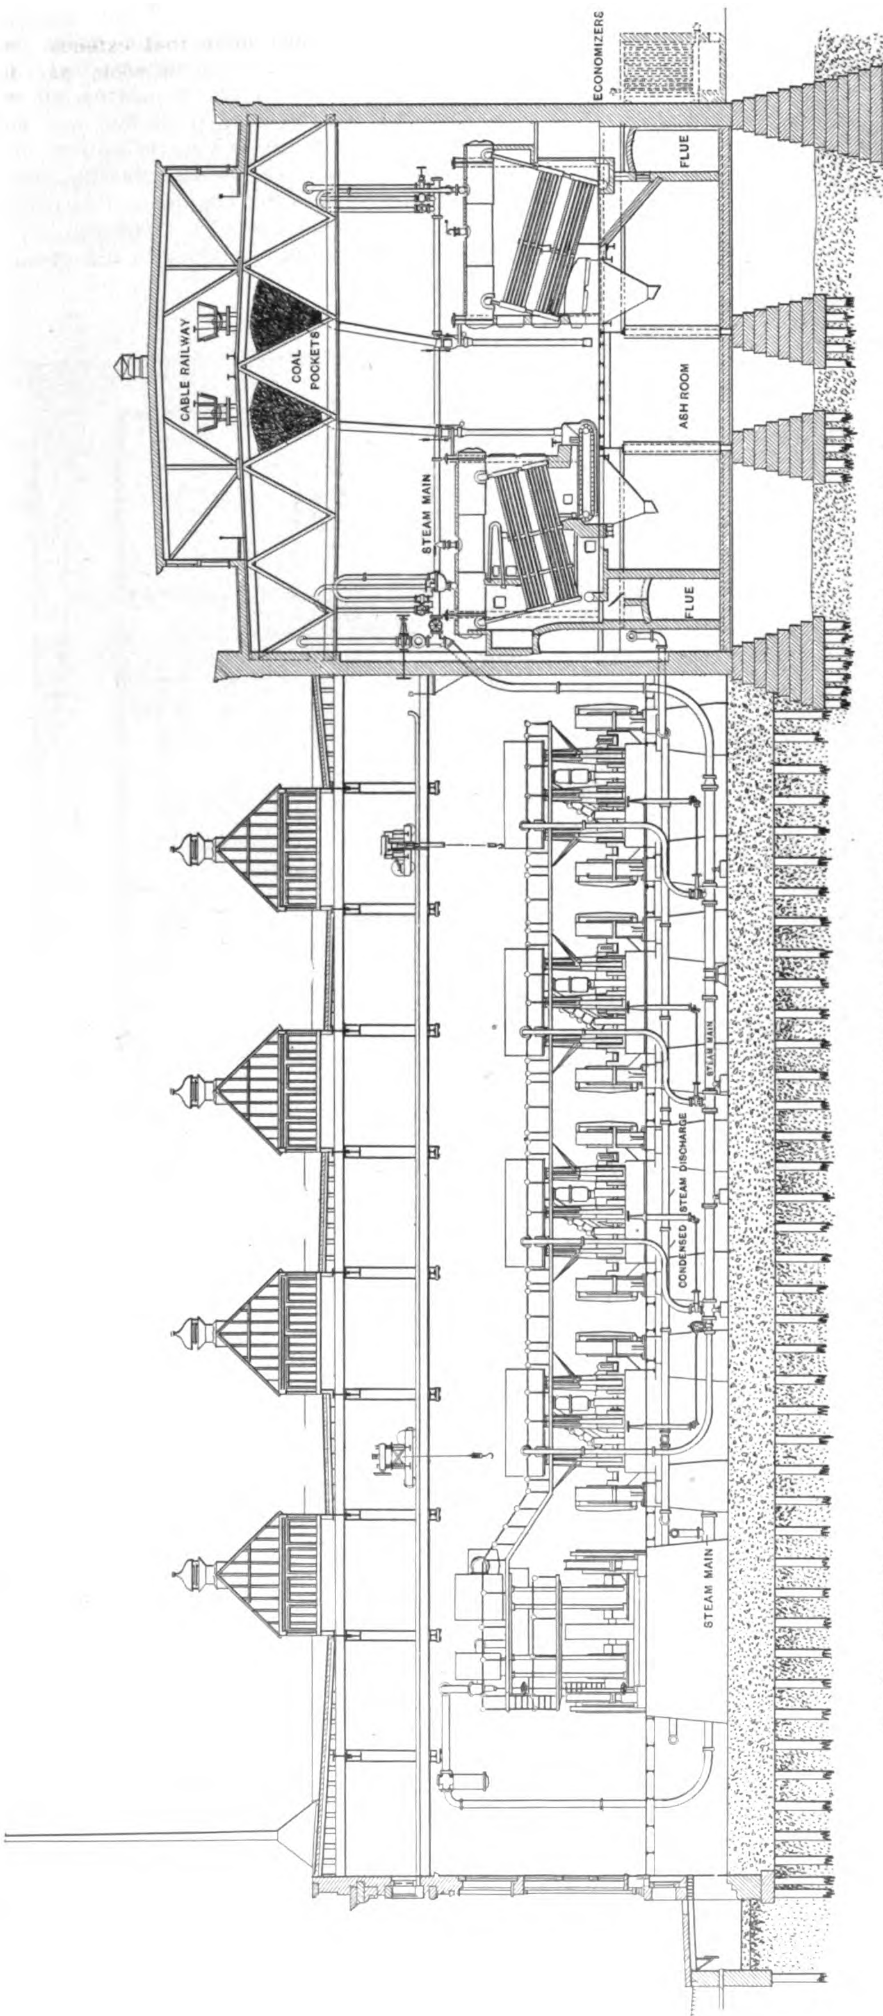

FIG. 12.—SECTIONAL ELEVATION LONGITUDINALLY THROUGH THE OLD ENGINE ROOM AND CROSS-WISE OF THE OLD BOILER ROOM.

These machines furnish current to the outside wires of the three-wire system. The frame consists of a circular cast-iron yoke with 16 inwardly projecting poles of cast steel. The armature is of the ironclad or slotted core type, ventilated by means of air ducts. The armature winding consists of copper bars, laid in slots and insulated from the armature core by means of alternate layers of oiled linen and paper. The outside diameter of the armature is 10 ft.

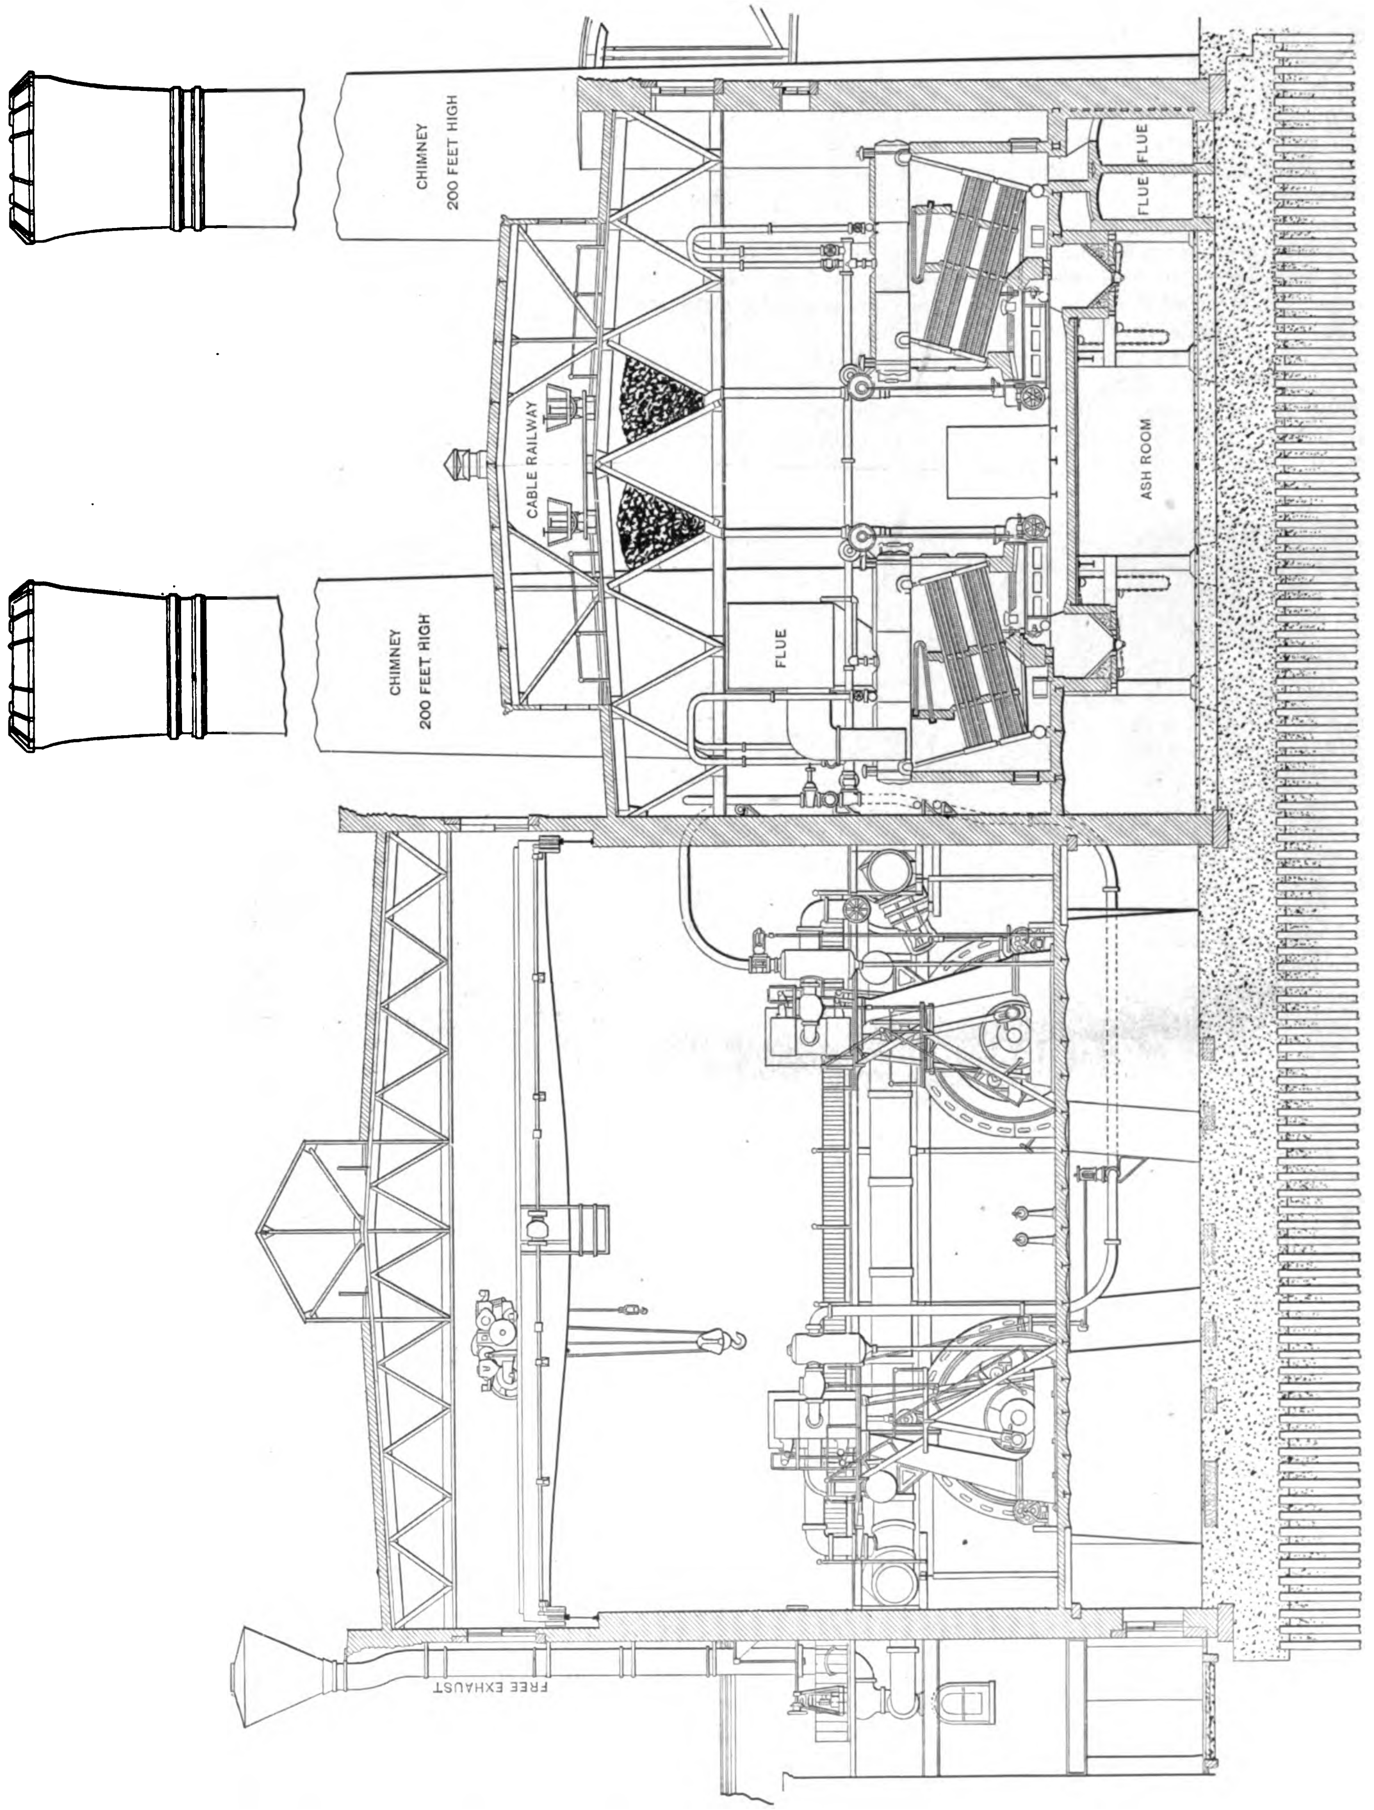

FIG. 18.—SECTIONAL ELEVATION THROUGH NEW ENGINE ROOM AND BOILER ROOM.

The two generators last installed, which are driven by the 2400-h.p. engines in the new engine room, are rated at 1600 kilowatts each, and designed for 300 volts. These dynamos are of standard modern design, like the two last mentioned. One of them has 22 poles and the other 30. This latter generator is also provided with six collector rings, making it a double-current machine. Its rated capacity is 5330 amperes at 300 volts, direct current, or 2500 amperes on each of the six phases at 184 volts, alternating current, or a proportional amount of either if both kinds of current are taken from the machine at the same time. As it has 30 poles and runs at 100 r.p.m., the frequency is 25 cycles per second. A double-current generator was adopted in this last case in order to cut down the cost of conductors to some distant parts of the system, which will ultimately be supplied with alternating current through step-up transformers at the station.

The engine room is equipped with a 50-ton overhead traveling crane, running the length of the room on tracks and built by the Morgan Engineering Company, of Alliance, Ohio. This crane is one of the largest in existence, having a span of 80 ft. 10 ins. It is provided with two hoists; a main hoist having a capacity of 50 tons, with a maximum lift of 56 ft. and an auxiliary hoist of 5 tons capacity and a lift of 62 ft. The main hoist has a speed of 11 ft. a minute at full load, the speed increasing with decrease of load. The auxiliary hoist has a speed of 50 ft. a minute. The cross travel varies from 80 ft. to 100 ft. a minute, and the longitudinal travel from 100 ft. to 150 ft. a minute. The armature of the hoisting motor is provided with an automatic electric brake, released by solenoids and applied by gravity, so that if the current should fail from any cause the brake would immediately apply itself and prevent the running down of the load. The main hoist is also supplied with a mechanical brake. The crane is operated by four 220-volt General Electric enclosed multipolar electric motors of different capacities, as follows: Main hoisting motor, 50 horse-power; auxiliary hoisting motor, 25 horse-power; trolley travel, 5 horse-power; and the bridge travel, 30 horse-power. The motors are all controlled from a cage suspended from the crane, in which are installed four Morgan lever controllers, and reversing switches. This crane can pick up the heaviest piece which comes into the station from a dray in the driveway, lifting it through the sliding door opening and depositing it in its required position without its being removed from the hoisting hook.

In the southeast corner of the old engine room, as has been stated before, there is partitioned off a switchboard room, containing a feeder switchboard gallery, a regulating room and a motor operated switchboard. On the north side of the gallery is located a feeder switchboard, made of Tennessee marble, equipped with 5-way switches, connecting the feeders to any one of five different bus-bars on each side of the system. These five sets of bus-bars are maintained at different potentials by means of motor-driven boosters connected between successive bars. There are two three-wire booster sets, each capable of an output of 1350 amperes at 55 volts. The booster switches are located on the same board with the five-way feeder switches mentioned above. Above the switches are ammeters, of both the Weston and Thomson astatic types, in series with the feeders. Located at the end of this feeder board are four dial posts of the Cory system of engine telegraph, there being one for each engine room. Each set consists of one disc, signifying the engine or booster in question, the other denoting the instructions to be given regarding that unit.

On the opposite side of the room is another feeder switchboard similarly equipped and containing also the battery switches. At the east end of the switchboard is the regulating platform, containing a board carrying all the main dynamo ammeters, also the control wheels of the field rheostats. A pressure wheel, having blocks connected to the pressure wires of all of the feeders, is so arranged that by moving the wheel around to a certain pressure block, the

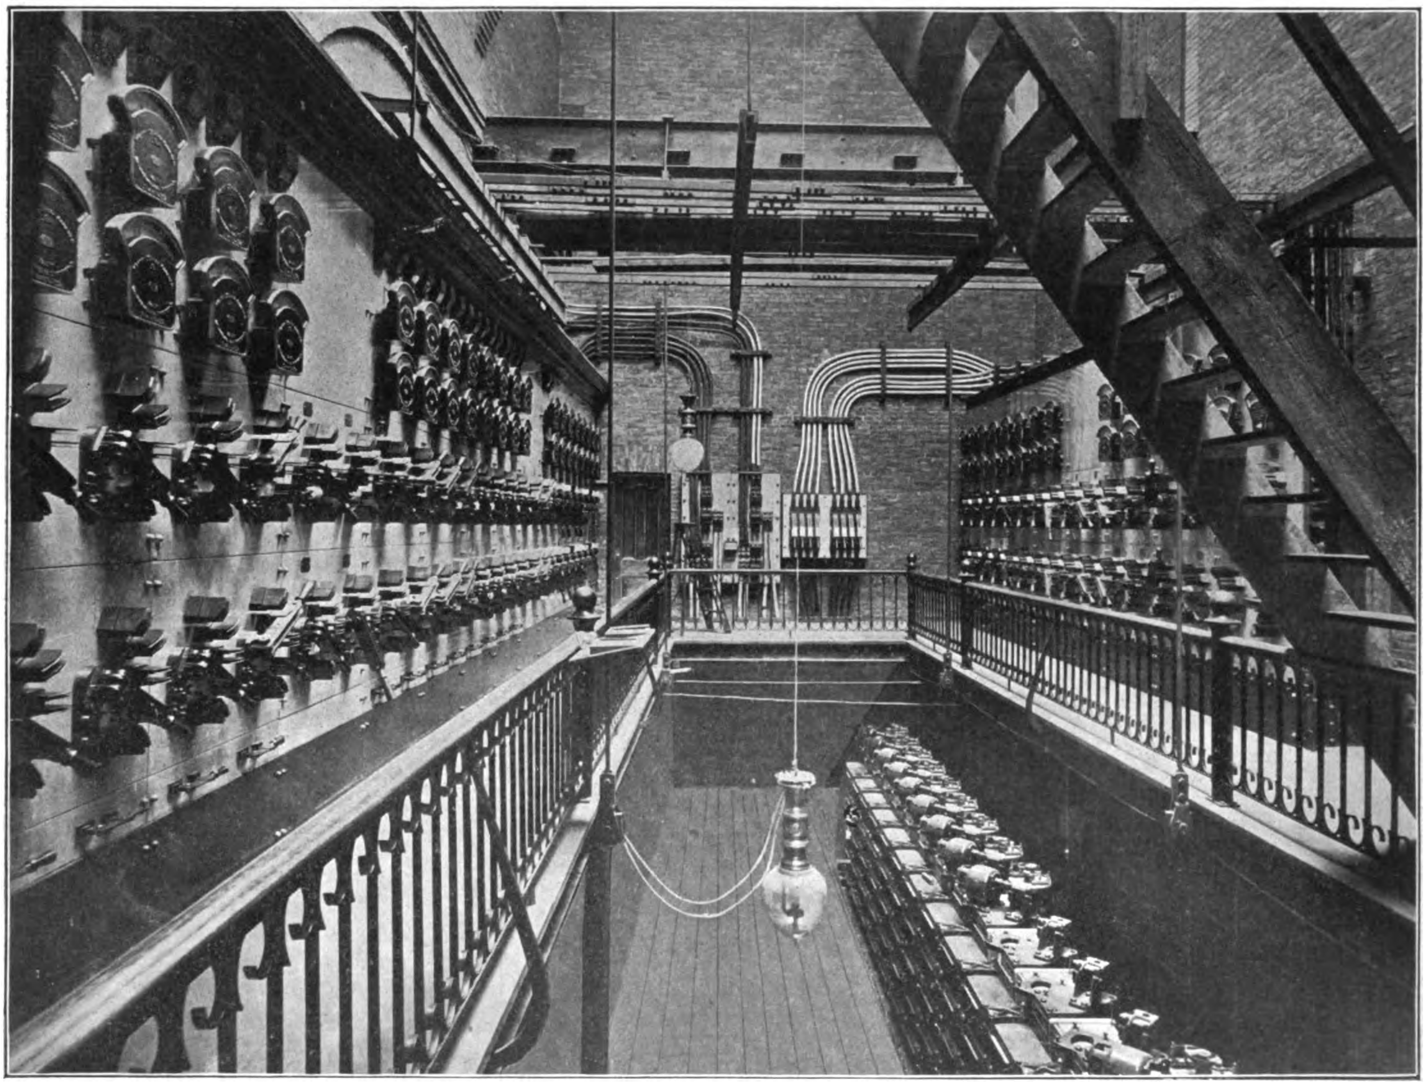

FIG. 14.—VIEW IN THE SWITCHBOARD ROOM OF THE ATLANTIC AVENUE STATION.

voltage on that feeder can be determined. An ammeter connected in series with the station neutral wire shows how much the system is out of balance and which way. There are also installed here the battery neutral meters, Weston galvanometers for switching in the machines and other miscellaneous instruments.

Extending across the regulating platform are located the operating tables, upon which are located the control wheels for the dynamo fields, also the apparatus for controlling General Electric motor switches located on the floor below. Each switch is made up as follows: A copper post extends vertically along the length of the switch, through the floor, and is connected to the source of the current. Behind each row of switches are five bus-bars, to which are attached, one for each switch, five blocks of copper having their faces in line with the face of the copper post. There are, mounted on a supporting pillar having a slate base, five copper pressure contact switches, which make connection between the copper post and the copper block on one of the bus-bars. The contact switch is made up of strips of copper, bent into the form of a hollow D, the ends making contact. These are each provided with an auxiliary circuit breaker and a magnetic blow-out. The whole switch is operated by a General Electric 2¼-h.p., 115-volt motor, so arranged that by pressing a certain button at the operating table, the corresponding switch will be closed or opened as desired.

If one switch is operated while another on the same post is making contact, the latter switch will open automatically before the former one closes, so that no two switches on the same post can make contact with two bus-bars at the same time. There are 40 of these sets of switches, located 20 in a row along the length of the switchboard room, the positive switches thus being separated from the negatives. Each set of switches is enclosed in a neat box-like casing, made of pink Tennessee marble, the magnetic blow-out driving the arc away from the switch toward the marble partition.

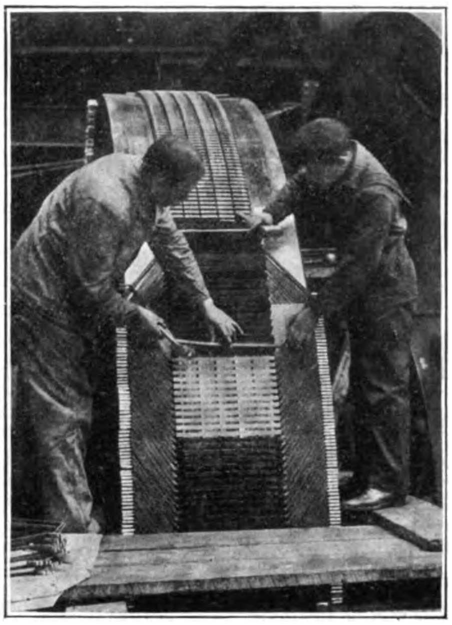

FIG 15.—PUTTING ON THE ARMATURE CONDUCTORS OF THE 800-KW. MACHINE.

As intimated in the first part of this article, storage batteries are employed for purposes of regulation and to take care of load peaks. At the First District station there are two sets of batteries, 144 Tudor cells having a capacity of 4890 amperes when discharged in three hours, and 150 chloride cells having a capacity of 2800 amperes for three hours. At the Second District station there is a battery of 140 chloride cells, and at the Atlantic Avenue station just described there are two batteries, each comprising 150 chloride cells. The three-hour discharge rate here is 5600 amperes. The regulating switches are installed in a small regulating room on the first floor, partitioned off from the battery room, and consist of 12 switches, three in multiple, on each side of each battery. These switches are operated by electric motors through a set of gears and are controlled in the regulating room of the station at a distance of 200 ft. by means of push buttons on the switchboard. The main current to and from the batteries flows along underground cables connected to the battery bus-bars on the third-station switchboard.

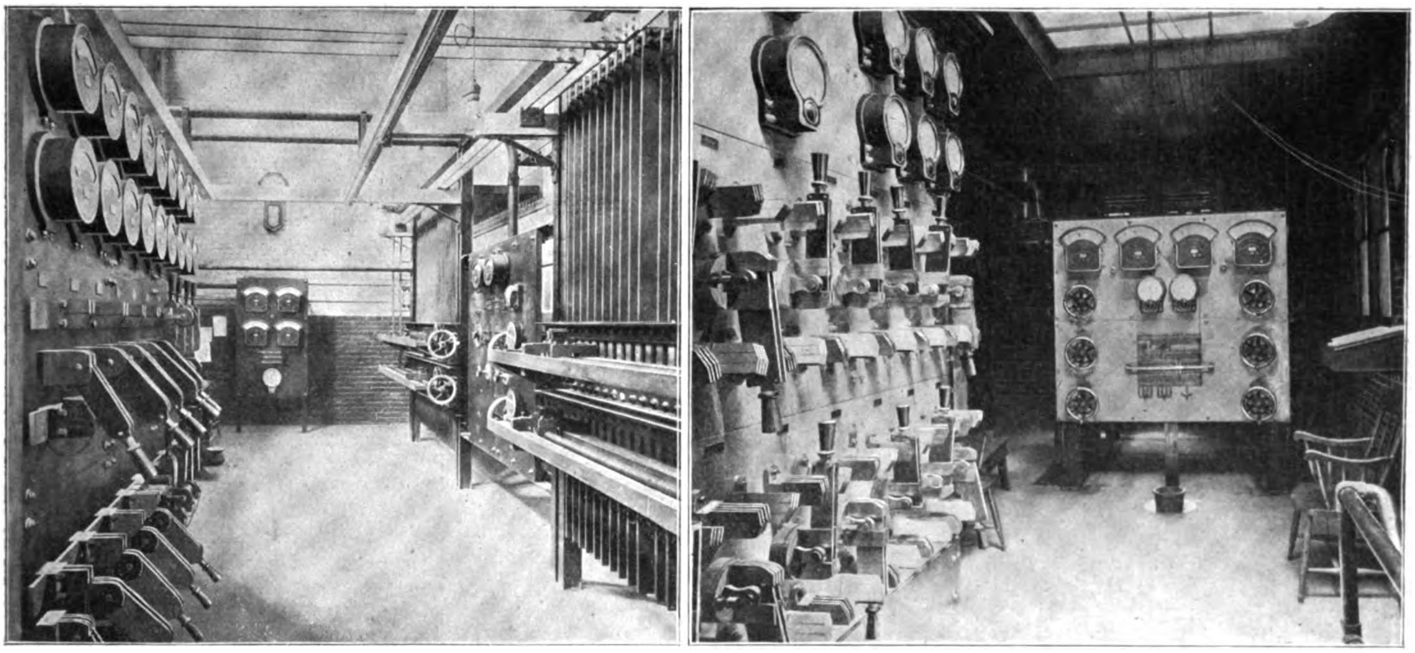

FIG. 16.—SWITCHBOARD ROOMS AT THE FOURTH AND FIFTH DISTRICT SUB-STATIONS.—FIG. 17.

The Fourth District station supplies the district known as the Back Bay, and was not only the first exclusive battery plant erected by the company, but the first one in existence. It contains a chloride battery of 144 cells. The copper bars from the end cells pass through the partition to the regulating room, where they are connected to three switches in multiple, on both sides of the system, so that the batteries can be discharged at three pressures at the same time. These switches are operated by hand. Between the two regulating switches is a slate-regulating board upon which are mounted Weston portable voltmeters, reading to three volts, so arranged as to read, through circular cell switches, the voltages of the regulating cells on each side of the system. There are also on this board two Weston round pattern galvanometers and two booster field regulators. Opposite the regulating switches is the feeder switchboard which has two busses on each side of the system, and to the apparatus and feeders are connected two double-throw switches, thus permitting of the connection of any of them to either bus. Weston round-pattern ammeters are used to indicate the load carried by each feeder. There is also installed at this station one three-wire booster set, consisting of four 60-kw. Edison bipolar dynamos, the booster armatures having been rewound. Fig. 16 is a view in the switchboard room of this station.

The Fifth and Sixth District stations, like the Fourth District, are battery stations only. At the Fifth District there are 144 Tudor cells having a three-hour discharge rate of 2570 amperes. There is also a three-wire booster set here like the one at the Fourth District station. The Sixth District station is the most recent one. It contains 140 chloride cells having a three-hour discharge rate of 1520 amperes.

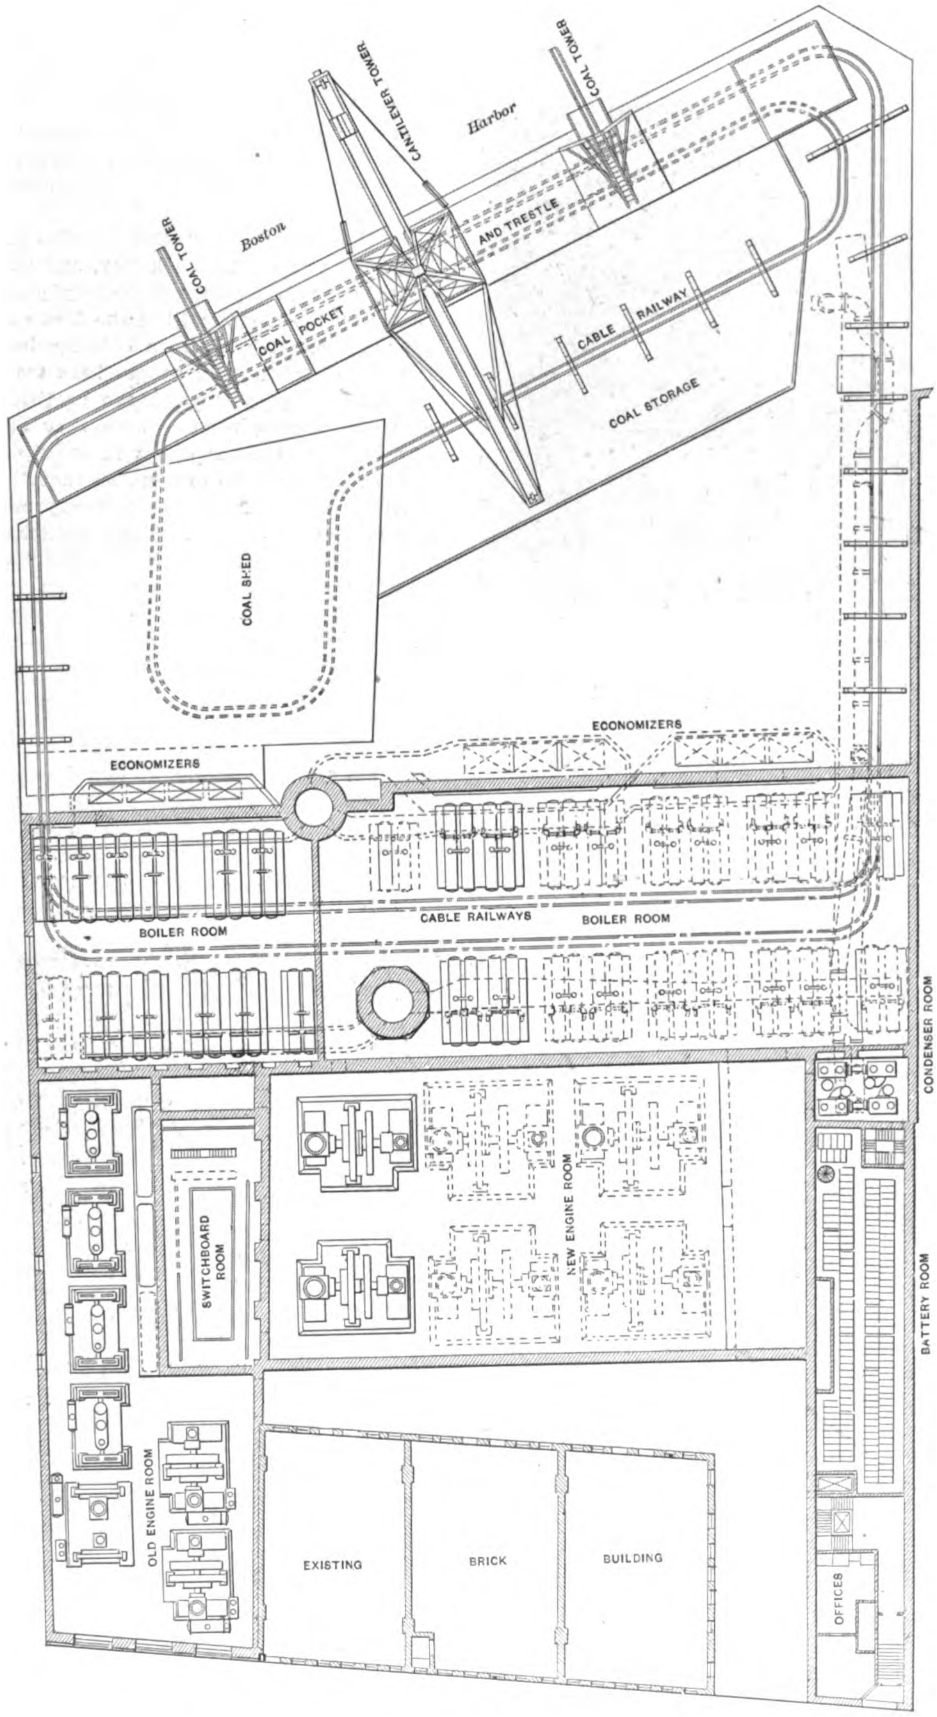

FIG. 18.—GENERAL PLAN OF THE ATLANTIC AVENUE STATION

The regulating apparatus and booster set are similar to those in operation at the Fourth and Fifth District stations, which have just been briefly described.

THE ARC LIGHTING PLANT OF THE HOBOKEN DIVISION, UNITED ELECTRIC CO. OF N. J.

The central-station plant at Hoboken, N. J., furnishes an excellent example of the general saving obtainable from the conversion of a plant containing engines and generators of all sorts into a modern systematic equipment in which the various units are reduced to the lowest number compatible with reliability of operation. Before it was remodeled, the Hoboken station was a "horrible example" of the mixed type, in which alternators and direct-current dynamos of promiscuous sizes, types and classes were jumbled together—a representative of the large class of plants which were increased in output by the addition of first one sort of equipment, then another, until the absolute limit of practical operation was anticipated by the reorganization of the generating machinery.

As the arc-lighting plant, which forms the subject of this article, is dependent for its motive power upon the generating plant which supplies current for the incandescent service, a brief reference to the latter division of the plant will be necessary in order to make the description complete.

The boiler equipment for the entire plant consists of five Babcock & Wilcox water-tube boilers rated at 520 horsepower each, and equipped with Roney mechanical stokers, the mechanism of which is driven by two Westinghouse vertical engines. At present, coal is delivered to the stokers by shovel, but preparations are being made for the installation of a coal-handling equipment that will take the coal from the bins and deliver it directly to the hoppers of the stokers. A Green economizer has been installed in the boiler room and the mechanism of this outfit is driven by a 7-h.p. General Electric motor and a 5-h.p. steam engine. Induced draft for the furnaces is used. The draft fans are of the Buffalo Forge Company's make, 14 ft. in diameter, and are driven by horizontal engines having cylinders 12 ins. x 16 ins. and running at 75 r.p.m. Feed water for the boilers is taken from the city mains and delivered by Worthington tandem compound duplex pumps, having cylinders 8 ins. and 7 ins. in diameter, respectively, and 12 ins. stroke. The steam piping from the boilers to the engines is carried under the engine room floor, which occupies a level about 8 ft. above the level of the boiler room floor. Steam is delivered to the engines at 140 lbs. pressure.

The steam engine equipment now consists of one cross-compound condensing engine, built by the Pennsylvania Iron Works Company, Philadelphia, Pa., and two cross-compound condensing engines, built by the Providence Engineering Works, of Providence, R. I., each engine being direct-connected to an S. K. C. 750-kw. inductor alternator, built by the Stanley Electric Manufacturing Company, Pittsfield, Mass. Each engine has cylinders 26 and 48 ins. in diameter, respectively, by 48 ins. stroke, all of the engines being of the same size and of the Corliss type. Fig. 2 gives a general view of the generating units, and Fig. 5 shows one of the alternators at close range. The alternators are two-phase machines, delivering current at 2600 volts and 60 cycles.

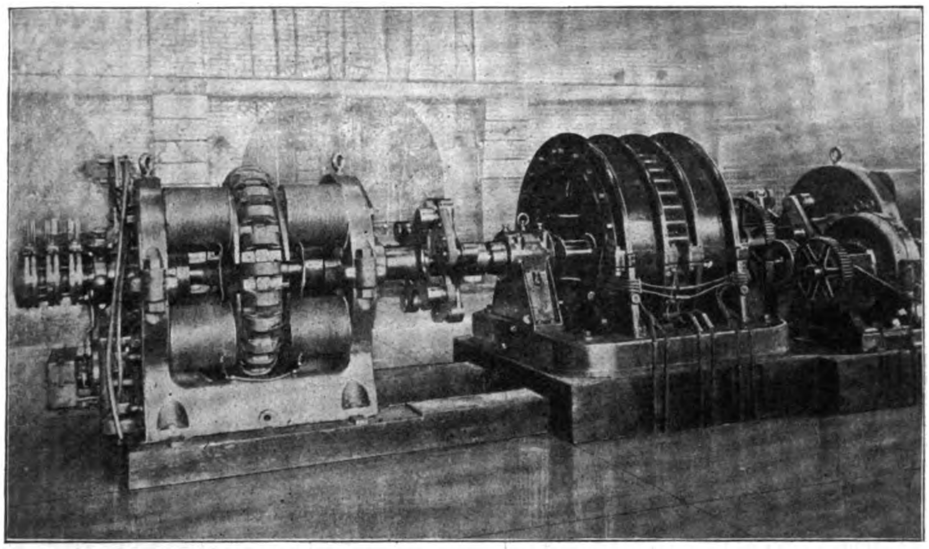

FIG. 1.—SYNCHRONOUS MOTOR AND ONE OF THE ARC DYNAMOS.

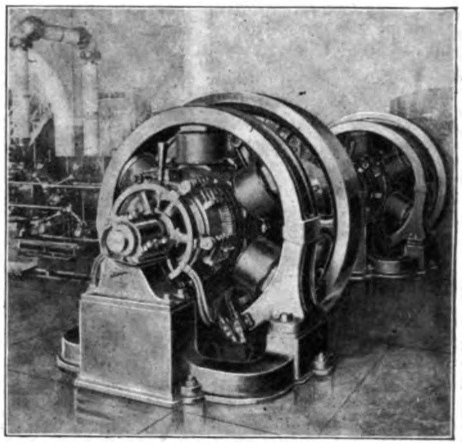

FIG. 3.—THE EXCITER DYNAMOS.

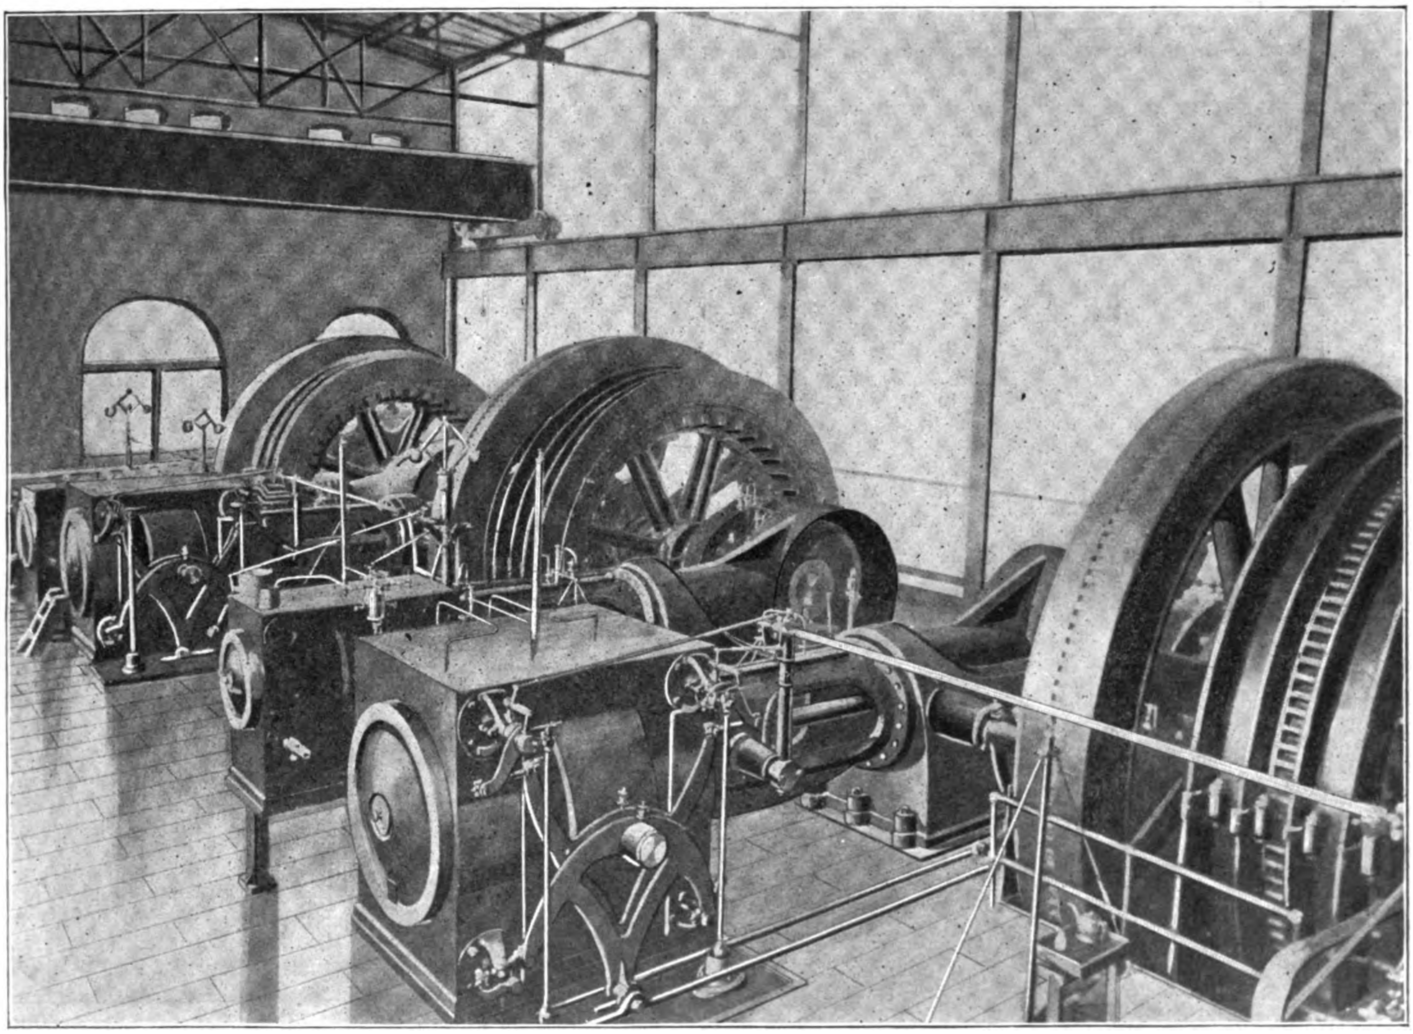

FIG. 2.—GENERAL VIEW OF THE MAIN GENERATING EQUIPMENT.

As previously stated, this current is used for both the arc-lighting and incandescent-lighting services, but it is not supplied directly to the arc-lighting circuits; these circuits are operated by direct constant current supplied from modern Brush arc-light dynamos, which are driven by S. K. C. two-phase synchronous motors. There are four of the synchronous motors, each of 150 kilowatts capacity; each motor is direct-connected to two 125-light dynamos, which it drives through the medium of link couplings, as indicated in Fig. 1. As the illustration plainly shows, these couplings consist of a four-arm spider mounted rigidly on the end of the dynamo shaft and connected by means of leather links to a similar spider on the end of the motor shaft. The synchronous motor is brought up to running speed by means of a 15-h.p. direct-current motor of the Sprague Electric Company's make. Three of these starting motors are supplied with current from the street-railway system, the generators of which are located in the same building. The starting motor is geared to the synchronous motor shaft through an intermediate raw-hide pinion, which is mounted on the end of a lever and adapted to be thrown out of mesh when the motor has been brought up to speed. The arrangement is such that in throwing the intermediate pinion out of mesh the arm on which it is pivoted is moved in the direction in which the pinion would be thrust by the action of the gear on each side of it if it were left floating free. It is put into mesh, of course, while the machines are stationary, so that there is no tendency whatever to strip the teeth.

The synchronous motor fields are excited from the same machines which supply the field current to the alternators. These are two 60-kw. 125-volt General Electric dynamos of the ordinary multipolar type, as illustrated in Fig. 3. The

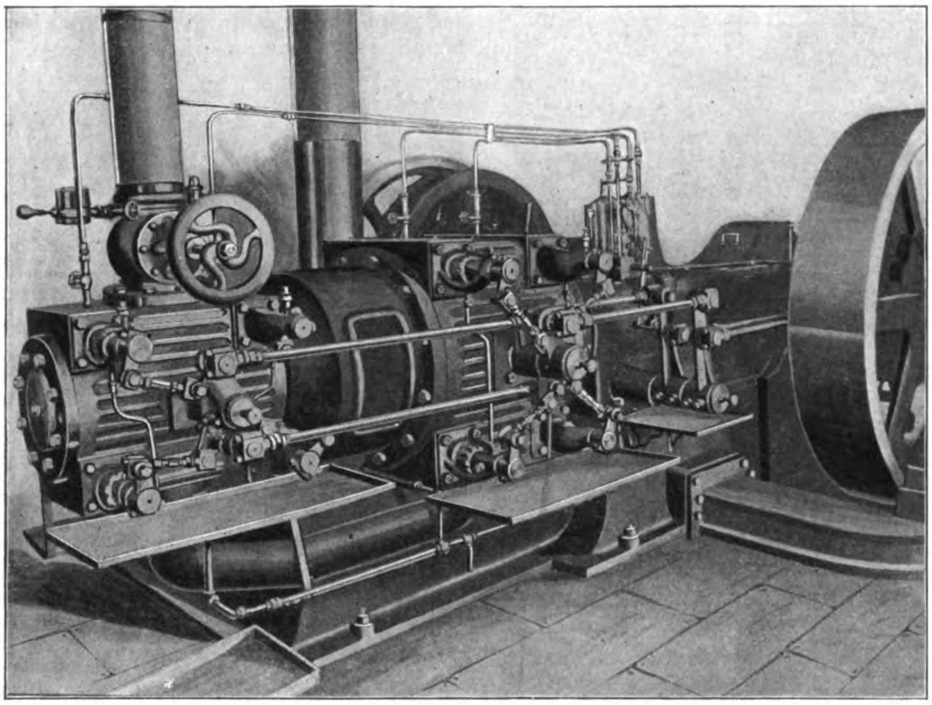

FIG. 4.—TANDEM-COMPOUND ENGINE DRIVING EXCITER DYNAMO.

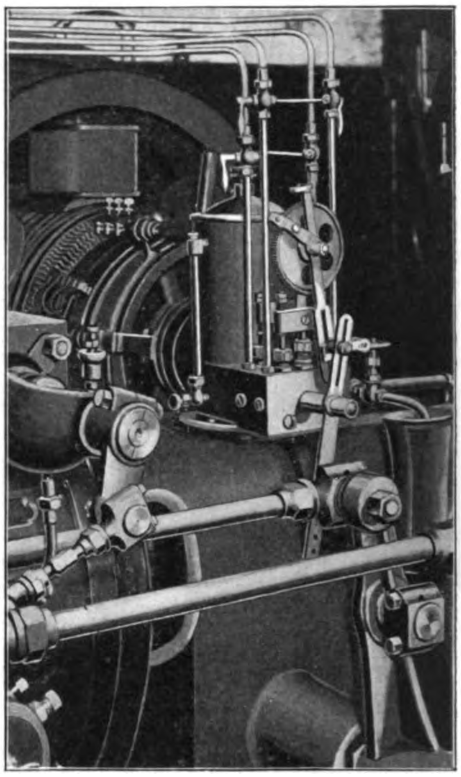

FIG. 6—THE AUTOMATIC OILING MECHANISM.

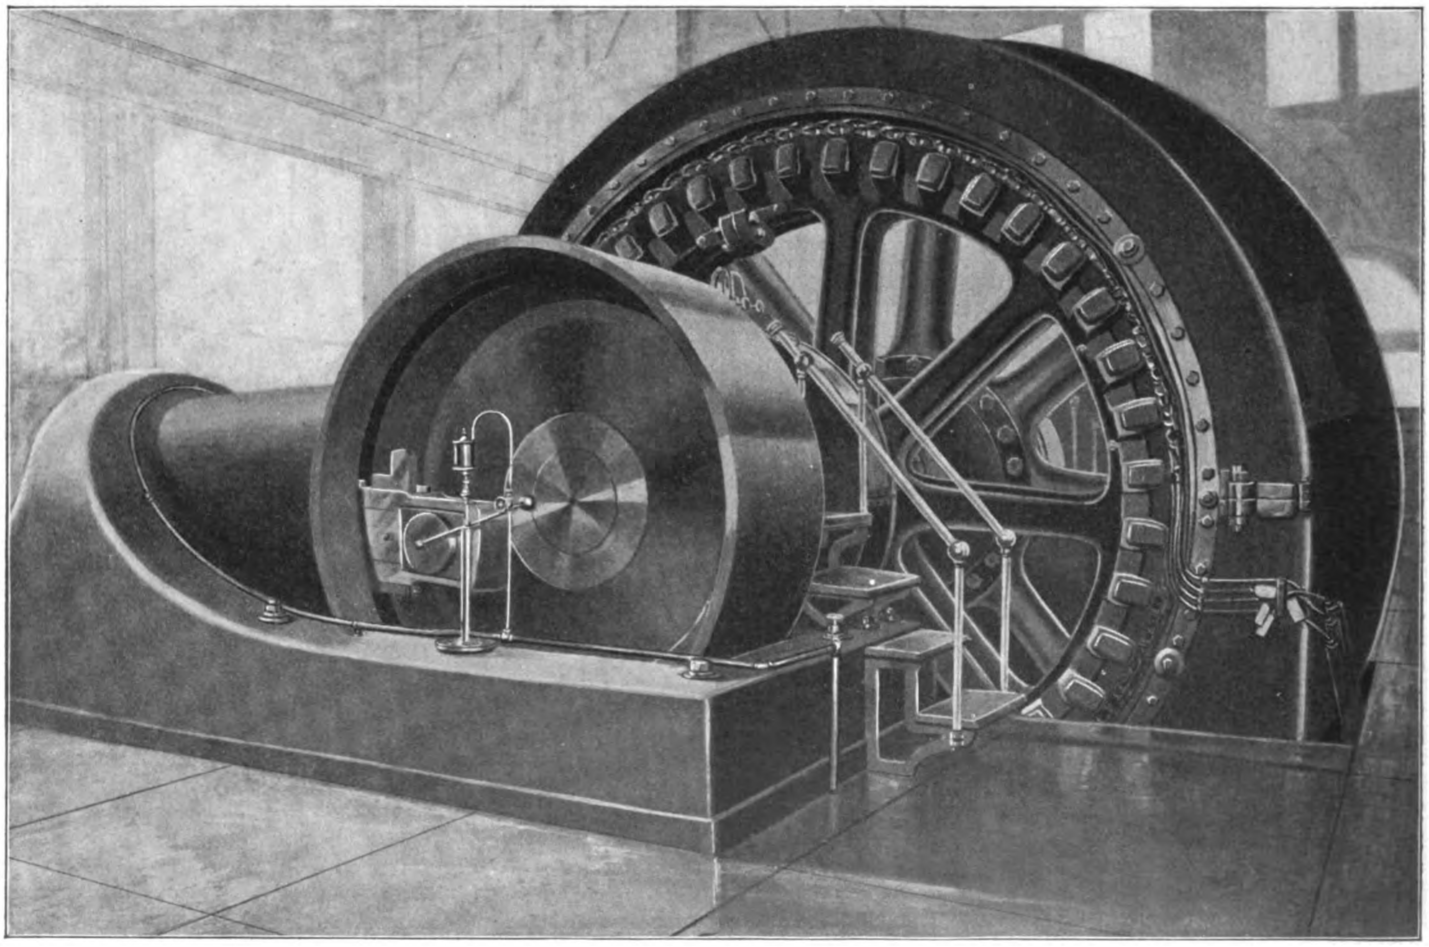

FIG. 5.—TWO-PHASE 750-KW. ALTERNATOR DIRECT-CONNECTED TO CROSS-COMPOUND CORLISS ENGINE.

two exciter dynamos are direct-connected to tandem-compound four-valve engines of 100 horse-power each, built by the Harrisburg Foundry & Machine Works, Harrisburg, Pa. The valve gear of one of these engines is of the modified Corliss type, and is shown very clearly by Fig. 4. On the side of each cylinder are mounted two rocker arms, pivoted concentrically, which take the place of the wrist-plate of the Corliss engines; each of these is oscillated by an individual eccentric. One rocker arm operates the admission valves and its eccentric is under the control of a shaft governor of the usual type. The other rocker-arm, operating the exhaust valves, is oscillated by the other eccentric, which, of course, is fixed on the shaft, as usual.

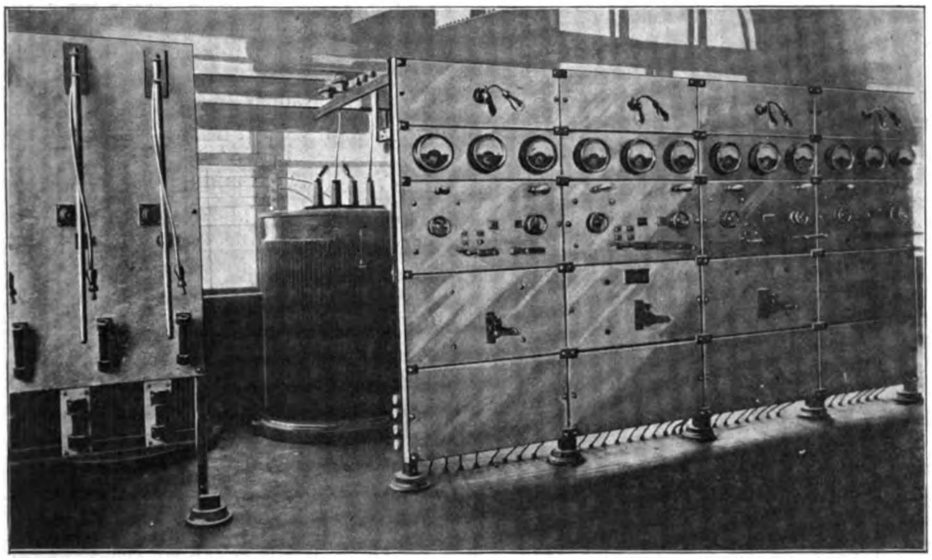

FIG. 7.—SWITCHBOARDS FOR THE CONTROL OF THE SYNCHRONOUS MOTORS.

An interesting attachment on these engines is the automatic lubricating device, illustrated by Fig. 6. This is a quadruple-feed improved lubricator, manufactured by Greene, Tweed & Co., New York, and consists of a reservoir tank, similar to that of an ordinary sight-feed lubricator, from which oil is delivered to the four feed pipes by means of small pumps which receive their motion from a link connected to the valve gear of the engine. The action of this lubricator is entirely automatic, the supply of oil being adjusted in accordance with the needs of the engine, and as the oil is pumped under pressure to the points where it is used, the supply is positive and reliable. Each of the four feeds is independent of the other three and can be independently adjusted.

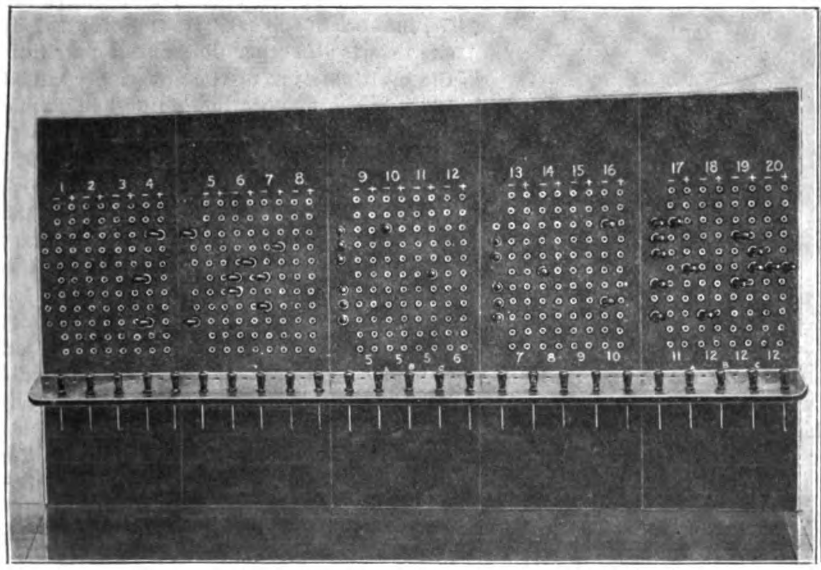

FIG 8 – THE ARC-CIRCUIT SWITCHBOARD.

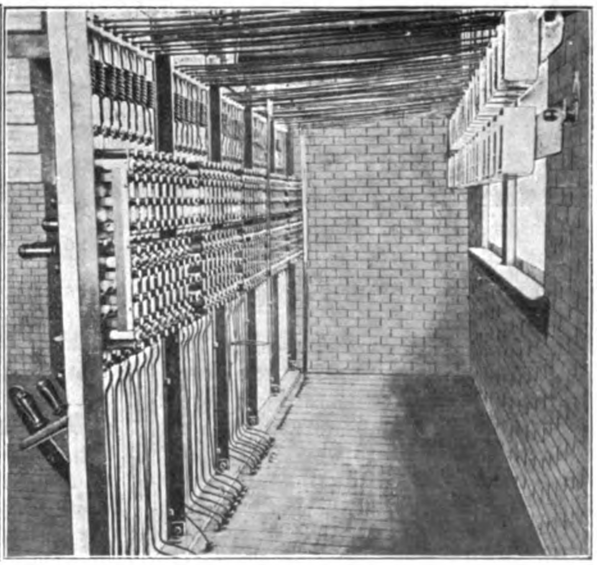

FIG. 9.—BEHIND THE ARC-CIRCUIT SWITCHBOARD.

The synchronous motors take current at the generator e.m.f. of 2600 volts through a special power panel in the main switchboard and the panel equipped with broom-handle switches shown at the left of Fig. 7. The panels from which the field circuits and starting motors are controlled are shown at the right of Fig. 7. There are four panels, one for each synchronous motor, and each panel is equipped with the usual indicating instruments, field switch and rheostat for the synchronous motors, and starting rheostat for the starting motors.

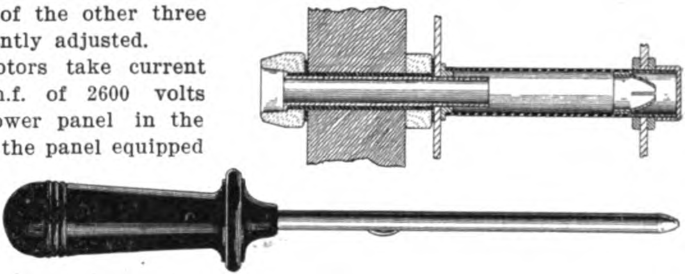

FIG. 10.—ONE OF THE PLUGS AND SOCKETS.

The arc-light dynamos deliver current to their circuits through a plug switchboard, as usual, the particular board in this plant being illustrated by Fig. 8. The board is equipped with an ammeter jack in each machine circuit, so that an ammeter placed at the top can be put in series with any one of the eight arc dynamos. One of the switchboard plugs and sockets is shown in Fig. 10. The socket is made of hard fiber and contains a solid metal sleeve at one end and a split metal sleeve at the other. The tip of the plug enters the split sleeve and the shank of the plug is pressed into intimate contact with one side of the solid sleeve by means of a spring mounted in a slot in the shank of the plug, from which it protrudes in exactly the same manner as the spring of an umbrella staff. The arc switchboard was built by the General Electric Company, and the synchronous-motor switchboard panels were built and equipped by the Stanley Electric Manufacturing Company.

The out-door arc-lamp circuits are overhead, the wires being hung on chestnut poles from 35 to 45 ft. high. The line work throughout is of a very superior character, and approaches closely to the standard established on the Orange division of this company's properties, which division is noted for the excellence of the line construction. The arc lamps are of the latest Brush type and of the Adams-Bagnall pony differential type; there are 900 lamps in all. Mr. King, the superintendent of the plant, has ingeniously converted a great many of the lamps into a sort of enclosed form by inserting an asbestos washer 1/16 in. thick between the globe and the reflector. The lamps

equipped with this washer have burned over 41 hours. The upper carbons are ⅝ in. x 10 ins., cored, and the lower ones are ½ x 9 ins., solid. It is intended to equip all of the lamps with these asbestos washers.

An interesting test was recently made of the plant by Stevens Institute graduates, the results of which are given herewith. The input of the synchronous motor was measured by a wattmeter in each phase, and the output of the two arc dynamos driven by it was measured by an ammeter in each circuit, and a voltmeter which was shifted back and forth from one circuit to the other. Readings from the alternating-current circuits were also taken from time to time in order to determine the power factor of the synchronous motor. All of the instruments were carefully calibrated at the laboratory of Stevens Institute before the test was made, and the space about the instruments was explored for stray fields and found to be practically free from such interference. The power factor of each synchronous motor was found to be 0.93. The table herewith gives the results of readings taken between 7.30 and 9 P. M. on two of the arc-lighting generating sets. A test was made at the same time of the engine and alternator equipment, and the result showed a full-load efficiency of 95 per cent for the alternator.

The new station was designed by the staff of the United Electric Company of New Jersey, of which the Hoboken plant constitutes one division. The plant is conspicuously creditable to the gentlemen who were responsible for its remodeling, and among whom may be mentioned Messrs. Dudley Farrand, general manager; Paul Spencer, at the time general superintendent; H. D. King, superintendent of the Hoboken division, and E. R. Dunbar, chief engineer at the Hoboken station.

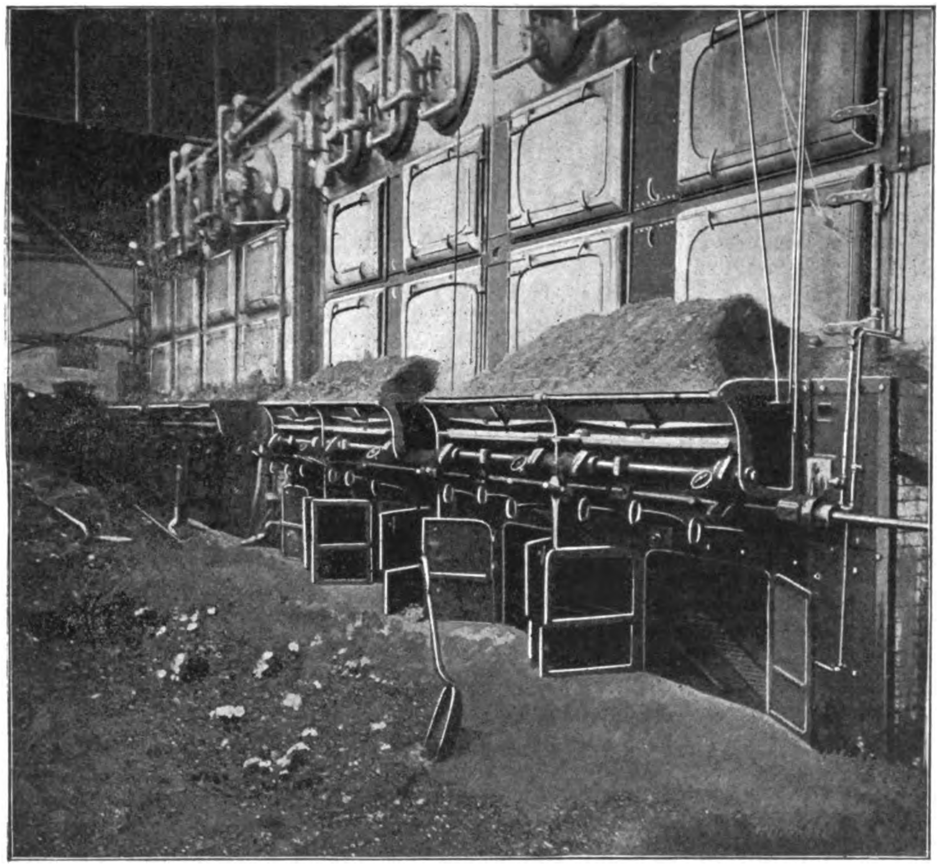

FIG. 11.—VIEW IN THE BOILER ROOM.

◆

The Longest Transmission Line in the World.—What is stated to be the longest line over which power is electrically transmitted for commercial purposes was put into operation on April 27. The transmission system referred to is that of the Bay Counties Power Company, which has lines extending from a generating station on the north fork of the Yuba River to Oakland, Calif., a distance of 140 miles. The line is operated at a potential of 40,000 volts.

THE MODERN TELEPHONE SWITCHBOARD.

BY KEMPSTER B. MILLER.

In a paper on telephone engineering which was recently read before the New York Electrical Society, Mr. Kempster B. Miller give a most interesting discussion of the fundamental features of modern telephone switchboards. The salient portions of this section of the paper are reprinted herewith:

The fundamental object of the multiple switchboard is to place within reach of every operator a line terminal or spring jack, as it is called, for every subscriber's line entering the exchange. As is well known, the switchboard is divided into sections, each section being of such size as to allow an operator, without undue exertion, to reach over its entire surface. On each section are placed a certain number of line signals, by which the subscriber is enabled to attract the attention of the operator and a corresponding number of line jacks, by means of which the operator may make the initial connection with that line in response to such signals. These jacks, which are associated with the line signals, are termed answering jacks. In addition to the line signals and answering jacks are provided what are termed multiple jacks, there being one of these on each section of every line in the exchange.

To express this in a little different way: the various lines entering the central office are divided up into suitable groups, these groups terminating in line signals and answering jacks at the various sections of the multiple switchboard. In addition to this, all the lines entering an exchange are carried to every section of an exchange, each line terminating in every section in a multiple jack. An operator seated at any section, in response to a display of one of her line signals, inserts one plug of a pair into the jack corresponding to the signal, and ascertains the number of the subscriber desired; then she inserts the other plug of the pair into the multiple jack of the subscriber called for. As every subscriber's line has a multiple jack at every section of switchboard, any operator is able to complete by herself any connection called for at her board.

The size of the section is limited by the reach of the operator, and it is this fact that places a mechanical limit to the size of an ordinary multiple switchboard. It has been found impracticable in most cases to place the jacks closer than on half-inch centers, and under these conditions no more than six thousand (6000) of the multiple jacks could be placed, in addition to the other apparatus, within the space afforded by one section. Two distinct methods have been employed with the intent of removing this limit. Each has been productive of excellent results; each has been used separately, but up to the present time they have not both been incorporated into the same installation. The first of these methods is an obvious one and contemplates the reduction in the size of the spring jacks with a view to getting more of them within the reach of the operator. The mechanical difficulties in this line have been great, owing to the fact that the circuits of the switchboard were so complicated as to require three, four, and sometimes even five contacts to each spring jack.

The second method of increasing the possible size of multiple switchboards was devised by Mr. M. G. Kellogg, and is now in use in two large exchanges in this country. In this system, which is known as the divided multiple system, the switchboard and lines are divided each into four divisions. The switchboard consists of four multiple boards, all in the same office, and to each of these is connected one of the groups of lines, in the same manner as if they were in separate exchanges. With this arrangement, if no further provisions were made, it would be possible for any subscriber in one division to obtain a connection with any other subscriber in his own division, but not with any one in any of the other three divisions. In order to enable any subscriber in, say, the *A* division to obtain a connection with a subscriber in the *B*, *C* or *D* division, means are provided, not for trunking between the divisions, but for enabling the calling subscriber to signal directly to one of the operators in the division in which the line of the called-for subscriber belongs. This necessitates the use of four line signals and four answering jacks for each line, one of each in each division, and of means whereby the subscriber may display any one of the signals to the exclusion of the others. Instead of trunking between exchanges, therefore, the subscriber sends his call directly into the division of the switchboard to which the desired subscriber belongs.

By the use of this divided multiple switchboard, it is evident, the ultimate capacity of any exchange is increased approximately fourfold; not quite this, however, because the extra line signals and answering jacks take up a portion of the room which would otherwise be available for multiple jacks.

During the past five years a complete revolution has been worked in the circuits and apparatus of telephone exchanges, due to the introduction of the system known under such names as "common battery," "central battery" and "central energy." These systems, when properly equipped, have proved vastly superior from both economic and operating standpoints to the old magneto systems, wherein local batteries were used for talking and magneto generators for making the calls. The local primary battery at the subscriber's station has been superseded by a large storage battery at the central office, which also takes the place of the old magneto generator. The mechanical signal or drop has given place to the lamp signal. By these innovations the apparatus at the subscribers' station has been rendered simpler and more compact, that at the central office more reliable, and the operation of the entire system has been rendered automatic, as far as the subscriber is concerned, and as much so as is desirable as far as the operator is concerned. Such a system employs batteries at the central office for furnishing all current, for signaling by the subscriber and for the operation of the talking apparatus. These batteries are invariably secondary rather than primary, for large exchanges, and operate almost universally at the voltage given by ten cells in series, i.e., 20 to 24 volts, according to state of charge.

In the modern common battery exchange the operation is such that when a subscriber removes his receiver from the hook, a lamp will be automatically lighted in front of the central office operator who handles the calls of the group of subscribers to which this particular subscriber belongs. The operator in response to this signal makes connection with the subscriber's line by inserting a plug into the spring jack of that line, and after having ascertained his wants, completes the connection with the subscriber called for by means of a second plug connected to the first one through flexible cords. As soon as a connection is thus made with a subscriber's line, the line lamp normally in control of the subscriber is disconnected from the line, but another lamp connected with the plug is placed under the control of the subscriber, this lamp being known as a supervisory lamp.

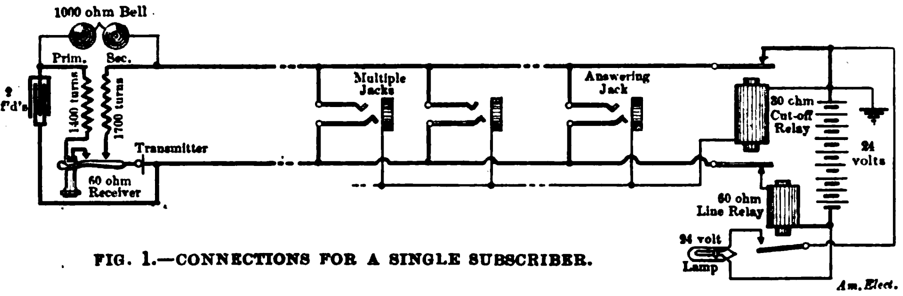

FIG. 1.—CONNECTIONS FOR A SINGLE SUBSCRIBER.

In Fig. 1 is shown a complete line circuit in diagram, including the apparatus at the subscriber's station, which is shown at the left, and the apparatus at the central office, which is shown at the right. The apparatus at the subscriber's station consists of an induction coil, a receiver, a granular carbon transmitter, a condenser of two microfarads capacity, a 1000-ohm bell and an automatic hook-switch. It will be noticed from the diagram that the circuit between the two sides of the line is held open to direct currents by the condenser, and to all currents by the hook-switch contact, while the receiver is on the hook. This leaves the bell in operative relation to the line, for the purpose of receiving calls; the path of the ringing current (which is alternating) being through one side of the line, through the bell and condenser to the other side of the line. When the receiver is removed from its hook, the circuit between the two sides of the line is closed, allowing the passage of direct current through the secondary of the induction coil and the transmitter in series. At the same time another circuit containing the transmitter, the receiver, the primary of the induction coil and the condenser is closed. The object of this latter circuit, which is local to the subscriber's station, will be pointed out later.

At the central office, in addition to the answering jack and the multiple jacks, there are two relays, one termed the line relay, which is normally in circuit across the line in series with the 24-volt storage battery common to all lines, and the other termed the cut-off relay, which is in an auxiliary circuit, and is adapted to open the circuit through the line relay and the battery as soon as a plug is inserted into any jack belonging to its line. Under normal conditions, both relays remain unoperated and the conditions are as shown. As soon, however, as the subscriber removes his receiver from its hook, the circuit between the two sides of the line is made complete at the subscriber's station and the current at the central office energizes the relay which closes the circuit containing the battery and the line lamp.

This lamp is located in immediate proximity to the answering jack, and the operator, seeing it light up, inserts a plug into the answering jack in response to the call. This plug is one of many pairs within the reach of the operator and has three contacts, two of which, the tip and sleeve, are adapted to engage the two springs of the answering jack, and thus complete the talking circuit. The third is adapted to engage the ring contact of the jack, and being in connection with the live side of the battery, causes a current to pass from this side of the battery through the ring contact of the jack and the coil of the cut-off relay back to the other side of the battery. The energization of the cut-off relay serves to open the circuit of the line relay, and thus extinguishes the lamp.

One of the cord circuits is shown in Fig. 2. In this diagram the answering and calling plugs are shown at the extreme left-hand and right-hand portions, respectively, each having, as before said, three contacts, two of which, the tip and sleeve, are connected by wires shown in heavy lines, which form part of the talking circuit, and the third of which is connected through the supervisory signaling lamp and one winding of a repeating coil to the live side of the battery, as shown. The tip and sleeve of the answering plug are connected together through the two halves of one side of a repeating coil, between which is connected the common battery. In the same manner the tip and sleeve strands of the calling plug are connected by the two halves of the other winding of the same repeating coil between which is connected the same battery.

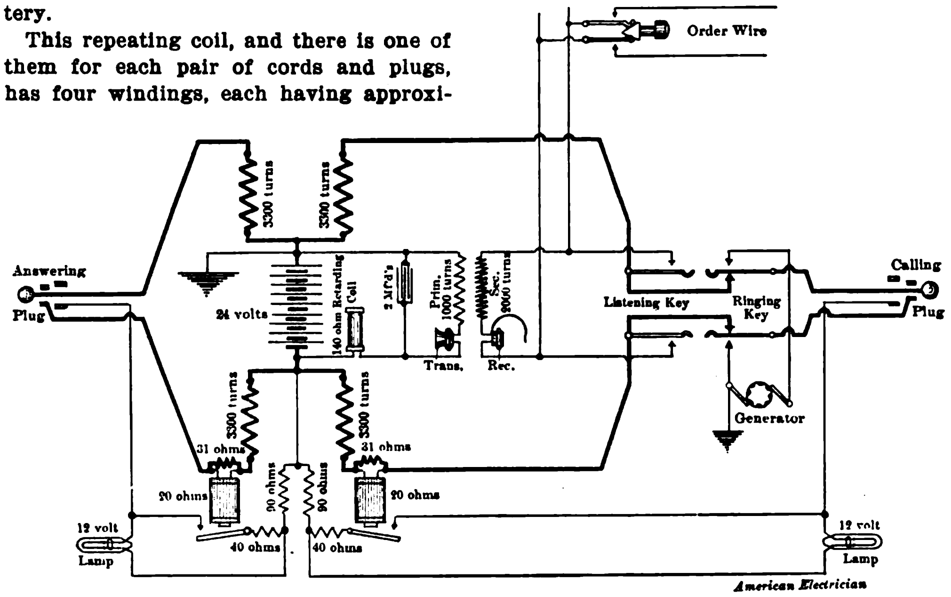

FIG. 2.—DIAGRAM OF A CORD CIRCUIT; COMMON BATTERY EXCHANGE.

This repeating coil, and there is one of them for each pair of cords and plugs, has four windings, each having approximately 3300 turns, all of these windings being on the same magnetic core. It is evident that these connections allow current from the storage battery to pass out over the metallic circuits of the two connected lines and energize the transmitters. A fluctuation in the current flowing in either line will, however, by induction between the windings of the repeating coil, cause a corresponding fluctuation in the current of the other line. In this way conversation between two connected lines is made possible, it being by induction rather than conduction.

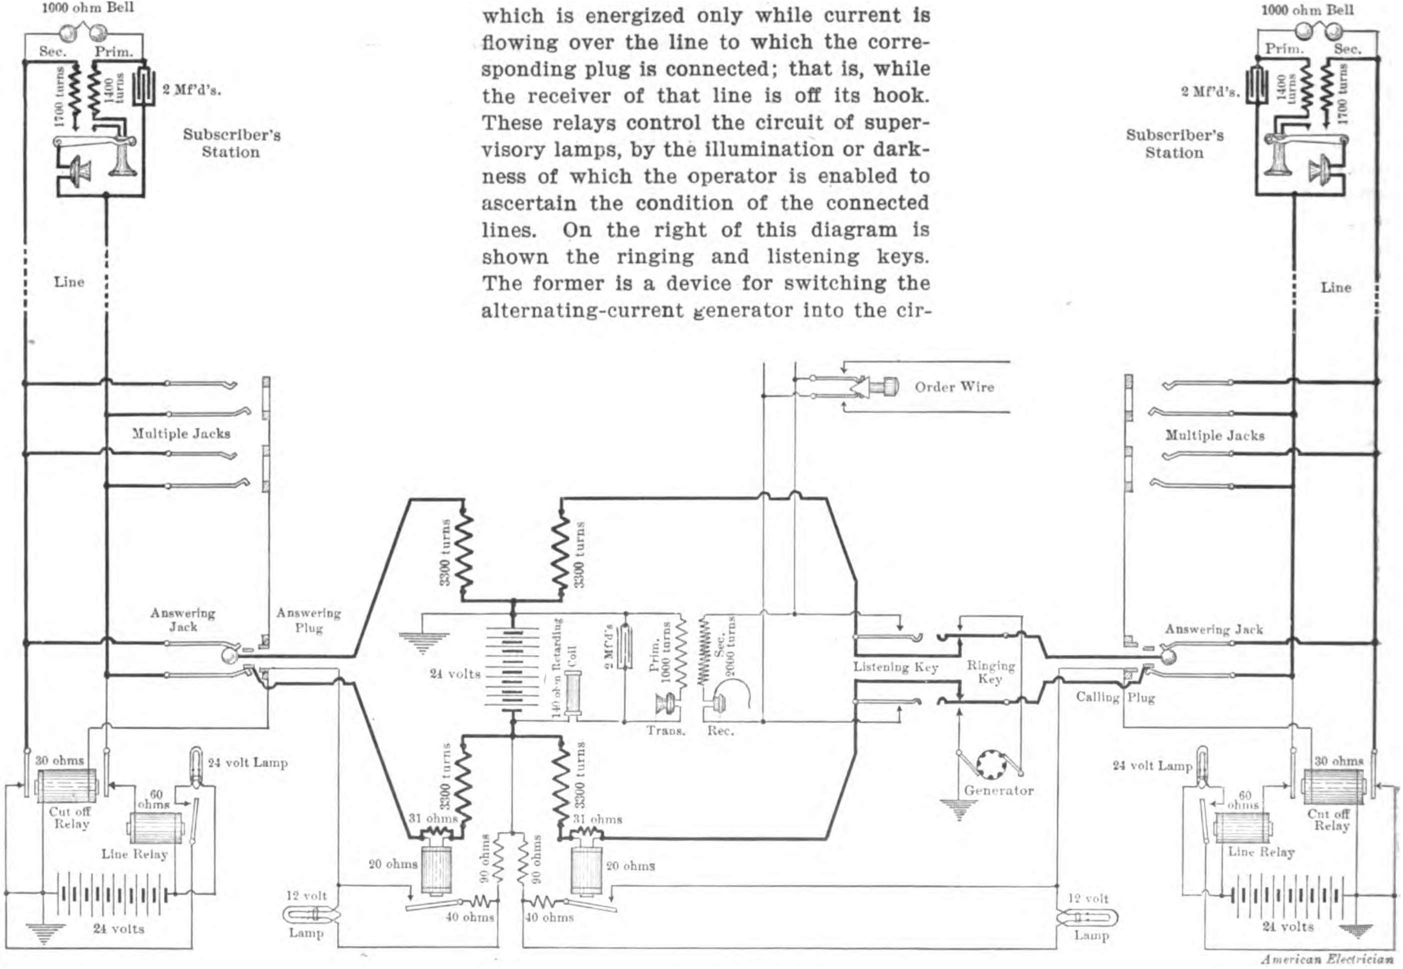

FIG 3.—DIAGRAM OF CONNECTIONS BETWEEN TWO SUBSCRIBERS, THROUGH THE EXCHANGE CORD CIRCUIT.

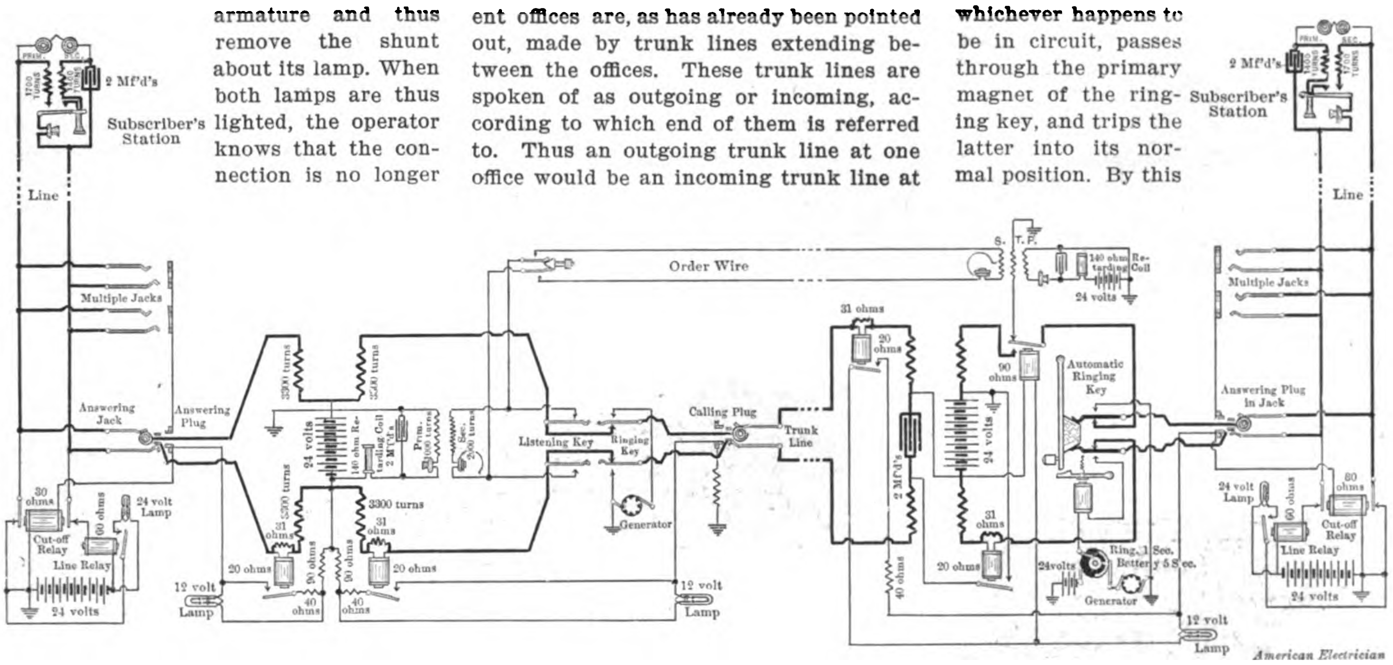
In the sleeve strand of the cord of each plug is connected a supervisory relay, which is energized only while current is flowing over the line to which the corresponding plug is connected; that is, while the receiver of that line is off its hook. These relays control the circuit of supervisory lamps, by the illumination or darkness of which the operator is enabled to ascertain the condition of the connected lines. On the right of this diagram is shown the ringing and listening keys. The former is a device for switching the alternating-current generator into the circuit of the calling plug and its connected line; the latter connects the operator's head telephone, which is shown near the center of the diagram, across the two sides of the cord in order to enable the operator to communicate with either subscriber.

The operation of this circuit and apparatus can best be understood by referring to Fig. 3, which shows two subscribers' lines equipped as already described and connected by a cord circuit at the central office. Consider the station at the left to be that of the calling subscriber and the one at the right to be that of the called. In the first place, the removing of the calling subscriber's receiver from its hook illuminates the line lamp, which remains lighted until the operator answers by the insertion of the answering plug into the answering jack. The operator, before inserting the calling plug into the jack of the called subscriber, must ascertain whether or not the line of that subscriber is already busy. This is automatically accomplished, for upon the touching of the tip of the calling plug to the ring contact of the multiple jack, she will hear a click in her head telephone if the line is busy, and no sound if it is free. If the line is free, she inserts the plug to its full extent, and presses her ringing key, which rings the subscriber's bell. As soon as the calling plug is inserted the supervisory lamp, shown at the right-hand lower portion of the figure, will be illuminated, because its circuit will be completed from ground through the battery, through the 90-ohm resistance coil and the lamp; thence through the third strand of the cord, the test ring contact of the jack, and to ground through the cut-off relay. This current will not only illuminate the lamp, but will operate the cut-off relay of the line called for as well.

As soon as the subscriber of this line responds, he will close the circuit between the two sides of his line and thus allow current to pass over the line to operate the transmitter. This current will pass through the supervisory relay, which will then close the low-resistance shunt circuit about the lamp and thus extinguish it. Both lamps are now out, and the operator pays no further attention to the connection until she sees one or both of the supervisory lamps again lighted. The corresponding lamp will be lighted when either one of the subscribers hangs up his receiver, which act will, by opening the circuit of the line, cause the corresponding supervisory relay to let go of its armature and thus remove the shunt about its lamp. When both lamps are thus lighted, the operator knows that the connection is no longer desired, and without further inquiry pulls down the plugs.



American Electrician

FIG. 4.—DIAGRAM OF CONNECTIONS BETWEEN TWO SUBSCRIBERS AT DIFFERENT EXCHANGES, THROUGH A TRUNK LINE.

It is evident that any fluctuation in the resistance of the current of a transmitter at one subscriber's station will cause a corresponding fluctuation of the current flowing in the line, and this fluctuation will pass through the two windings forming one side of the repeating coil, which will act inductively on the two windings forming the other side of the repeating coil and produce a corresponding fluctuation in the other line. This latter fluctuation will pass through the secondary winding of the induction coil and the transmitter at the subscriber's station and induce a corresponding fluctuation in the local circuit containing the receiver and the condenser.

One of the functions of this local circuit, which has already been referred to, is that of putting the receiver in inductive relation to the line without subjecting it to the passage of direct current through it, which circumstance might tend, if the receiver were connected up the wrong way, to demagnetize its magnets. This local circuit is, however, designed to accomplish still another result, this being the formation of a comparatively short path through which the fluctuations set up by the transmitter may more readily pass; in other words, it is supposed to act as the local circuit of a sort of booster to the outgoing telephone currents. The fluctuations in current caused by the transmitter pass through the condenser and primary winding of the induction coil, and thus induce in the secondary, which is in the line, fluctuations which tend to increase the fluctuations directly produced in the line by the transmitter.

So far, only such means have been described as would admit of the connecting of two subscribers whose lines terminate in the same exchange. Where several offices are used in the same system, the connections between subscribers in different offices are, as has already been pointed out, made by trunk lines extending between the offices. These trunk lines are spoken of as outgoing or incoming, according to which end of them is referred to. Thus an outgoing trunk line at one office would be an incoming trunk line at another. The outgoing trunk lines usually terminate in jacks in the regular sections of the multiple switchboard, while the incoming trunk lines usually terminate in plugs and cords and special apparatus, arranged at special incoming trunk sections, which sections are provided with multiple jacks in the same manner as the regular sections.

Fig. 4 shows a subscriber in one exchange connected through the local cord circuit at that exchange, and a trunk line, with a subscriber at another exchange. Assuming that the subscriber at the left has sent in a call, the operator at one of the regular sections of the switchboard will answer it in the ordinary way by inserting a plug into the answering jack, and having learned that the connection desired is for a subscriber in another exchange, she presses her order wire key and communicates over the order wire with the "incoming-trunk" operator at one of the incoming-trunk sections of the branch exchange. The incoming trunk operator repeats the order and gives the number of an idle trunk line to the operator at the first exchange. The incoming-trunk operator at the second exchange then tests the line in the ordinary way with the trunk line plug, and if it is found free she completes the connection by inserting the plug in the multiple jack of that line.

As soon as this is done, she sets the automatic ringing key, shown just to the left of her plug, which locks in the ringing position, because its controlling relay is not operated. The ringing generator is provided with an interrupter, each revolution of which switches the ringing current on to the line for one second and the 24-volt battery on to the line for five seconds. Thus the subscriber's bell rings for one second of every six until he removes his receiver from its hook. When he does this, the current from the 24-volt battery or from the ringing generator, whichever happens to be in circuit, passes through the primary magnet of the ringing key, and trips the latter into its normal position. By this means the bell of the subscriber is rung at intervals until he responds without any further attention on the part of the operator.

The insertion of the trunk plug into the jack of the called subscriber's line allows current to flow from the battery through the test relay and disconnect lamp, shown at the extreme lower right-hand portion of the figure, and thence through the cut-off relay to ground. This does not light the disconnect lamp, because that lamp is already shunted by the armature of another relay contained directly in the trunk line circuit, this latter relay having been operated by the insertion of the plug into the trunk line jack at the other exchange. As soon as the ringing key is tripped, the current from the battery at the incoming end of the trunk line flows through the metallic circuit of the subscribers' line to furnish current for talking. This operates the supervisory relay in the incoming cord circuit, and puts a ground on the sleeve side of the cord circuit at the first office, thereby operating the calling supervisory relay at that office, and this shunts the corresponding supervisory lamp and extinguishes it, thus notifying the regular operator at the first office that the subscriber has responded.

As soon as the subscriber called for hangs up his receiver, the supervisory relay at the incoming trunk section lets go of its armature and removes the ground from the sleeve side of the trunk line. This causes the calling supervisory relay at the first office to let go of its armature and remove the shunt from around the corresponding lamp. When both lamps of the regular pair of cords at the first office are lighted, the operator at that office pulls down the connection. By thus removing the calling plug from the trunk jack, current ceases to flow in the trunk line relay at the second office, which removes the shunt from the disconnect lamp at that office and allows it to be lighted for the first time. This is a signal for the incoming-trunk operator to disconnect.

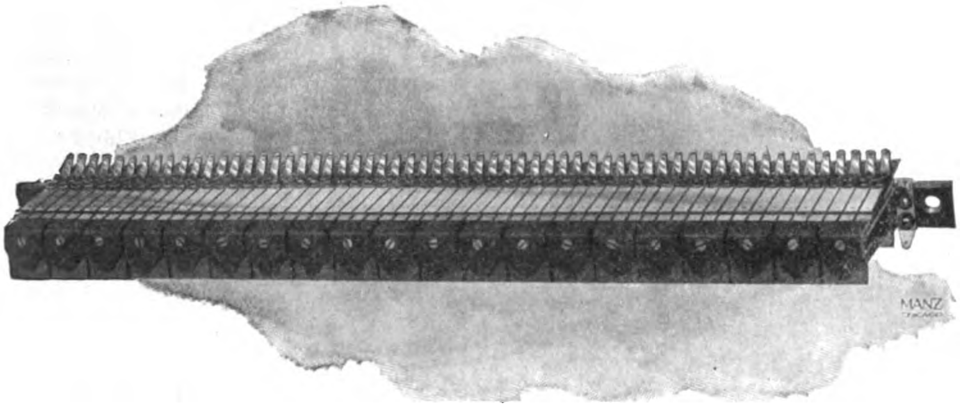


FIG. 5.—A STRIP OF TWENTY LINE RELAYS.

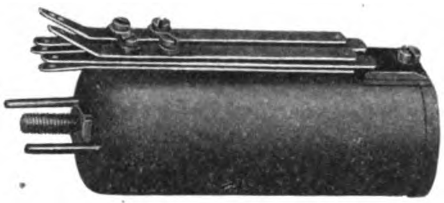

FIG. 6.—A CUT-OFF RELAY.

It will be seen from the above that when two subscribers are connected over a trunk line, they are under the control of the originating operator. The disconnect signals from both subscribers go direct to this operator, and it is not until she has pulled down this connection that the disconnect signal is given to the operator at the other exchange. The latter operator has no means of listening in on the circuit.

An interesting feature about such trunking systems is the means by which the incoming-trunk operator at the second office informs the calling subscriber and the regular operator at the first office that the line called for is busy. When she finds on testing that a line is busy, she inserts the trunk line plug into a "busy-back" jack, which jack has connected in its circuit a machine giving an interrupted current which gives a peculiar, familiar, and, to most subscribers, an extremely disagreeable sound. This sound is heard by both the operator and the subscriber at the first office, whereupon disconnection is made.

Fig. 5 illustrates the arrangement of line relays on a switchboard. As the illustration shows, these are mounted in "strips," the strip here shown containing 20 relays. Fig. 6 shows a single cut-off relay. The magnet of this is enclosed in an iron shell which forms a portion of the magnetic circuit. The armature of this relay, when attracted, causes the two long springs to break contact with the lower springs, and to make contact with the two upper springs. I may say, in passing, that all contacts in the best relays of this description are made of platinum. These relays are about 1¼ ins. in diameter, and the shells are of soft iron about ⅛ in. thick.

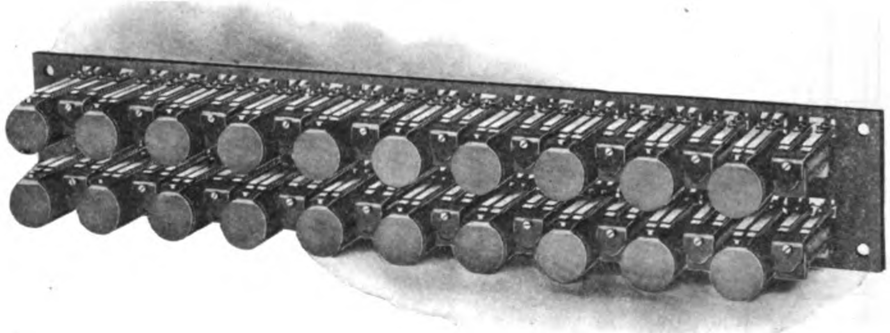

FIG. 7.—A STRIP OF LINE AND CUT-OFF RELAYS.

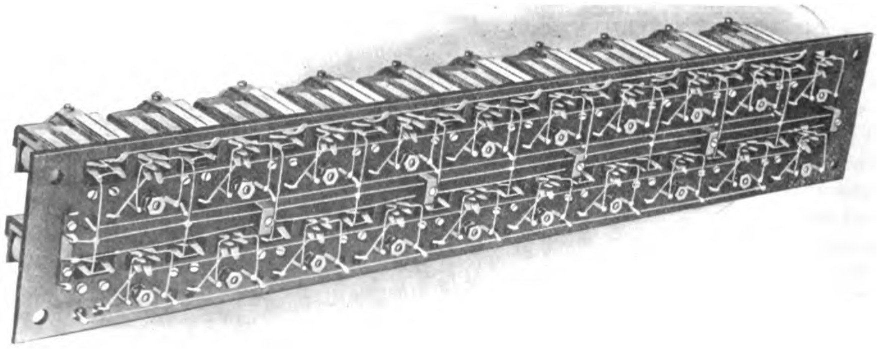

FIG. 8.—REAR VIEW OF LINE AND CUT-OFF RELAYS.

In the latest Kellogg exchanges the line and cut-off relays are mounted side by side on the same strip. Fig. 7 shows such a strip with twenty relays of each kind, the line relays being the smaller of the two. This strip represents a unit of twenty lines, which unit is carried throughout the entire scheme of wiring in the central office. Fig. 8 shows the other side of this relay strip, showing the connecting wires from the various terminals. These terminals pass through walls in the iron mounting strip and are readily accessible for soldering in the wires. In mounting the line and the cut-off relay in such close proximity, many of the wires which would otherwise have to be formed up in cables are reduced to the short, stiff bare wires clearly shown in this picture.

Coming now to the line signals themselves, in Fig. 9, I show a strip of drops, these being mounted on ½-in. centers so as to correspond to the spacing of the jacks. These were used before the adoption of the line lamp signals by the Kellogg Company, a strip of which signals is shown in Fig. 10. This strip is formed from a single piece of hard rubber about 10 ins. long and ½ in. thick. The lamps, one of which is shown in the front of the engraving, are so arranged as to slide into their sockets between the jack springs in such a manner as to make the proper circuit connections. In front of each lamp is a little lens, usually of opalescent glass, this lens being carried in a spun brass cap.

The advantages of the line lamp signal over the old form of mechanical signal are obvious, the principal ones being simplicity, cheapness and the fact that they may be removed instantly if found defective and replaced by good ones. A defective line lamp may be taken out and another one substituted in less than one-half minute. Another beauty of the line lamp is that when it is out of order it may be thrown away, which is much easier than repairing a mechanical drop. These lamps usually operate at 20 or 24 volts, take about ¼ ampere, and give approximately 1/3 candle-power. The calculated life of these lamps, with their present degree of perfection and with the average rate of use, is about thirty years, but, of course, this figure remains to be verified by actual service, for the telephone business is not yet old enough to prove the statement.

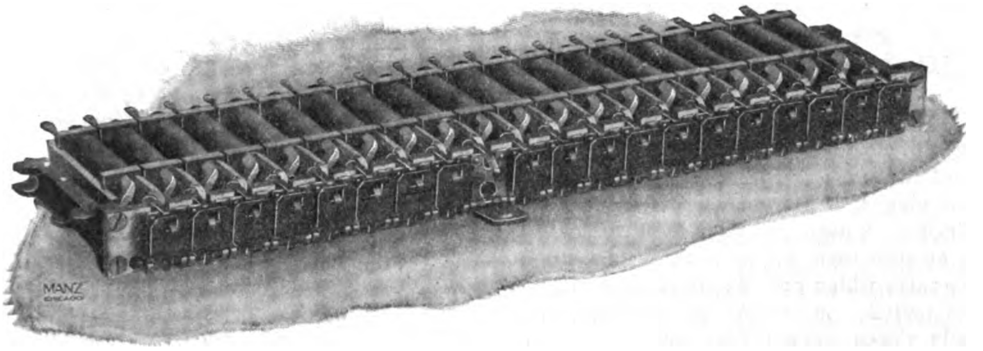

FIG 9.—A STRIP OF LINE DROPS OR ANNUNCIATORS

The next view (Fig. 11) shows a strip of ten supervisory relays, these relays being the ones used in connection with the cord circuit for controlling the supervisory lamps. These are ironclad, being enclosed by a shell precisely like the one used for the cut-off-relay. The armature, a disc of iron about 1¼ ins. in diameter, is suspended in front of the poles of the electromagnet by a thin leaf spring. The working parts of the relay, including the armature and contact points, are enclosed in a brass cap which locks on the shell with a bayonet joint.

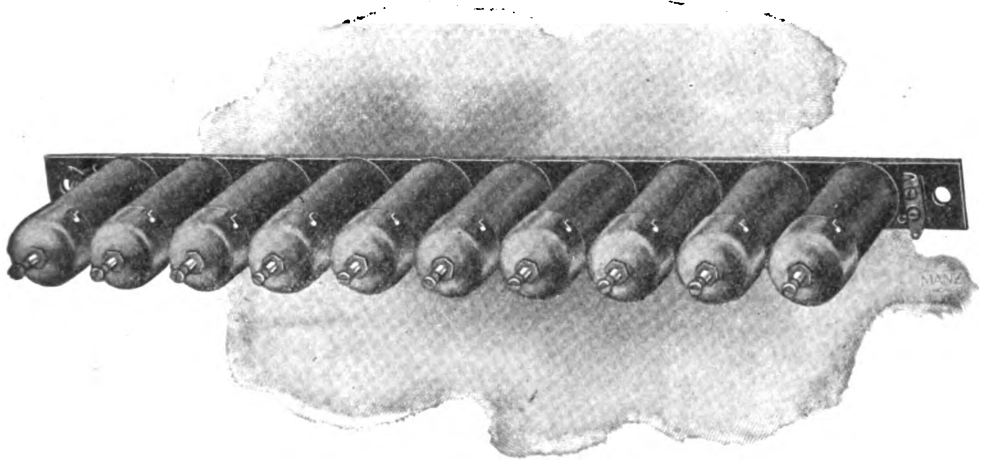

FIG. 11—A STRIP OF SUPERVISORY RELAYS.

I now show (Fig. 12) what is by all odds the most important piece of apparatus in a telephone exchange—the spring jack. This is a strip of the two-point jacks already referred to, and it will be seen that they are mounted twenty to a strip on spaces corresponding to those of the lamp jacks. The same spring jack is used for both answering and multiple. This strip is built up of hard rubber, brass and German silver, the front being a solid piece of hard rubber slightly over 10 ins. long drilled for receiving the sleeve contact. The rear of the strip is a piece of hard rubber milled to receive the line springs and the rearwardly projecting lugs from the sleeve contacts. This rear strip is reinforced by a heavy brass strip, into which the screws holding the line springs are threaded. In this particular strip the jacks are on ½-in. centers and the strip is 7/16 in. high. The spacing with this same construction may be readily reduced to ⅝ in. Where a smaller spacing than this is required, as in a board of extreme size, a somewhat different construction would be used.

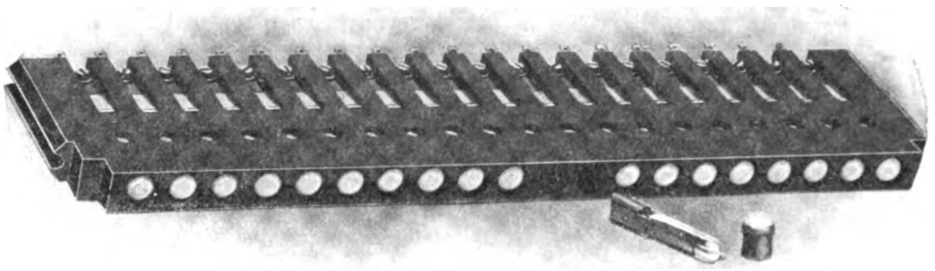

FIG. 10.—A STRIP OF SIGNAL LAMPS, USED INSTEAD OF DROPS.

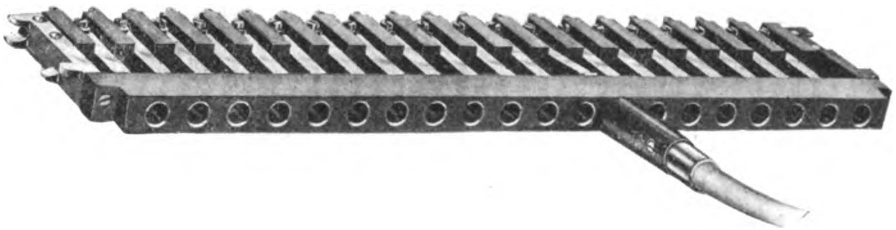

FIG. 12.—A STRIP OF SPRING JACKS; ONE PLUG INSERTED.

The design of telephone switchboards and apparatus is a matter requiring attention to almost infinite detail. Besides having a knowledge of the requirements of telephone service and a thorough appreciation of the engineering problems involved, the designer must have a peculiar faculty, which has been termed "telephone sense." Ability to distinguish between apparatus and circuits that will work successfully in practice and those that will work only in the laboratory is not acquired by all; and the problems are so remote from those of other branches of electrical engineering that it is seldom that a precedent can be found in any other branch.

◆

A Peculiar Combination.—In Southern California the use of water for both irrigation and power purposes recently gave rise to a peculiar combination of circumstances. In states where irrigation is necessary the laws usually provide that if a person or corporation discharges a certain amount of water into a stream at one point he is entitled to take an equal amount from the stream at some point lower down, less a certain allowance for evaporation and seepage. Thus a company owning land on the plains sometimes builds storage reservoirs far up in the mountains, turns water into a river there and takes it out of the river miles away from the point where it is put in. In the case in Southern California referred to above, a well was sunk near a river up in the mountains and the owner then bought electric power from a hydraulically-driven power station to pump water from his well into the river for irrigation purposes lower down. This water then passed through the turbines at the power house and so helped to generate the power which its owner paid to have supplied to him to pump the water. Further down the valley it was used for irrigation. The fall between the well and the power house being much more than the depth of the well, the power derived from the water at the power house was considerably more than the power required to pump the water.

Abstracts from Foreign Contemporaries

Direct-Current Brake Electromagnets.—To obtain a certain tractive force with an electromagnet, a relatively large number of ampere turns is required at the beginning of the attraction, since the magnetic lines of force pass through a long air-gap; while, after the air-gap is closed, only a very small number of ampere turns is required for holding the weight. Max Vogelsang describes in a recent number of the "Elektrotechnische Zeitschrift" the shunt brake electromagnets built by the Helios Company. In starting, a strong current is fed to the electromagnet, which current is considerably lessened when the armature is held by the magnet. In order to cut down the current after the brake has been started a special switch is used which is operated by the magnet itself. When the armature is almost at the magnet it actuates a switch which puts into circuit a resistance that was previously short-circuited. The magnet is shown in cross section by Fig. 2. A steel cylinder, *B*, is enclosed in an iron case, *A*. At *G* there is a simple valve which permits air to enter when the cylinder is raised, and is automatically closed when the cylinder descends. When the cylinder is raised it opens the switch, *S*, at the last moment, which switch is closed by a spring when the cylinder recedes. In Fig. 2 it will be seen that resistance is inserted in series with the magnet winding by the switch. Another resistance is always in shunt with the magnet coils which serves to receive the current of self-induction at the moment of disconnecting. The resistance inserted in series by the switch reduces the current to from one-eighth to one-sixth of its original value.

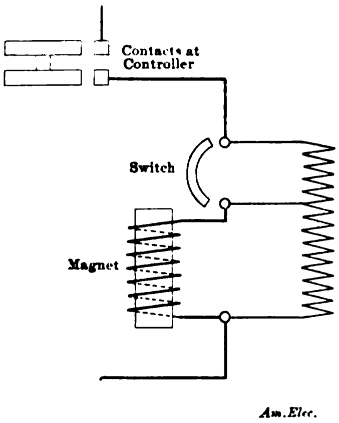

FIG. 1—BRAKE MAGNET CONNECTIONS

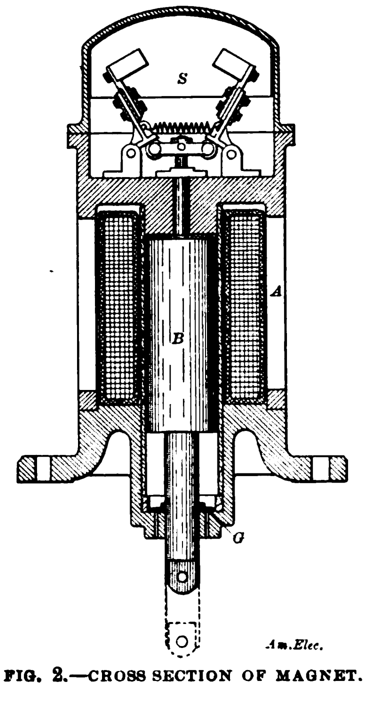

FIG. 2.—CROSS SECTION OF MAGNET.

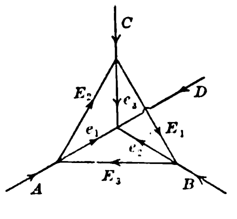
Aron Meter for Four-wire Three-phase Systems.—H. Aron contributes to the "Elektrotechnische Zeitschrift" an illustrated article describing a modification of his well-known meter for three-phase systems having four electrical conductors. The meter reads correctly for star as well as for delta connections, and is independent of the differences in the load in the three phases. In Fig. 3, *A*, *B* and *C* represent the currents in the three main circuit wires; E_1, E_2, and E_3 the e.m.fs. between wires, and e_1, e_2 and e_3 the e.m.fs. between the fourth wire and each of the other three. The author shows that the power may be expressed by the formula, $W = A\ e_1 + B\ e_2 - C\ (e_1 + e_2)$, which is applied in his meter, the arrangement of which is indicated diagrammatically by Fig. 4. Three coils are placed side by side, and are supplied by currents, *A*, *B* and *C*, respectively. Two pendulums bearing potential coils oscillate above the three current coils so that each pendulum is acted on by two current coils. To the potential coil which is acted on by the currents *A* and *C* is applied the e.m.f. e_1, which is the e.m.f. between the phase *A* and the fourth wire, *D*. The other coil which is acted upon by currents *B* and *C* is at the potential e_2, which is the e.m.f. between the phase *B* and the fourth wire, *D*.



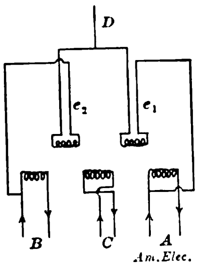


FIG. 3.—ARON METER CIRCUITS —FIG. 4.

Electrolytic Interrupter.—A recent issue of the "Elektrotechnische Zeitschrift" contains an illustrated description of an electrolytic interrupter which has been in successful use for some time past. It is a modification of the Caldwell interrupter. A china insulator, *a*, is suspended in a lead cylinder, *d*, by means of the lead rings, *c c*; the insulator has a hole, *b*, of about 0.06 in. diameter drilled in the bottom of it. A water-cooling cylinder, *e e*, surrounds the lead cylinder, *d*, which is the cathode, while a lead strip, *g*, is the anode which may be lowered or raised at will. Dilute sulphuric acid is used as the electrolytic. To prevent the spilling of the acid a bottle, *l*, having a hole in the bottom is inverted above the insulator. The interruptions occur at the hole, *b*, which connects the electrolyte in the cylinder, *d*, with that in the insulator, *a*. During the operation the author observed a peculiar periodical change of the level of the electrolyte in the insulator, which has an influence upon the successful operation of the interrupter.

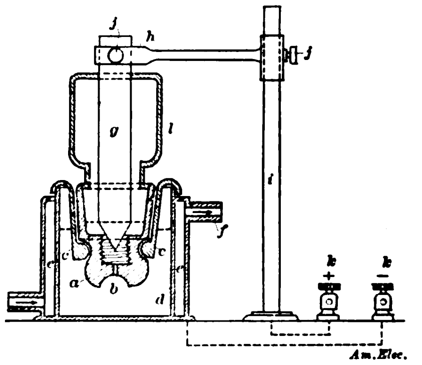

FIG. 5.—ELECTROLYTIC INTERRUPTER.

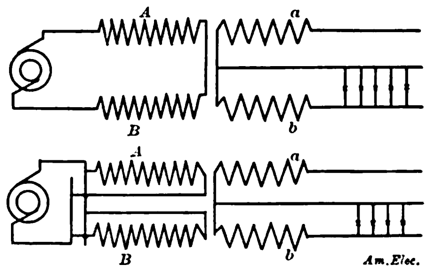
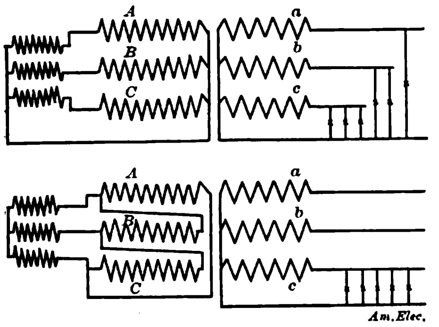
Transformer Connections—According to an article in the "Elektrotechnische Zeitschrift" in single-phase and three-phase plants where relatively few consumers scattered over large areas are to be supplied with light, the use of many small transformers being undesirable, a system similar to the three-wire direct-current system is often used, which leads to the use of so-called neutral conductors. In the three-wire single-phase system difficulties in transformer connections are met with; since if there are two cores and the connections are made as in Fig. 6, a great difference of voltage occurs when the loads in the two halves of the system are unequal. For instance, if the load in coil, *b*, is greater than that in coil *a*, the current in the primary coil, *B*, should be larger also; but this current cannot be obtained



FIGS. 6 AND 6A.—TRANSFORMER CONNECTIONS

in sufficient quantity, as it would also flow through the coil *A*, which has only a light load and the result is an entirely unsymmetrical distribution of the magnetizing and demagnetizing forces and magnetic flux. The voltage in *b* consequently decreases and that in *a* increases. The following remedy is recommended. Both high-tension coils are built for the full high-tension voltage, and are connected in parallel as shown in Fig. 6A. The load in the halves, *a* and *b*, may be entirely different, but the voltage drop is the same whether only one half or both halves are loaded. A somewhat similar arrangement is proposed for three-phase currents. The system shown in Fig. 7 in which the lamps are connected between the three phases and the neutral wire, has generally been used for low-voltage installations. For high-voltage the three-phase system shown in Fig. 7 A is used. It is sufficient for all practical purposes, to make the neutral wire half the diameter of the outers, as in the direct-current system.



FIGS. 7 AND 7A.—TRANSFORMER CONNECTIONS

Prony Brake.—F. Hubert describes in a recent issue of the "Elektrotechnische Zeitschrift" the Prony brake used by Siemens & Halske at their works at Charlottenburg. Fig. 8 shows the method of application. One end of the series of brake shoes is pivoted at *D* to the lever, while the other end is hung to the block, *B*, which slides in a curved slot in a lug on the lever. The grip on the wheel may be tightened or loosened, as the case might require, by the turnbuckle and a finer regulation is secured by turning the screw, *S*, which controls the position of the block, *B*. The lever is fulcrumed at *A* in the manner shown. The periphery of the wheel and the surfaces of the brake shoes are smeared with tallow; no water is applied to the friction surfaces, the brake discs being hollow and cooled by water within them. By reason of this method of cooling, the coefficient of friction and load fluctuations are almost nil. In order to secure a correct measurement of the brake horse-power it is necessary that the center *M* of the axle, the pivot at *A* and the point of application of the weight be in a straight line parallel with the ground line.

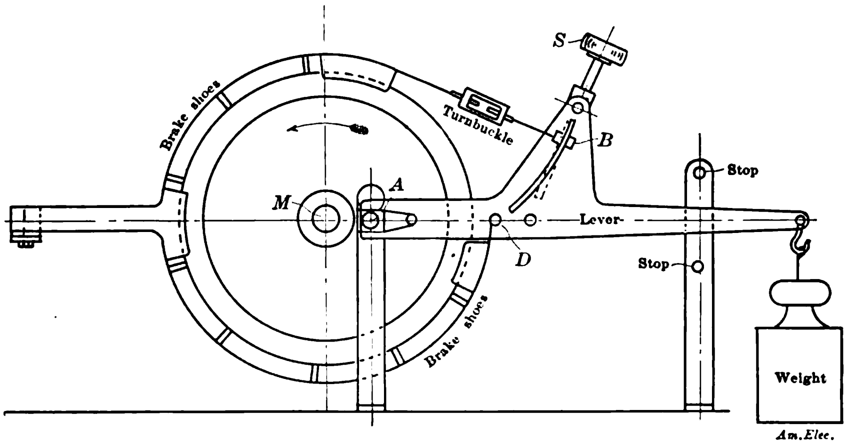


FIG. 8.—IMPROVED FORM OF PRONY BRAKE.

Outhenin-Chalandre Electrolytic Alkali Process.—This process for the production of alkalies and chlorine compounds by the electrolysis of solutions of sodium or potassium chloride is described by J. B. C. Kershaw in the London "Electrician." Fig. 9 is a sectional elevation of the cell, which consists of an outer vessel, *K*, and an inner vessel, *A*, entirely closed and built of materials not affected by the action of chlorine or its compounds. The inner vessel is filled with rows of porous-diaphragm tubes, *o*, *o*, open at each end to the outer chamber *K*, of the cell, and inclined at a slight angle, as shown. Each tube is hermetically sealed into the walls of the chamber *A* by a special device shown at *Z* and contains an iron sheet cathode running the whole length of its interior, which joins to a common terminal at *M*. Each vertical row of diaphragm tubes is thus served with current by one electrical contact. The anodes, *I*, are round rods of specially prepared carbon, fixed into the common lead head-piece *U*, and communicating at *e* with the negative terminal of the dynamo. They hang vertically in rows of seven between the rows of diaphragm tubes, and the chlorine evolved at their surface collects in the upper portion of the anode chamber, and is carried away by the outlet pipe *H*. The right-hand side of the inner cell is provided with a sheet-iron movable hood, *V*, and an outlet pipe, not shown. This serves to collect and carry away the hydrogen liberated within the diaphragm tubes and facilitates its utilization for other purposes. In operation the inner chamber, *A*, is filled with salt water and the outer vessel with a dilute solution of sodium hydrate. The chlorine liberated from the salt water passes off through the pipes, *H*, and is used for the manufacture of bleaching powder. The sodium liberated at the surface of the sheet-iron cathodes decomposes the water present, yielding hydrogen gas and a solution of sodium hydrate. The former is collected in the chamber *V*, and the latter collects at the bottom of the cell and is collected through the outlet pipe, *V*.

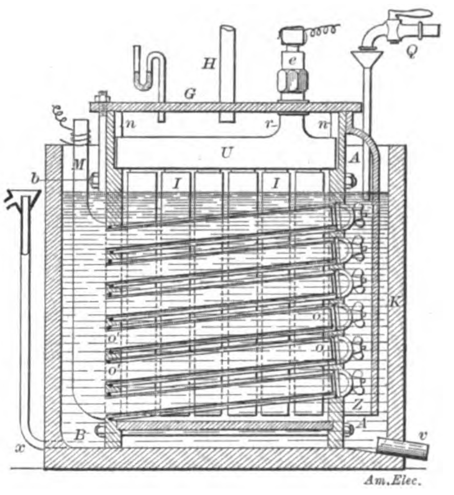

FIG. 9—ELECTROLYTIC ALKALI CELL.

Slip in Induction Motors.—To a recent issue of the "Elektrotechnische Zeitschrift" Georg Siebt contributes an article giving simple methods for measuring the slip in induction motors. If the armature has slip rings the armature current can be measured and this is a convenient means of measuring the slip. If an ammeter be connected between two slip rings, the needle oscillates near the average value at which it would rest at higher frequency, and for the same effective current; and if these oscillations are counted for a certain time the slip may be computed; it is equal to one-half the number of complete oscillations divided by the product of the time and the frequency of the primary current. A squirrel-cage armature admits of a simpler method, in which an artificial alternating current is made, having the same frequency as the armature current. The author elucidates the principle by the supposition that in the circuit of an incandescent lamp supplied at the same voltage as the motor, there is a switch which is opened and closed in synchronism with the frequency of the alternating current. In this case the lamp will burn continuously with a certain luminosity or will be entirely dark, depending on whether the voltage at the time during which the circuit is closed is at maximum or zero. The Joubert contact maker may be used as a switch; but if this is fixed on the axle of the motor under test, the closing and opening of the contact is not in synchronism with the alternating-current supply, on account of the slip. Assume at starting a maximum voltage, with a smaller voltage at the moment of the next contact, etc. The starting point is again reached when the motor is lagging by $\frac{1}{p}$ revolutions; *p* being the number of pairs of poles. During this time the incandescent lamp is supplied with an often interrupted alternating current of the frequency of the armature current. The lagging of the motor by $\frac{1}{p}$ revolutions corresponds to the lighting of the lamp twice. If the oscillations of the lamp light are counted per minute, the slip is readily found by the simple formula: slip $= \frac{y}{2\,p\,n + y}$ where y represents the oscillations in the light per minute; p, pairs of poles, and n, the number of revolutions made by the motor.

High-Tension Voltmeters.—A recent issue of the "Elektrotechnische Zeitschrift" contains a paper read before the Electrotechnical Society of Berlin by Herr Benischke in which the author describes the high-tension voltmeters of the Allgemeine Elektrictats Gesellschaft of Berlin. These instruments have two scales, one reading to 7500 volts, and the other reading to 25,000 volts. The first reading is taken on the ordinary static voltmeter while the second reading is obtained by means of condensers. The arrangement is based upon a suggestion of Peukert, who recommended reducing high-tension measurements to low-tension measurements by connecting several condensers in series and shunting one of them by a static low-tension voltmeter. As seen in the diagram, the author uses the same idea to obtain the second scale reading of 25,000 volts besides the original scale reading of 7500 volts. The dielectric of the condensers is micanite; the condenser is located in the base of instrument.

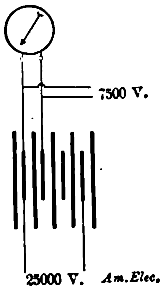

FIG. 10.

Storage Battery End-Coil Switch.—The switching of cells is not so simple a problem as might appear at first sight. One difficulty is the arrangement of contacts. If a single contact touches two contacts at the same time a cell is short-circuited and trouble arises. If the contact leaves one cell contact before it reaches the other the main circuit is broken and sparking occurs. This difficulty is easily overcome in hand-worked switches by using two contacts with a resistance between them, the resistance being low enough to allow the full load current to pass when subjected to a potential difference of two volts. But this arrangement does not suffice for an automatic switch if the mechanism is such that the resistance may be left in shunt to one cell for a considerable time. If the resistance is low enough to take the maximum current and it is left across a cell for a considerable time, that cell may be discharged at a rate greatly different from that of the remainder of the cells, to say nothing of the waste of power, which may be considerable.

Fig. 11 shows the Schneider end-cell switch as described in a recent issue of the London "Engineer." The potential difference between the points where constant e.m.f. is desired is measured by a voltmeter which has two contacts. These contacts open and close the circuits of two relays which control the motor that drives the screw shaft of the switch. In order to avoid short-circuits, the cell contacts are made double, with a guard resistance between them, and to avoid having the carriage stop with a cell short-circuited through the guard resistance the carriage is not connected rigidly to the screw, but has some longitudinal play in relation to it; this play is taken up normally by a spiral spring. A series of notches is provided, one for each cell, and the arrangement of the mechanism is such that the contact carrier goes by jumps, and always stops in register with the cell contacts.

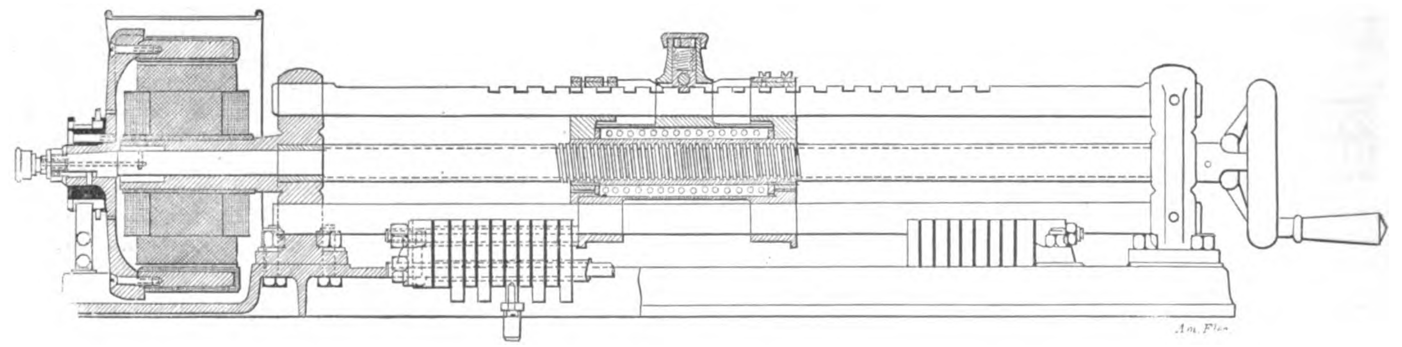

FIG. 11.—SEMI-SECTIONAL VIEW OF THE SCHNEIDER END-CELL SWITCH.

Some Recent Electrical Patents

Prevention of Cross Talk in Telephone Switchboards.—It is well known that the line drops, relay magnets, and other electromagnetic devices of a telephone switchboard are commonly arranged in parallel rows just as close together as mechanical conditions will permit in order to reduce to the smallest possible value the space occupied by the switchboard. In order to prevent mutual induction between neighboring magnets and consequent cross talk between the lines, it is customary to make these magnets of the tubular or iron-clad form. A disadvantage, however, of tubular or iron-clad magnets is that the impedance of the magnet is diminished by currents induced in the tubular shell; were this disadvantage reduced by splitting the shell then mutual induction between neighboring coils would be no longer prevented, and cross talk would result. Fig. 1 herewith represents an arrangement which has been patented by Frank R. McBerty for the purpose of obviating both of the disadvantages referred to. The subject of the illustration is an ordinary impedance coil, the core, g, of which carries a single coil of wire, h. The coil and both sides of the core, however, are enclosed in a copper tube, i, embracing the complete magnetic circuit. This sheath does not reduce the impedance of the coil as in the case of the ordinary tubular construction for the reason that it encloses both sides of the magnetic core, the effects of which are equal and opposite. The copper tube, however, tends to suppress the leakage of magnetic lines sidewise by reason of the currents induced in it by such lines. Patent No. 665,923.

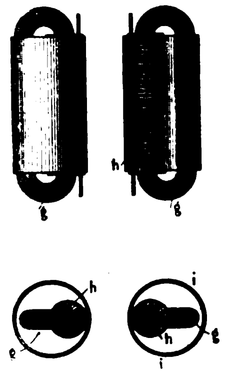

FIG. 1.

Polyphase Transformer.—It is well known that in transforming three-phase currents two transformers may be used instead of three, the primary terminals of the two transformers being connected to the three line wires exactly as two incandescent lamps would be connected to the wires of an ordinary three-wire system, and the secondary wiring similarly connected to the three secondary wires. E. W. Rice, Jr., has patented a single transformer which combines the two transformers used in this manner. Fig. 2 rep-

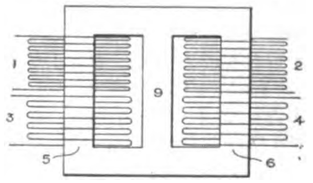

FIG. 2.—THREE-PHASE TRANSFORMER.

resents the arrangement, which consists of a core similar to that of a shell-type transformer, except that the central leg, 9, is of the same size as the two outer legs, 5 and 6. On the two outer legs the two primaries, 1 and 2, and secondaries, 3 and 4, are wound. As the phases of the magnetic fluxes are 120 degrees apart the resultant flux will be equal to each of the individual fluxes. It is for this reason that the central leg, 9, is given the same cross-section as the two outer legs, 5 and 6. The patent also includes a method of changing the secondary voltage by means of taps in the secondary winding, as illustrated in Fig. 3, the object of this arrangement being to provide a low voltage for starting an induction motor. Patent No. 669,662.

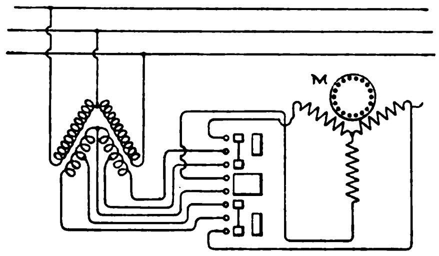

FIG. 3.—DIAGRAM OF TRANSFORMER WINDINGS AND CONNECTIONS.

Multiple Nernst Lamp.—This invention relates to a multiple-series arrangement of Nernst glowers, and is the subject of a patent issued to Alexander J. Wurts. Mr. Wurts states that in the manufacture of high-potential Nernst lamps it is usually undesirable to make individual glowers for a voltage higher than, say, 220. When the circuit e.m.f. is higher than this it is usually desirable to connect the glowers in series or in multiple-series. It is also advisable to use a small amount of resistance wire in series with the glowers to compensate for the reduction in the resistance of the glower as its temperature increases. Fig. 4 illustrates the arrangement patented by Mr. Wurts. The glowers, 16, are mounted vertically on opposite sides of a heat-resisting and non-conducting plate, 13. Each pair of glowers is connected by means of coiled wires, 17, having a positive temperature coefficient. The various pairs of glowers are connected in parallel to the terminals, 19 and 20. The heater is also mounted on the vertical plate, 13, and connected to the terminals, 10 and 11. The coils of resistance wire connecting the lower ends of the glowers are disposed in slots along the bottom of the vertical plate, and are thus prevented from coming in contact with each other. Patent No. 668,246.

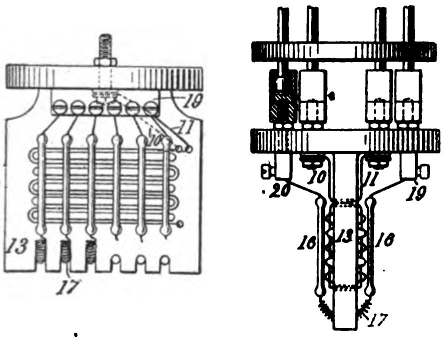

FIG. 4.—MULTIPLE SERIES ARRANGEMENT OF NERNST GLOWERS.

Third-Rail Electric Railway.—The arrangement of the third or conductor rail for electric railways has been made the subject of considerable thought, and numerous patents have been taken out covering methods of mounting the conductor rail and housing it in order to protect it from outside interference as well as to protect careless pedestrians from coming in contact with it. One of the latest methods of this class has been patented by Wm. T. Van Dorn, and is illustrated by Fig. 5 herewith. The conductor rail, *F*, is inverted and mounted in an insulating trough or continuous hood, as shown at the left of Fig. 5, the bolts which secure the rail in position being insulated by means of bushings and washers. The rail and its trough are mounted on the horizontal arms of a series of brackets or standards along the side of the roadway, as indicated in the main part of the drawing, and it will be evident that the conductor rail in this system occupies exactly the same position with relation to the collector shoe or trolley on the car that the ordinary overhead trolley wire does with relation to the trolley arm and wheel. The arrangement shown at the right-hand side of the truck is a safety device consisting of an insulated roller, *J*, mounted on an extension of the car-wheel axle; the brackets, *E*, on which the conductor rails, *F*, are mounted are of such a height that the insulated roller, *J*, is normally out of contact with the conductor rail, but the clearance is less than the depth of the flange on the car wheels, so that any tendency on the part of the wheel flanges to ride the track rails will be opposed by the roller, *J*, coming in contact with the inverted conductor rail. It is presumably proposed to put conductor rails on both sides of the track and extend both ends of each axle, putting a safety roller, *J*, on each end of each axle. Patent No. 670,651.

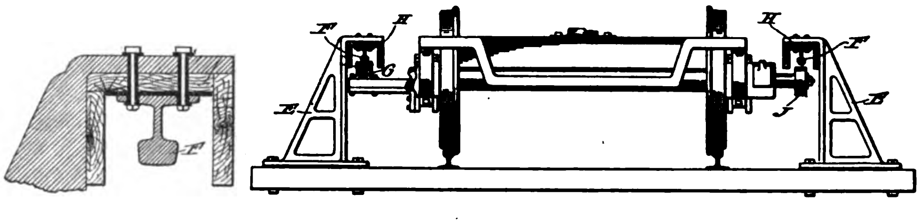

FIG. 5.—THIRD-RAIL ARRANGEMENT FOR ELECTRIC RAILWAYS.

Telephone Cord Circuit.—This invention, which has been made the subject of a patent to Charles E. Scribner, relates to central-energy telephone systems and dispenses with the impedance coils usually employed in association with the transmitter to prevent incoming talking currents from being short-circuited through the transmitter. The central battery, *a*, is connected across the cord circuit, through impedance coils, *b* and *b'*. The subscriber's transmitter is connected to two taps, each of which is midway of one of two windings disposed on a common core, *e*. The outer ends of these windings are connected to the circuit and the inner ends to the subscriber's receiver through a condenser. The two windings on the core, *e*, are in such position that if a direct current were passed through the entire winding both halves of it would magnetize in the same direction. The steady current from the central battery finds a circuit, of course, across the transmitter. Any increase in the resistance of the transmitter at one station tends to diminish the current through the windings, e^1 and e^2, and a momentary current is diverted into the receiver circuit, *r*, charging the condenser. The current flowing through the windings, e^3 and e^4, is then in the proper direction to induce an e.m.f. in the windings, e^1 and e^2, in opposition to the battery, tending to still further diminish the line current. A subsequent decrease in the resistance of the transmitter permits an increase in the line current and the discharge of the condenser. This discharge through the windings, e^3 and e^4, induces an e.m.f. in the windings, e^1 and e^2, which tends still further to increase the line current. The undulations in the line current, produced by the transmitter, therefore, are greatly amplified by the action of the condenser. Patent No. 669,710.

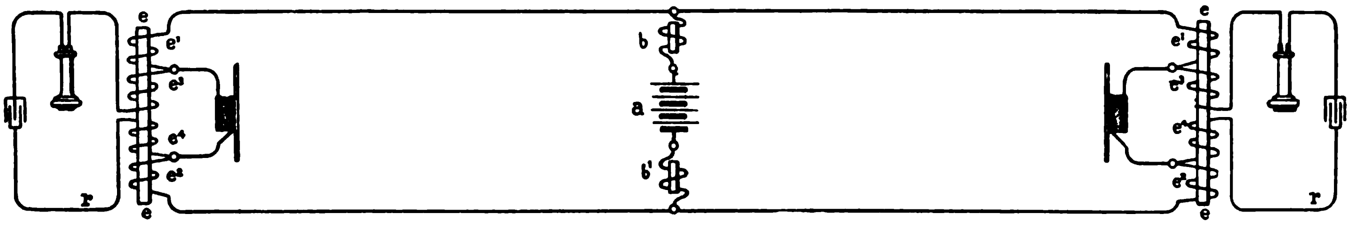

FIG. 6.—DIAGRAM OF CONNECTIONS, CENTRAL-ENERGY TELEPHONE SYSTEM.

The Heat Waste of a Gas Engine

To the Editor, American Electrician;

Sir:—In the editorial columns of your April issue there was a discussion of The Heat Waste of a Gas Engine, suggesting a means whereby the efficiency of the engine might be increased by utilizing the waste heat of the water-jacket. The writer wishes to state that the principle involved in this article has met with considerable consideration by inventors, chief among which are perhaps Tavernier, Patent No. 428,764 of May 27, 1900; Marrder, Patent No. 233,268 of October 12, 1880; Baldwin, Patent No. 270,748 of May 1, 1883; British Patent 7943 in 1892 to Sennett; British Patent No. 433 to Simon in 1878; German Patent No. 98,043 to Wultze; English Patent No. 1501 to Marchant, dated March 22, 1883, and English Patent No. 688 to Macgeorge, dated June 5, 1885. It might be stated, however, that the chief difficulty which these inventors have experienced lies principally in the fact that the temperature of the water-jacket under such conditions would be too high, commensurate with the requisite amount of temperature reduction for best results in the working cylinder and it has therefore been a matter of considerable experiment to accomplish the end which is set out in your editorial.

The writer, however, has gone somewhat deeply into this proposition and has designed an engine with the express purpose of not only recovering the waste heat of the water-jacket, but also that of the exhaust gases to a greater or less extent. As a result of an investigation into the heat losses by cooling the cylinder and the exhaust gases there seems to be considerable hope of reducing these losses sufficiently to increase the efficiency of the internal combustion motor from 18 to 25 per cent in engines of from 2 to 50 horse-power capacity and in a manner whereby the advantage gained in efficiency would have a corresponding advantage in the kinematics of the motor, putting it more on the level of a steam engine in this respect.

Pending applications for patents do not permit of any detail illustration of the apparatus, so that the writer is obliged to reserve any description which would interfere with the foreign patent applications. Philip K. Stern.

New York, May 9, 1901.

NEW BOOKS.

Induction Coils. Second Edition. By H. S. Norrie (Norman H. Schneider). New York: Spon & Chamberlain. Cloth; 282 pages, 4½ x 6½ ins.; 79 illustrations. Price, $1.

This is a welcome revision of Mr. Schneider's little book originally published five years ago. The only defect in the first edition was incompleteness, and this has been remedied in the present edition. There has been added a considerable amount of matter relating to gas lighting apparatus, wireless telegraphy and batteries. A most useful addition also is a table of dimensions of coils and condensers for various spark lengths. In its present form the book is a highly satisfactory and useful one.

Telephone Lines and Their Properties. By William J. Hopkins. Sixth Edition. New York: Longmans, Green & Co. Cloth; 307 pages, 5 x 7 ins.; fully illustrated. Price, $1.50.

This is the sixth edition of Prof. Hopkins' excellent work, and it contains a chapter on wireless telephony and composite telephone and telegraph systems, together with an account of recent developments in long-distance lines, in addition to the matter previously published. The older part of the book is a comprehensive discussion of the functions and properties of telephone circuits and the practical construction of overhead and underground lines. An annoying feature of the typographical make-up is the lack of figure numbers under most of the illustrations and conflicting numbers under the others.

American Street Railway Investments. New York: Street Railway Publishing Company. Cloth; 322 pages, 9½ x 12½ ins.; 29 maps. Price, $5.

This is the 1901 edition of the annual "red book" which has become the standard source of information to those interested in the financial development of street railways. The data contained in the book is singularly complete; one can but wonder how the compilers were able to persuade such a large majority of railway companies to supply the exhaustive information that is furnished here. This information comprises the capitalization, bonded indebtedness, annual receipts and expenses, size and character of equipment and the names of the officials of practically every road in the country. Besides this there are copies of the balance sheets of most of the companies and maps of twenty-nine of the more important systems.

NOTES.

Freight-Carrying Trolley Cars.—The statute book of the city of Detroit contains an ordinance which allows street railway cars to carry freight for compensation within the city limits.

Another Power Plant for Niagara Falls.—It is announced that work will be commenced at once on another power plant at Niagara Falls, to be located on the Canadian side of the river. The plans call for an initial development of 35,000 horse-power, and the plant is to be constructed under an agreement made by the Canadian authorities with the Canadian Niagara Power Company nearly two years ago. Under the terms of this agreement the power company must have the plant in condition by July 1, 1903, to develop, transmit and deliver 10,000 horse-power, and also have water connection made for the remaining 25,000 horse-power. The plant will be developed in co-operation with the plant of the Niagara Falls Company on the New York side of the river. The two power houses will be connected by cables so that either one can supplement the other whenever it may be necessary.

The International Association of Municipal Electricians. — The executive committee of this association, at a meeting held at Niagara Falls, April 27, set the date for the next annual convention at September 2, 3 and 4. Special rates will be secured from the hotels and railways, and information concerning these can be supplied within the next week or so upon application to Mr. Frank P. Foster, secretary of the association, at Corning, N. Y.
